Paper Coatings. The world of printing is changing dramatically and is becoming more and more digital. Digital data sources, digital transfer, and certainly digital printing. The past decades have already seen tremendous technological advances especially in non-impact printing technologies. This is particularly true for ink jet systems in which the development of hardware has paralleled the advanced made in computerized image-processing systems. High speed and low cost availability are now driving the so-called SOHO (small office home office) markets, while the professionals have learned to use inkjet for a great variety of applications. However, to get the best possible quality levels, specialized inkjet media have to be developed.

The majority of ink used in ink jet printing contains water soluble organic dyes and dispersed pigments with the overwhelming majority of the typical ink formulation containing water. Once deposited on the substrate, the ink must dry quickly to avoid spreading through the paper fibers adjacent to the printing pixel. Otherwise, wicking and a subsequent loss in resolution occur. With the drive to accelerate print speed and reduce drop size, fast drying becomes crucial. A key to meeting these requirements is coating the surface of the substrate with silica-based materials. These coatings allow for rapid ink absorption, thereby promoting sharp edge acuity, spheric and defined spreading of the ink drop, no shine-through or strike-through of the inks, and an excellent image density.

Silicone Rubber. Silicone rubber parts are typically used in the automotive industry in, i.e., ignition cables, spark plugs, membranes, and bellows. In electrical and electronics applications, silicone rubber is used in key pads, housing seals, in insulating hoses and high voltage insulators. Swimming goggles, snorkels and mouth pieces are usually made of silicone rubber too. Even in hospitals and pharmacies seals for medical appliances, baby nipples, catheters and inflating bellows are made of silicone rubber.

In the silicone industry, synthetic silica is used predominantly as a reinforcing agent in order to give the silicone rubber sufficient mechanical strength. In principle, both fumed and precipitated silica can be used. Precipitated silica can give advantages to silicone rubber applications which can not be obtained with fumed silica and vice versa. The vulcanization temperature is the distinguishing feature of the different silicone systems.

Unsaturated Polyester Resins (UPE). Compared to precipitated silica and silica gels, fumed silica is by far the largest product in the UPE industry having the following advantages: very efficient viscosity modifier, efficient in adding thixotropy, and better clarity of the formulation. Fumed silica contributes significantly to the stability of the formulation and prevents segregation. Precipitated silica has found a niche in UPE gel coats. Gelcoats are a high performance UPE resin that is applied to the outside of a composite part for aesthetics and to provide resistance to weathering. Other advantages of precipitated silica are fast dispersion, lower costs, better leveling of the coating or casting and, in some cases, less viscosity drift (change of the formulation viscosity over time).

Rubber Applications. Silica, in conjunction with organosilanes as coupling agents, is widely used in the manufacture of mechanical rubber goods such as seals, cables, profiles, belts, and hoses. The silica–silane system is needed for industrial rubber goods that require high reinforcement combined with the possibility to manufacture white or colored products. The silica is used to improve tear resistance, and in some dynamic applications the silica–silane systems are needed to reduce heat buildup. Another important field for silica–silane systems is the segment of non-marking colored shoes, which require good abrasion resistance, high stiffness, and high elasticity.

Since the introduction of the "green tire concept" in 1992, precipitated silica in conjunction with special solution polymers and functional organosilanes acting as coupling agents, has been used in passenger car tire treads. The latest generation of silica, highly dispersible silica, makes it possible to achieve considerable improvements in wet-skidding properties and rolling resistance of car tires, but also to improve their wearing characteristics.

SILICA: AMORPHOUS. [CAS: 7631-86-9]. Amorphous silica, ie, silicon dioxide, SiO_2, does not have a crystalline structure as defined by X-ray diffraction measurements. Amorphous silica, which can be naturally occurring or synthetic, can be either surface-hydrated or anhydrous. Synthetic amorphous silica can be broadly divided into two categories of stable materials: vitreous silica or glass, which is made by fusing quartz at temperatures greater than ~1700 °C, and microamorphous silica, which is discussed herein. See also **Silica: Vitreous**.

Microamorphous silica includes silica sols, gels, powders, and porous glasses. These consist of ultimate particles of the inorganic polymer $(SiO_2)_n$, where a silicon atom is covalently bonded in a tetrahedral arrangement to four oxygen atoms. Each of the four oxygen atoms is covalently bonded to at least one silicon atom to form either a siloxane, −Si−O−Si− or a silanol, −Si−O−H, functionality. The bond distances and bond angles in amorphous silica are similar to those of cristobalite [CAS:14464-46-1]: Si−O bond distances are ~0.16 nm, and Si−O−Si bond angles are ~148°. Surface silanol groups can be isolated from one another, so that intramolecular hydrogen bonding does not occur; vicinal to one another, thus promoting the formation of intramolecular hydrogen bonding; or geminal to one another, whereby two silanol groups are bonded to the same silicon atom. Initially formed low molecular weight species condense to form ring structures so as to maximize siloxane and minimize silanol bonds.

A random arrangement of rings leads to the formation of complex structures of generally spherical particles less than ~100 nm in diameter. These particles have high surface area values, generally greater than ~3 m^2/g. Crystallinity is usually determined spectroscopically by using X-ray diffraction to establish the absence or presence of definitive lines in the diffraction pattern of silicas.

Chemical methods to determine the crystalline content in silica have been reviewed. These are based on the solubility of amorphous silica in a variety of solvents, acids, or bases, with respect to relatively inert crystalline silica, and include differences in reactivity in high temperature fusions with strong bases. These methods are qualitative, however, and fail to satisfy regulatory requirements to determine crystallinity at 0.1% concentration in bulk materials.

Microamorphous silica can be divided into microparticulate silica, i.e., microscopic sheets and fibers, and highly hydrated silica. The microparticulate silicas are the most important group commercially. These include silicas precipitated from aqueous solution and silicas formed in the vapor phase, called pyrogenic or fumed silica. Several synthetic routes exist to prepare any form of microporous silica, where microporous often refers to the ability of the silica to adsorb gases or liquids. For example, pyrogenic silica can be prepared by either (*1*) vaporizing silicon dioxide in an arc or in a plasma jet, and condensing it in an inert gas; (*2*) oxidizing the more volatile silicon monoxide, SiO, in the vapor phase with air, and condensing it; or (*3*) oxidizing silicon compounds, eg, SiH_4, $SiCl_4$, or $HSiCl_3$, in the vapor phase in a hydrocarbon flame, and then condensing to produce branched-chain aggregates of silica up to ~1 μm in length. Pyrogenic silica is collected as a finely divided powder.

Amorphous silica formed in aqueous solution can occur as sols, gels, or particles. A silica sol can either consist of polysilicic acid having a molecular weight of SiO_2 up to ~100,000, or be a stable dispersion of fine colloidal particles of diameters >5 nm. A silica gel has a three-dimensional, continuous structure. Macroscopic particles formed by aggregation of a sol or very small particles of a gel to afford bunched aggregates of silica up to approximately 1 μm in diameter are called precipitated silica. This is collected as a powder by physically agglomerating these aggregates and evaporating the water. See also **Silica: Precipitated**.

Microscopic sheets of amorphous silica have been prepared in the laboratory by either (*1*) hydrolysis of gaseous $SiCl_4$ or SiF_4 to form monosilicic acid [CAS: 10193-36-9] (orthosilicic acid), $Si(OH)_4$, with simultaneous polymerization in water of the monosilicic acid that is formed; (*2*) freezing of colloidal silica or polysilicic acid; (*3*) hydrolysis of $HSiCl_3$ in ether, followed by solvent evaporation; or (*4*) coagulation of silica in the presence of cationic surfactants. Amorphous silica fibers are prepared by drying thin films of sols or oxidizing silicon monoxide. Hydrated amorphous silica differs in solubility from anhydrous or surface-hydrated amorphous silica forms in that the former is generally stable up to 60 °C, and water is not lost by evaporation at room temperature. Hydrated silica gel can be prepared by reaction of hydrated sodium silicate crystals and anhydrous acid, followed by polymerization of the monosilicic acid that is formed into a dense state. This process can result in a water content of approximately one molecule of H_2O for each silanol group present.

Characterization

Amorphous silica is distinguished by chemical composition, physical properties, and characteristics of the particles. Exact analytical procedures depend on the type and intended application of the amorphous silica. The most important chemical information is the amount of silica, % SiO_2; percentage of associated water, determined by weight loss at 105 °C (221 °F); total solids content of nonoxidizable materials, determined by weight loss upon ignition at ~1200 °C (~2,192 °F); presence of stabilizers, organic carbon, determined by combustion to carbon dioxide; level of soluble salts determined by X-ray fluorescence spectroscopy or by chemical methods, e.g., extraction; level of nonsiliceous ash; level of metal impurities, determined by X-ray fluorescence, or by atomic absorption; and silanol group density, determined by infrared (IR) spectroscopy or chemical titration.

Physical characteristics include measurements of pH determined as a 5% aqueous slurry, density and tamped density, viscosity, turbidity, refractive index, light-scattering properties, and/or sedimentation rate by ultracentrifugation. Silica particles are characterized by specific surface area as determined by the adsorption of nitrogen gas by the BET method or by the adsorption of cetyltrimethylammonium bromide (CTAB); average particle size and size distribution; sieve residue; porosity such as average pore diameter and pore volume as determined by intrusion of mercury or adsorption of nitrogen gas; degree of aggregation as determined by mean projected area (MPA) measured using transmission electron microscopy; oil absorption, eg, dibutylphthalate, dioctylphthalate, or linseed oil; and rate of dissolution. Particle size is measured by transmission electron microscopy, light scattering, absorbance of visible light, low angle X-ray scattering, centrifugation, rate of reaction with molybdic acid, or surface area measurement of dried particles.

The typical range of properties for commercial colloidal silicas, silica gels, precipitated silicas, and pyrogenic silicas is given in Table 1.

TABLE 1. PROPERTIES OF COMMERCIAL AMORPHOUS SILICA

Property	Colloidal Silica	Silica Gels[a]	Precipitated Silica	Pyrogenic Silica
SiO_2, %	15–50	96.5–99.6	85–95	98.3–99.8
Surface area, m^2/g	50–750	200–800	25–700	35–410
Oil absorption, g/g	0.9–3	1.5	1.5–3.5	0.5–3
pH, aqueous	3–5, 8–11	2.3–7.4	5–9	3.5–5
Weight loss, %				
At 105 °C	50–80		4–7	0.5–2.5
At 1200 °C	50–90	2–17.5	10–14	1–4
Density, g/cm^3	2.2–2.3	2.22	1.9–2.1	2.16
Bulk density, g/cm^3	1.2–1.4	0.1–0.9	0.03–3	0.03–0.12
Particle size

[a] Dry.

Heterogeneous Reactions

Dissolution. Amorphous silica dissolves or depolymerizes in water according to equation 1:

$$SiO_2(s)+2H_2O(1) \longrightarrow H_4SiO_4(aq) \quad (1)$$

H_4SiO_4 (aq), which is either a monosilicic or an orthosilicic acid, is also expressed as $Si(OH)_4$ (aq) or H_2SiO_3 (aq). This material has not been isolated.

The solubility of amorphous silica in water at 25 °C (77 °F) ranges from 70 to 150 ppm SiO_2 (1.2–2.2 mmol/kg). The variation results from differences in particle size, degree of hydration, and level of trace impurities. Areas having a small positive radius of curvature (convex) dissolve most extensively, and areas having a small negative radius of curvature (concave) dissolve least extensively. Particles having a diameter of less than ~5 nm have a progressively greater solubility than do particles of continually increasing diameters. Particles <3 nm in diameter are very soluble. The solubility of amorphous silica in water increases with increasing temperature and pressure.

Hydrated amorphous silica dissolves more rapidly than the anhydrous amorphous silica. The solubility in neutral dilute aqueous salt solutions is only slightly less than in pure water. The presence of dissolved salts increases the rate of dissolution in neutral solution. Trace amounts of impurities, especially aluminum or iron, cause a decrease in solubility. Acid cleaning of impure silica to remove metal ions increases its solubility. The dissolution of amorphous silica is significantly accelerated by hydroxyl ion at high pH values and by hydrofluoric acid [CAS: 7664-39-3] at low pH values. Dissolution follows first-order kinetic behavior and is dependent on the equilibria shown in equations 2 and 3. Below a pH value of 9, the solubility of amorphous silica is independent of pH. Above pH 9, the solubility of amorphous silica increases because of increased ionization of monosilicic acid.

$$H_2SiO_3(aq) \rightleftharpoons H^+(aq) + HSiO_3^-(aq) \quad K_1 = 1.6 \times 10^{-10} \quad (2)$$

$$HSiO_3^-aq) \rightleftharpoons H^+(aq) + SiO_3^{2-}(aq) \quad K_2 = 7.4 \times 10^{-13} \quad (3)$$

Amorphous silica is essentially insoluble in methanol [CAS: 67-56-1], thus solubility in methanol–water mixtures decreases with increasing percentages of methanol. Natural biogenic silica often has an organic coating that inhibits dissolution. The coating can be removed by acid washing. The point of zero charge for the silica surface is between pH 2.5 and 3.

Polymerization. Dissolved silica undergoes polymerization to give discrete particles that can further react. The three stages of reaction are polymerization of monomers to form particles, growth of particles, and linking of particles to give chains and then networks. In basic solution, the particles grow in size and decrease in number. In acid solution or in the presence of flocculating salts, particles aggregate into three-dimensional (3D) networks and form gels.

At concentrations below ~100 ppm of SiO_2, the solubility of amorphous silica in water is such that monosilicic acid is in a true solution in water. Polymerization occurs only when solubility is exceeded and there is no solid phase present on which the silica can be deposited. The polymerization is an ionic reaction proportional to the concentration of hydroxyl ion at pH > 2. Because of the thermodynamic tendency to maximize siloxane, −Si−O−Si−, and to minimize silanol (−Si−O−H) bonds, initially formed low molecular weight species are condensed, forming ring structures, such as cyclic tetramer, hexamer, and octamer. These species continue to react with additional monomer and become linked to one another. Internal condensation reactions continue to occur that lead to formation of a small particle. At temperatures >80 °C (>176 °F) and pH values >7, the particle is anhydrous. The silanol groups generally only form on the surface. These particles serve as nuclei on which 3D particle growth occurs. Because of the solubility difference, small particles dissolve and the silica is deposited on larger particles that grow in average size. This process is known as Ostwald ripening. Increasing temperature either increases the growth of sol particles or causes gel formation. The presence of dissolved salts assists in neutralizing particle surface charges to enhance aggregation of the particles into 3D gels. The rate of aggregation also increases with dissolved silica concentration in solution. As polymerization occurs, the solution still contains dissolved silica at a concentration equivalent to the solubility of amorphous silica.

Pyrogenic Silica

Amorphous pyrogenic (fumed) silicas are fluffy white powders that are generally less dense and of higher purity than are silicas precipitated from solution. Pyrogenic silicas have a much lower hydrated surface and are sometimes completely anhydrous. Surface silanol density normally ranges from 2–4/nm^2 of surface area. The particle size is controlled by combustion conditions during the flame hydrolysis. Pyrogenic silicas having surface areas <300 m^2/g are essentially nonporous, whereas those having higher surface areas can have some porosity. They generally can contain a few hundred ultimate particles fused into branched-chain, 3D aggregates. Pyrogenic silicas in the 100-nm to 2-μm diameter particle size range are common.

Pyrogenic silica can be prepared in several ways, including vaporizing silica and oxidizing organic or inorganic silicon compounds. Vaporizing silica at high temperatures of ~2000 °C (~3632 °F) forms anhydrous amorphous silica particles upon cooling. In the presence of a reducing agent, eg, coke, silica sublimes at ~1500 °C (2732 °F) to produce the volatile silicon monoxide, SiO, [CAS: 10097-28-6], which can then be oxidized to produce particulate fumed silica, SiO_2. Oxidation of silicon tetrachloride, $SiCl_4$, [CAS: 10026-04-7], vapor at high temperatures produces fumed silica and Cl_2. Alternatively, silicon tetrachloride can be burned in the presence of methane, CH_4, [CAS: 74-82-8] or hydrogen, H_2, gases to produce fumed silica, H_2O, and HCl. The latter process is an important commercial method. Silicon ester vapors can be oxidized and hydrolyzed to produce particulate silica of high purity, though at high cost. Silicon tetrafluoride, SiF_4, a by-product of the phosphate fertilizer industry, can also be used to produce pyrogenic silica by hydrolysis of the vapor at 1600–2200 °C (2912–3992 °F). HF is a by-product that can then react with sand to produce more SiF_4.

Pyrogenic silica is used in rubber applications that require a low level of surface water per unit surface area of the silica, primarily as a reinforcement in adhesives, sealants, and elastomer compounds based on silicone polymers. Pyrogenic silica also has a variety of other uses. It serves as a thixotropic agent in plastics, eg, in polyester casting resins; gel coats; sealants and adhesives; cosmetics in ointments and lotions; toothpastes; coatings; printing inks; free flow, antistatic agent in animal feedstuffs and hygroscopic powders; carrier for active ingredients, eg, pharmaceuticals, catalysts, and liquid spice extracts; gloss control agent in coatings and foils; coating additive to improve the mechanical reliability of fused silica optical fibers; and antifoaming or defoaming agent in the manufacture of paper, decaffeinated coffee and tea, poultry and seafood processing, and oil refining.

Fused Silica

Transparent fused silica can be formed at a temperature of 1200 °C (2,192 °F) and a pressure of 13.8 MPa (2000 psi) from silica powder consisting of 15-nm ultimate particles or by electric arc fusion of pure silica sand having low iron and alkali metal contents. The cooled product is ground to the desired particle size, usually powders >8 μ in diameter. Based on 2002 data, an estimated 170,000 metric tons of fused silica were used as a sacrificial component or investment casting in the manufacture of metals and as a component in refractory materials and in the lithography industry.

Naturally Occurring Amorphous Silica

Formation. Most naturally occurring amorphous silica deposits are biogenic forms deposited from the exoskeleton, plates, or spines of aquatic organisms, e.g., diatoms, radiolarians, silicoflagellates, and certain sponges. These organisms extract silica from very dilute solutions, eg, 0.1 ppm of SiO_2 or 2 mmol/kg, and are found in both marine and freshwater environments. Large deposits of these materials are found as loosely coherent chalk-like sediments in the equatorial Pacific area, ie, radiolarians, and in high latitude areas of all oceans, ie, diatoms. All biogenic silicas are noncrystalline because the kinetic barrier to crystallization is high [~800 kJ/mol (191 kcal/mol)] in neutral aqueous environments. In all

these structures, the mineral exists as a hydrated, covalent inorganic polymer having the general structure $(SiO_{n/2}(OH)_{4-n})_m$, where m is a large integer representing the degree of polymerization and n ranges from 0 to 4 to indicate the degree of hydration.

The silica structure has a close relationship to the cellular structure of the organism. Silica is deposited as gels, sheets, fibers, tubes, and globular assemblies. It has been found that the macroscopic geometric structure of the deposited silica is replicated in the short-order (two–three siloxane unit) structure. Although the dissolution of silica is inhibited by inclusion of various metal ions in the structure and often an organic coating, these deposits are converted over millions of years to opal-CT and opal-C, which are well-crystallized cristobalite. These siliceous materials are also transformed by dissolution, precipitation, recystallization, and compaction over geological time to form a less soluble, denser material, which is called chert if granular, chalcedony if fibrous, or flint if dark gray. Amorphous silica can be formed by the alteration of sand to a colloidally subdivided high surface area, amorphous silica volcanic ash. Amorphous silica is sometimes precipitated from the hot supersaturated waters of hot springs (siliceous sinter) and geysers (geyserite) where it is often found along with calcareous sinter.

Applications

The most significant commercial material from the biogenic silicas is diatomaceous earth [CAS: 7631-86-9], also called kieselguhr or diatomite. These deposits are the sediment of fragments and shells of one-celled algae, which form very fine particles having high surface area and as high as 94% silica content. Initially, silica in diatomite is amorphous, but portions of these deposits have been converted to cryptocrystalline quartz. Approximately 1,500,000 metric tons of diatomaceous earth is used as absorbents, fillers, insulating materials, and polishing agents. Tripoli, a white-to-gray, soft, porous material used as an abrasive or a filler, is mined from the Devonian deposits in southern Illinois. It is sold as amorphous silica, although it is actually a microcrystalline quartz (<10 μm dia) formed by leaching of carbonates from calcite- or dolomite-bearing chert.

Health and Safety

Amorphous silica is classified as nontoxic by ingestion. Soluble silica is present in most drinking water. It has been observed that silica passes through the body in soluble form being excreted with the water.

Unlike crystalline silica, amorphous silica has not been shown to cause silicosis, even in workers having long exposure to the product. This is presumed to be a result of the differing surface chemistry and solubility between crystalline and amorphous silica. The biological effects in animals of inhaled amorphous precipitated, fumed, and gelled silicas have been studied. After 12–18 months exposure to an environment containing an average daily respirable dust concentration of 6.9–9.9 mg/m^3, rats, guinea pigs, and Cynomolgus monkeys were tested for pulmonary function and by microscopic examination of internal organ tissue sections. Respiratory function was impaired for all animals and the presence of macrophage and cell aggregate lesions in the lungs of the monkeys were reported. It has been reported that these lesions regress after exposure to the dust is stopped. Monkeys exposed to fumed silica show the presence of reticulin fibers in the lungs as well.

Amorphous silica is classified by the Occupational Safety and Health Administration as a nuisance dust. The principal reported health reaction is contact dermatitis resulting from the absorption of protective oils from the skin. Effective May 15, 2002, the Environmental Protection Agency regulated an exemption from the requirement of a tolerance for residues of silica, amorphous, fumed (crystalline free), also known as silicon dioxide fumed amorphous, when used as an inert ingredient when applied to animals.

SILICA GEL. [CAS: 7631-86-9]. Silica gel is a coherent, rigid, continuous 3D network of spherical particles of colloidal silica. Both siloxane, −Si−O−Si−, and silanol, Si−O−H, bonds are present in the gel structure. The pores are interconnected and filled with water and/or alcohol from the hydrolysis and condensation reactions. A hydrogel is a gel in which the pores are filled with water. A xerogel is a gel from which the liquid medium has been removed, causing the structure to collapse, thus decreasing porosity. If the liquid medium is removed in a manner such that shrinkage and collapse of the gel structure do not occur, an aerogel is formed. Porous glass is similar to a silica gel. Silica powder can be made from xerogels by grinding or micronizing, which decreases the size of the gel fragments but leaves the ultimate gel structure unchanged. Gels and powders are characterized by the density, size, and shape of the particles, particle distribution, and aggregate strength or coalescence. See also **Aerogels**.

Silica gels are classified into three types: regular, intermediate, and low density gels. Regular density silica gel is made in an acid medium, which gives high (eg, 750 m^2/g) surface area, small ultimate (or primary) particles having average pore diameters of 2.2–2.6 nm, and a pore volume of 0.37–0.40 mL/g. This regular density silica gel contains ~6 wt % water as surface hydroxyl groups, which imparts a high capacity for adsorption of water and other polar molecules. See also **Desiccants**. The gel exhibits a high selectivity for polar molecules and has a large percentage of small pores. Intermediate density silica gel consists of larger ultimate particles having a lower (300–350 m^2/g) surface area, larger (0.9–1.1 mL/g) pore volumes, and larger (12–16 nm) average pore diameters. Because of the large pore size, intermediate density silica gel has a high capacity for water adsorption at high humidities. It is often used as a fine powder because aggregate (or secondary) particle size and porosity can be controlled. Low density silica gel (eg, an aerogel) has lower (100–200 m^2/g) surface areas, larger (18–22 nm) average pore diameters, and larger (1.4–2.0 mL/g) pore volumes. It is usually prepared as a very fine powder of extremely low density. Shrinkage of the gel during drying is minimized.

Preparation. Silica gels can be prepared by several methods. Most commonly, a sodium silicate [CAS: 1344-09-8] solution is acidified to a pH value of <10–11. The gelling time varies, as shown in. Syntheses include the bulk-set, slurry, and hydrolysis processes. The bulk-set process consists of preparing a silica hydrosol (gel) by mixing sodium silicate and a strong mineral acid, followed by mechanically breaking, washing the hydrogel particles free of electrolytes, drying, and activating. In the slurry process, sodium silicate solution and acid are mixed, either in batch or semicontinuously, to produce a gelatinous precipitate that is washed and dried, often by spray drying. These gels usually have a small particle size and the salts must be washed away before use. Gels can also be made directly from salt-free colloidal silica, which provides larger ultimate particle sizes, and hence greater stability, along with low salt contents. Such gels may also have lower specific surface areas and larger pore diameters. Hydrolysis of pure silicon compounds, such as ethyl silicate [CAS: 78-10-4], silicon tetrachloride [CAS: 10026-04-7], and other volatile hydrolyzable silicic esters, is another method of preparing gels. Although more expensive, this process produces dense gels of high purity and very small pore size.

The properties of a finished gel are determined by the size of the primary particles at the moment they aggregate into the gel network, called the gelation point (or gelation time). It is usually defined as the point at which aggregation in the sol forms a 3D network that can support a stress elastically. The sol-to-gel transformation is not well defined because it occurs as a continuous increase in viscosity. The concentration of the primary particles in solution affects the physical properties of the gel, including the compactness of the gel network, the pH, salt concentration, temperature, and time during which the gel is aged while wet, and the mechanical pressure or shear forces applied to the gel before or during drying. Additionally, the physical properties are influenced by the temperature, pressure, pH, salt content, and surface tension of the liquid

medium as it is being evaporated from the pores of the gel, and the temperature, time, and type of atmosphere in which the gel is heated after being dried. The type of catalyst used in gelation can have significant effects on the kinetics of the process and the structure of the silica gels formed. For some applications, silica gel is converted to pelletized or granular form by extruding pulverized gel with a binder or by shaping the hydrogel during drying. Silica can be gelled in spherical form by spray-drying, or by spraying droplets into an immiscible liquid (emulsion polymerization). Freezing of a silica sol produces silica gel particles of nonspherical shapes.

Characterization. When silica gel is used as an adsorbent, the pore structure determines the gel adsorption capacity. Pores are characterized by specific surface area, specific pore volume (total volume of pores per gram of solid), average pore diameter, pore size distribution, and the degree to which entrance to larger pores is restricted by smaller pores. These parameters are derived from measuring vapor adsorption isotherms, mercury intrusion, low angle X-ray scattering, electron microscopy, gas permeability, ion or molecule exclusion, or the volume of imbibed liquid.

Modifications. Once a gel structure is formed, it can be modified in the wet state to strengthen the structure or enlarge the pore size and reduce surface area, through a process called aging. Silica gel reinforcement can be carried out in several ways: (*1*) active silica, ie, low molecular weight polysilicic acids, can be added to a broken-up gel in order to deposit it at a uniform rate on the gel; (*2*) active silica can be added to a sol as the gel is growing, causing strong gel bridges to form between particles; (*3*) wet gel can be heat-aged to increase coalescence of the particles.

Applications. The largest application areas for silica gels include healthcare products as thixotropic agents in cosmetics and dentrifices; selective absorbents to maintain clarity during the brewing of beer; desiccants; thixotrope and flatting agents in coatings; and supports for polymerization catalysts. Specialized silica gels that have uniform pore structure, and that are often surface treated, are used in the production of chromatography columns for gas- and liquid-phase separations. Amorphous silica gels and aerogels are also used as insulating materials and sol–gel coatings for optical applications.

SILICA GLASS. See **Glass**.

SILICA SOLS AND COLLOIDAL SILICA. Colloidal silica is a stable aqueous dispersion or sol of discrete amorphous silica particles having diameters of 1–100 nm. It is derived from sodium silicate [CAS: 1344-0908]. Silica sols do not gel or settle out of solution for at least several years of storage. Aqueous sols that contain up to 50% silica have been developed. Particle sizes of ~130 nm in diameter are possible, but slowly settle out of solution.

In the absence of a suitable solid phase for deposition and in supersaturated solutions of pH values from 7 to 10, monosilicic acid polymerizes to form discrete particles. Electrostatic repulsion of the particles prevents aggregation if the concentration of electrolyte is below ~0.2 *N*. The particle size that can be attained is dependent on the temperature. Particle size increases significantly with increasing temperature. For example, particles of 4–8 nm in diameter are obtained at 50–100 °C (122–212 °F), whereas particles of up to 150 nm in diameter are formed at 350 °C (662 °F) in an autoclave. However, the size of the particles obtained in an autoclave is limited by the conversion of amorphous silica to quartz at high temperatures. Particle size influences the stability of the sol because particles <7 nm in diameter tend to grow spontaneously in storage, which may affect the sol properties. However, sols can be stabilized by the addition of sufficient alkali.

The stability of a silica sol depends on several factors and can be controlled by the surface properties of the silica. The pH value should be >7 to maintain sufficient negative charge on the silica particle surface to prevent aggregation. This surface charge is neutralized by soluble salts that ionize and reduce the size of the double layer around the silica surface, allowing aggregation. Therefore, sols are only stable at low salt concentrations. In the low pH value region sols are metastable, and gelling and aggregation are catalyzed by even very small amounts of fluoride ion. In this low pH value region, water-miscible organic solvents, like alcohol, retard gelling. Gelling occurs more rapidly at higher temperatures and is facilitated by a high silica concentration in the sol.

Silica sols can be destabilized by aggregation, gelation, crystallization, or particle growth plus settling. Aggregation occurs by coagulation in which particles collide or by flocculation in which particles become linked by bridges of flocculating agent. See also **Flocculating Agents**. Aggregation is prevented at neutral or lower pH values by the presence of an adsorbed layer of inert material, such as a surfactant, on the silica surface, thus preventing the direct contact of silanol groups with one another. Aggregation, as well as particle growth, is minimized by maintaining either a low silica concentration, a low reaction temperature, and/or a pH value of 9–10. Destabilization of a sol by crystallization of silica rarely occurs because this is a slow process at ambient temperatures.

Preparation

To produce sols that are stable at relatively high silica concentrations, particles must be grown to a certain size in weakly alkaline aqueous dispersion. Sols can be prepared by (*1*) neutralizing a dilute solution of sodium silicate with acid to a pH value of 8–9. A sol is produced if the sodium salt concentration is less than ~0.3 *N* and the neutralization reaction is performed at elevated temperatures to promote rapid particle growth. Rapid mixing prevents formation of low pH regions where gelation might occur; (*2*) washing sodium ions from the sodium silicate solution by electrodialysis or using an ion-exchange resin to form active silica, ie, low molecular weight polysilicic acid, which is stored at 82–100 °C (180–212 °F). Additional active silica is added to grow the sol particles, which can then be concentrated by evaporation or ultrafiltration; (*3*) washing out the salt from a freshly formed silica gel and peptizing at elevated temperature and pressure; (*4*) hydrolyzing $SiCl_4$ or organosilicates, such as ethyl silicate [CAS: 78-10-4] plus isopropyl alcohol [CAS: 67-63-0]. However, such sols are generally not stable and gel quickly; (*5*) cleaning pulverized silicon metal with hydrofluoric acid [CAS: 7664-39-3] to remove the oxide coating, which causes a reaction with water in an alkaline medium to produce hydrogen gas and colloidal silica, which can be stabilized as a sol with alkali; and (*6*) oxidizing $SiCl_4$ or ethyl silicate at high temperature, or vaporizing silica in the presence of a reducing agent to give pyrogenic silica powder. Particles are partly coalesced, have a low concentration of surface silanol groups, and are difficult to disperse in water to form sols without the addition of a wetting or other dispersing agent, or such treatment as grinding. The resultant sols contain aggregates.

Silica sols can be purified with the aid of an ion-exchange resin, dialysis, electrodialysis, or washing. Washing is usually affected by centrifugation, flocculation, ultrafiltration, or electrodecanting, followed by redilution and reconcentration. A preservative, such as formaldehyde is sometimes added to prevent the growth of microorganisms. Sols are concentrated by evaporation using forced circulation evaporators. If the sol becomes too concentrated, a hard layer of silica is deposited on the equipment walls, especially on heat-exchanger surfaces, so evaporation must be carefully monitored. Sols having particle size >30 nm in diameter are concentrated by centrifugation. Ultrafiltration, where the sol collects near the impermeable filter, can be used to remove water and salts. Sols that are low in soluble salts are concentrated by electrodecantation. See also **Dialysis**; **Electrodialysis**; and **Ultrafiltration**.

Modifications

Coagulation, flocculation, or gelation of silica sols and their subsequent drying produce amorphous silica powders. Gelation is rapid at pH values of 4–6. It is effected by increasing the silica content, such as by evaporation. See also **Evaporation**. Further drying of the resulting gel yields colloidal aggregates. Coagulation of a sol is prevented by surface charge and surface hydration; conversely, neutralizing the surface charge by lowering the pH value or by adding salt causes coagulation. Addition of salts also causes surface adsorption of cations that reduce surface hydration. Polyvalent cations, eg, Al^{3+}, are strongly adsorbed by silica surfaces and neutralize the surface charge. Hydrated metal cations act as bridging compounds or flocculating agents for silica particles. Flocculating agents used with silica sols are cationic surfactants, eg, octadecyltrimethylammonium bromide, or

organic polymers, eg, polyethyleneimine or polyacrylamide [CAS: 9003-05-8].

Sol particles are extremely small, and particulate silica obtained from sols is composed of aggregates or porous particles that have a much higher specific surface area than estimated from apparent size. Aggregates are also called *secondary particles*. Once silica particles have been formed as a sol, the surface can be modified by the attachment of different atoms or groups to obtain specific properties. Addition of aluminate ions gives an aluminosilicate surface that is much less soluble than is the silica surface and much more stable toward gelling, even at pH values of 4–6 and in the presence of salts. Addition of polyvalent metal oxides reverses the surface charge of silica and prevents bridging by siloxane bond formation. Organic groups can be added to silica surfaces in the form of organic ions through the formation of Si−O−C bonds as in esters or Si−C bonds as in organosilicon compounds. These surface alterations make silica easily dispersible in organic solvents, including nonpolar hydrocarbons. Some of these processes may cause the silica surface to become hydrophobic. Even a small change in particle surface characteristics may change the chemical behavior of the particle. Thus, a silica particle covered with alumina behaves in many ways as an alumina particle, and a silica particle covered with a hydrocarbon coating acts in many ways as a large hydrocarbon molecule.

Applications

Colloidal silicas are typically used for making silica gels having uniform pore sizes and pore volumes; as binders in molds for precision casting of superalloys; for increasing the friction properties of surfaces, such as paper, floors, fibers, and films; as antisoiling finishes on paper, textiles, and painted surfaces; for hydrophobizing surfaces and increasing their wettability by water; for strengthening polymer and latex goods; for polishing silicon wafers used in electronics industry; for improving performance of agents used for wetting and dispersing; as photographic emulsions; and for clarifying wines.

SILICA: SYNTHETIC QUARTZ CRYSTALS. [CAS: 7631-86-9]. Silicon dioxide, SiO_2, exists in both crystalline and glassy forms. In the former, the most common polymorph is α-quartz (low quartz). All commercial applications of crystalline quartz use α-quartz, which is stable only below ca 573 °C (1063 °F) at atmospheric pressure.

Quartz is mainly used in electronic applications, for which it must be free of electrical and optical twinning, voids, foreign minerals, and liquids. Moreover, it must be large enough for convenient processing. The principal source of electronic-grade natural quartz is Brazil, but manufacturers generally use synthetic quartz for electronic devices. Until the discovery of economic processes for quartz synthesis in the 1950s, natural quartz was used for commercial applications. The size, perfection, and properties of natural quartz vary. In addition, because natural crystals are generally irregular in shape, automated cutting is cumbersome and the yield is lower.

Synthesis

α-Quartz cannot be crystallized from its pure melt because viscous SiO_2 melts almost always form silica glass upon cooling. When crystals are formed, these are high temperature polymorphs of SiO_2, eg, cristobalite [CAS: 14464-46-1] and tridymite [CAS: 15468-32-3], that do not easily transform to untwinned α-quartz. α-Quartz is soluble in a variety of molten salts but the melts are viscous and crystallization below the α-transition temperature is not practical. Silicon dioxide is insoluble in most aqueous solvents at ambient conditions, except in HF solutions, and α-quartz is not the stable solid phase in equilibrium with such solutions. No successful practical vapor transport reaction for α-quartz growth has been discovered. However, α-quartz is stable and soluble in water at elevated temperatures and pressures, ie, under hydrothermal conditions. The solubility at a convenient temperature (400 °C (752 °F) and pressure (ca 17 MPa (25,000 psi)) is only a few tenths of a wt% and is not large enough for crystal growth. However, reactions of the following type take place in basic solutions under hydrothermal conditions.

$$2OH^- + SiO_2 \rightleftharpoons SiO_3^{2-} + H_2O$$

The result is that the weight solubility of quartz is increased to several percent. α-Quartz is the stable solid phase in equilibrium with such solutions and large crystals can be grown.

The first known successful attempt to grow quartz crystals hydrothermally was in 1905. Small crystals were formed in a thermal gradient from a sodium silicate solution. In Germany during World War II, quartz crystals were grown in an isothermal system using α-quartz seeds and vitreous silica nutrient. After that war, research programs aimed at practical quartz production began. It soon became apparent that processes depending on the supersaturation caused by the presence of silica glass were impractical. Metastable phases have a higher solubility than stable phases, but the supersaturation caused by their presence persists only as long as they are present. In the case of silica glass, its surface devitrifies rather quickly under hydrothermal conditions and growth on α-quartz seeds ceases. All successful quartz growth processes depend on the supersaturation produced by dissolving small particles of quartz nutrient in a hot region of the high pressure system and crystallizing it onto α-quartz seeds in a cooler part of the system. Thus, it is necessary to employ a solvent in which quartz is the stable solid phase having reasonable solubility and in which the dependence of solubility upon temperature produces an appropriate supersaturation, ΔS, and an appropriate temperature differential, ΔT, between the dissolving and growth zones.

All commercial processes use either sodium hydroxide NaOH [CAS: 1310-73-2] or sodium carbonate Na_2CO_3 [CAS: 497-19-8] as solvent systems. The dissolving mechanism is similar in both solvents because CO_3^{2-} hydrolyzes to OH^-. Sodium salts are required because insoluble sodium iron silicates form on the steel walls of the high pressure vessels when Na^+ and silicates are present. These compounds are relatively insoluble under hydrothermal conditions and form a protective coat on the walls, allowing the use on unlined, relatively inexpensive vessels. The slope of the solubility–temperature curve is greater in CO_3^{2-} than it is in OH^-. Thus loss of control in CO_3^{2-} with poor quality growth and spontaneous nucleation is more likely than it is in OH^-. The practical solution to this problem in CO_3^{2-} is to use a lower ΔT, which produces a ΔS safely below the poor quality region. Thus in CO_3^{2-} processes the growth rates are usually lower. Indeed, in OH^- the temperature control required is generally less than that in CO_3^{2-}.

The hydroxide process developed by Bell Telephone Laboratories is used by most producers. It is usually operated at higher pressures than the carbonate process and quartz is grown at faster rates. Less precise temperature controls are needed.

Hydrothermal Crystal Growth of Quartz

The hydrothermal technique is the only mean of producing the most important piezoelectric material, such as α- quartz, which is one of the most extensively studied materials. The principal source of electronic grade natural quartz is Brazil. Today the electronic industries are largely inclined to use synthetic quartz, because natural quartz crystals are generally irregular in shape, automatic cutting is cumbersome, and the yield is low. Over 3000 tons of quartz is produced annually for a variety of applications. The cost involved in the production of quartz is as follows:

End users	~US$1,000,000,000,000
Equipment	~US$5,000,000,000
Components	~US$1,00,000,000

Thus quartz takes first place in value and quantity of single-crystal piezoelectric materials produced by humans.

In the growth of α-quartz by the conventional method, the autoclaves used by most of the workers were modified Bridgman types of autoclaves. The typical laboratory size autoclave is 1 inch diameter × 1 ft length. The pressure autoclave used in Europe and The United States is the "13 inch" diameter and >10 ft — length autoclave with 350-L internal volume. This autoclave gives some 150 kg of quartz per cycle. But an evolution concerning the vessel's dimensions has to be noted, especially in Japan, where autoclaves with 1000–5000 L of internal volume are in operation producing 500–5000-kg quartz per cycle.

In the growth of α-quartz, available nutrient material such as small particle size α-quartz, silica glass, high quality silica sand, or silica gel is

placed in a liner made up of iron or silver with a suitable baffle and a frame holding the seed plates. A mineralizer solution with a definite molarity is poured into the liner to make the required percent fill.

The optimum growth conditions for synthesis of quartz based on the work from Bell Laboratories are:

dissolution temperature	425 °C (797 °F)
growth temperature	375 °C (707 °F)
pressure	15,000–25,000 psi
mineralizer concentration	0.5–1.0 *M* NaOH
temperature gradient (ΔT)	50 °C (122 °F)
% fill	78–85%
growth rate in (0001)	1.0–1.25 mm/day

The quality of the grown crystals is also a function of the seed orientation and its quality. Strained seeds generally produce strained growth regions. Most high quality crystals are grown using seeds, the surface of which is perpendicular to the *Z* direction, since the *Z*-growth region is the lowest in aluminium concentration. Though the main part of quartz production consists of "*Y bar*" crystals, ie, small crystals ($Z = 20–25$ mm, 64-mm seed) capable of several *Y* bars/crystal, the "*pure Z*" bars are also produced representing 10–20% of this production. But in medium and high quality grades we notice a rise in demand for crystals of very large dimensions and upper medium quality, especially in the United States, for manufacturing wafers used in surface wave applications. Earlier, most of the seeds used were natural quartz cut into a definite orientation, but in recent years this practice is only used when a high quality crystal is desired.

The growth of quartz crystals has been understood precisely with reference to the growth temperature, temperature gradient, and percent of fill, solubility, percent of baffle opening as a function of percent of fill.

The type of crystal to be grown depends on the application, as different properties are required in each case. The more precise the need, the more stringent are the requirements. For most applications, a truly high quality material is not needed. For high precision uses, such as in navigational devices and satellites, a very high quality material must be used. Most of the recent research on quartz growth is for improved resonator performance, which requires the growth of high quality, and low dislocation quartz.

See also **Hydrothermal Processing**.

Health and Safety Factors

The principal consideration in quartz synthesis is the safe management of the high pressures required for growth. The autoclave must be designed on the basis of proper stress analysis and materials selection. Autoclaves are shielded either by armor plate or by placement in cement-lined pits in the ground. Rupture disks that release pressures of ca 35 MPa (5000 psi) above the operating conditions as well as pressure and temperature overrides and alarms are standard practice. Autoclave embrittlement over long service life must be monitored and those in danger of operating at pressures much above ambient in the brittle range should be removed from service. The hydroxide solutions used in growth should be handled with standard safety measures, including eye shields for operators and safety showers. Activities in high pressure areas should be limited to essential maintenance. The disposal of spent solutions presents no special pollution problems because, at the conclusion of growth, runs are not strongly basic and can be easily neutralized.

Uses

The principal uses of α-quartz are mostly related to the piezoelectric effect. See **Ferroelectrics**; and **Piezoelectric Effect**. Crystals are used in electrical filters and oscillators for frequency and timing and frequency-division multiplexing and demultiplexing. They have also been used as electromechanical transducers in ultrasonic generators and electronic weighing microbalances. Crystal quartz is generally the material used wherever precise timing control is required. Thus, it is widely used in computers, portable as well as stationary telephones, citizen band (CB) radios, and watches. The use of quartz surface-acousic wave devices in cellular phones is an expanding market. The piezoelectric properties and design of filters and resonators have been discussed.

The advent of satellites for timing and communication requires the use of quartz that is not only radiation resistant but of greater mechanical strength and accuracy than material used for other purposes. Whereas the amount of quartz required for these, as well as some military uses, is small, exceedingly careful preparation of devices is essential. The global positioning satellites operate in the range of the radioactive Van Allen belt. Because aluminum substituted for quartz has been shown to be detrimental to radiation resistance, the concentration of aluminum must be reduced to a few parts per billion in the crystals. This is done by using slow growth and special starting materials low in aluminum, such as previously grown crystals or crystals grown from high purity fused quartz. The resonator is not fabricated using the AT, but from a doubly rotated stress-compensated (SC) crystal, which has been shown to be less temperature sensitive. Use of computerized fabrication equipment has made device preparation possible. Because these devices are subject to large stresses during liftoff into space, they must be free of etch channels which can reduce the mechanical strength of the device. In addition, during the chemical part of the device fabrication, hydrofluoric acid (HF) [CAS: 7664-39-3] is used. The HF tends to etch into dislocations and cause etch channels, which not only weaken the device but can affect the frequency stability.

Quartz also has modest but important uses in optical applications, primarily as prisms.

SILICATES (SOLUBLE). The most common and commercially used soluble silicates are those of sodium [CAS: 7440-23-5] and potassium [CAS: 7440-09-7]. Soluble silicates are systems containing varying proportions of an alkali metal or quaternary ammonium ion and silica. The soluble silicates can be produced over a wide range of stoichiometric and nonstoichiometric composition and are distinguished by the ratio of *silica* to *alkali*. This ratio is generally expressed as the *weight percent ratio* of silica to alkali-metal oxide (SiO_2/M_2O). Particularly with lithium and quaternary ammonium silicates, the molar ratio is used.

Sodium silicates find wide application in many types of detergents and cleaning compounds and have been used for many years as adhesives and cements. Both sodium and potassium silicates are important bonding agents in a large variety of ceramic cement and refractory applications, notably because of their heat stability and resistance to chemicals. Alkali-metal silicate bonds are used in high-temperature ceramic products in the fabrication of electrical components. Soluble silicates find wide application for pelletizing, granulating, and briquetting finely divided particles, such as clays, fertilizers, and ores. Sodium silicates also are used as bonding materials for foundry mold and core compositions. Because of their adherence properties, soluble sodium and potassium silicates are widely used as coatings. Frequently, sodium silicates are used to protect against water-line corrosion in tanks. The ability to form sols and gels is an interesting and very useful characteristic of soluble silicates. Silica gels are used in a major way as desiccants and as carriers for the production of petroleum-cracking catalysts, as well as raw materials in the manufacture of zeolites. Activated sols are used in water clarification.

Generally, sodium and potassium silicates are made by fusion of pure sand with alkali-metal carbonate or alkali-metal sulfate and carbon.

This operation is carried out in large open-hearth furnaces heated to a temperature range of 1300–1500 °C (2372–2732 °F). The resulting glasses may be used in this form, or dissolved in water to produce silicate solutions. Sodium [CAS: 1344-0908] and potassium [CASl 1312-76-1] silicate solutions also can be made by dissolving sand in sodium [CAS: 1310-73-2] or potassium [CAS: 1310-58-3] hydroxide solution at elevated temperatures and pressures. Lithium silicate [CAS: 13568-46-2] glasses, although insoluble in water, can be made by dissolving silica gel in, or mixing silica sols with lithium hydroxide [CAS: 1310-65-2] solutions. Anhydrous sodium metasilicate [CAS; 6834-92-0] is made from the anhydrous melt. This salt crystallizes rapidly from its aqueous solution at temperatures in the range of 80–85 °C (176–185 °F).

The most important property of sodium and potassium silicate glasses and hydrated amorphous powders is their solubility in water. The dissolution of vitreous alkali is a two-stage process. In an ion-exchange process between the alkali-metal ions in the glass and the hydrogen ions in the aqueous phase, the aqueous phase becomes alkaline, due to the excess of hydroxyl ions produced while a protective layer of silanol groups is formed in the surface of the glass. In the second phase, a nucleophilic depolymerization similar to the base-catalyzed depolymerization of silicate micelles in water takes place.

When sodium silicate solutions of intermediate ratios are concentrated to a thick gum, they become very sticky and tacky. This property is important to many of the adhesive applications. It is related to high cohesion and low surface tension rather than primarily to viscosity.

The stability of soluble silicate solutions depends strongly on pH and concentration. The addition of acids and acid-forming compounds gives rise to the formation of silica gels. Soluble alkali-metal silicate solutions are not compatible with most organic water-miscible solvents. The addition of alcohols and ketones causes phase separation into liquid layers. A few organic systems, however, particularly polyols, such as glycols, glycerins, sugars, and polyethylene glycols, are compatible and miscible with alkali-metal silicate solutions. SILICA: VITREOUS. [CAS: 60676-86-0] Vitreous silica is an amorphous phase of silicon dioxide. Modern methods of manufacture use chemical precurosrs to prepare the glass, however, vitreous silica was traditionally formed by heating crystalline SiO_2 above its melting point, 1730 ± 5 °C (41 °F), and then cooling it rapidly enough to avoid recrystallization. Because molten SiO_2 [CAS: 1343-98-2] is extremely viscous, glass formation is possible at a relatively slow cooling rate. Vitreous silica is available in a variety of forms, including powders, coatings, fibers, porous bodies, and bulk (dense) glass. See also **Silica: Amorphous**.

Vitreous silica has a wide range of commercial and scientific applications. Its unique combination of physical properties includes good chemical resistance, minimal thermal expansion, high refractoriness, and excellent optical transmission from the deep ultraviolet (UV) to the near-infrared (IR).

Although vitreous silica is a simple, single-component glass, its properties can vary significantly, depending on thermal history, the type and concentration of defects, and the presence of dopants and impurities. Vitreous silica can, however, be one of the purest commercially available glassy materials. In synthetic vitreous silicas, eg, total metal contamination is typically measured in the 50–100 ppb range. Even at such a low level of impurities, differences in properties, eg, uv transmission, are observed for various silicas.

Vitreous silica is a difficult material to manufacture, and as such is more expensive than most commercial glasses. It has a high vapor pressure, a strong tendency to devitrify, and a high viscosity even at its melting point. These physical characteristics preclude the use of standard glass-forming techniques. For optical-quality glass in particular, there is a need to maintain high purity and obtain excellent homogeneity of the refractive index; these specifications have, in part, led to the development of several unique manufacturing approaches, eg, electric fusion and flame hydrolysis.

This material is known largely as a synthetic material, but there are instances of the material occurring in nature. Vitreous tubes called *fulgurites* are produced when lightning fuses quartz sand. Large deposits of fulgurite exist in the Libyan desert. Vitreous silica can also be produced by meteor impact. The impact leads to rapid adiabatic heating of the quartz above its melting point. The quartz forms a glass on cooling. Examples of this type of vitreous silica have been found near Canyon Diablo, Arizona, and in meteorite craters in Australia and Arabia.

Vitreous silica is known by a number of names, most of which were developed to describe vitreous silicas formed using a particular processing method. These names are often misapplied as generic names for all vitreous silicas. Silica is a general term that refers to all forms of silicon dioxide [CAS: 14808-60-7], both crystalline and glassy; silica glass is an ambiguous term because it sometimes refers to any silica-containing glass composition; fused silica applies to vitreous silicas formed by fusion; fused quartz refers to vitreous silica formed specifically by the direct melting of quartz crystals; and synthetic fused silica describes vitreous silicas formed from chemical precursors, such as silicon tetrachloride [CAS: 100026-04-7]. Uses of the terms quartz and quartz glass should normally be avoided. These confuse vitreous silica with quartz, a crystalline form of silicon dioxide. See also **Silica**.

The optical quality of vitreous silica can range from transparent to opaque. Opaque glass contains a large number of isolated bubbles ranging in size from 5 to 200 μm. The bubbles scatter light, giving the glass a milky appearance. This material, produced by melting quartz sand, also tends to be less pure (99.5–99.9 wt% SiO_2) than more transparent materials. The opaque glass is an inexpensive form of vitreous silica and is often used where purity and optical properties are not important.

Transparent vitreous silicas have historically been classified by an informal scheme that differentiates the glasses by manufacturing method.

Structure

Vitreous silica is considered the model glass-forming material, and as a result has been the subject of a large number of X-ray, neutron, and electron diffraction studies. These investigations provide a detailed picture of the short-range structure in vitreous silica, but questions about the long-range structure remain.

The basic structural element in both vitreous and crystalline silica is the SiO_4^{4-} tetrahedron, which arises from the sp^3 hybrid orbitals of the silicon. Each silicon atom sits in the center of the tetrahedron surrounded by four oxygen atoms that hold the corner positions. Tetrahedrons bond together by corner sharing. In a properly developed structure, each oxygen is shared by only two tetrahedrons. This bonding scheme can produce a large variety of three-dimensional (3D) structures and is the reason that silica has a number of crystalline phases.

In the crystalline form of silica, the SiO_4^{4-} tetrahedrons link together in a series of interconnecting, six-membered rings. In the glassy form, the tetrahedral network can be modeled using a distribution of ring sizes normally ranging from three- to eight-membered units. The six-membered ring is the most common size but it can exist in distorted configurations which are not present in the crystalline structures. Detailed ring statistics of the glassy phase cannot be extracted directly from diffraction data. The three- and four-membered rings have been studied using Raman scattering.

The longer range structure of vitreous silica has been the subject of much debate. Two basic models have been presented. The random network model assumes that the SiO_4^{4-} tetrahedrons are connected in a completely random fashion and that there are no ordered microregions. The crystallite-based models argue that vitreous silica consists of very small, randomly oriented microcrystals.

Manufacture

Vitreous silica, a hard glass having a limited working range, is not conveniently produced using conventional glass-melting techniques. Rather, its high melting point and high melt viscosity have forced the development of a number of unique forming methods that utilize sintering or some type of deposition process. Many of the key physical properties depend on the specific forming process used because the forming process defines the material's thermal history and impurity–dopant profile. However, in most cases these developments have led to very high purity glasses with high index homogeneity and other properties that can be largely engineered.

The first reported instances of fusing silicon dioxide occurred early in the nineteenth century. In 1813, fusing of small crystals of quartz by injecting oxygen into an alcohol flame was described. This was followed in 1821 by the description of the fusing of quartz crystals using a hydrogen–oxygen

torch. Properties of vitreous silica were first measured in 1839. A glass produced using a hydrogen–oxygen flame exhibited remarkable strength, good elasticity, and excellent thermal shock resistance. This glass also had a tendency to volatilize and to devitrify. Later, the glass was shaped into tubes and bulbs. In 1887, a flame was used to draw fibers of vitreous silica.

Several efforts to develop commercial processes began ~1900 and were centered mainly in England, France, and Germany. It was during this early commercialization of vitreous silica that the distinction between the opaque and transparent glasses arose. The opaque material, called fused silica, was made by fusing sand. Resistance heating with carbon electrodes was an effective method for generating the desired temperature. The transparent material, called fused quartz, was made by fusing clear, selected quartz crystals. Achieving transparency by this approach required overcoming the problem of bubble formation in the glass. Crystalline quartz undergoes a transformation, ie, an inversion from its low to high crystalline form, at 575 °C (1067 °F), which also includes a rapid volume change. If heating is not uniform, the crystals can fracture (splinter) and lead to air encapsulation and the formation of bubble lines. This problem was overcome in 1900 by using the fracturing phenomenon to produce a fine crystalline frit that could be subsequently flame fused without splintering. Fracturing was promoted by heating the quartz crystals to a red heat and then quenching in water. An approach in which a glass boule was produced by injecting this powder into a flame was also advanced.

The production of vitreous silica from chemical precursors was first described in patents filed in 1934, including a fabrication method in which fine, high purity powders were produced by decomposing silanes. Forms were then cast from aqueous slips. More importantly, a flame hydrolysis process which used $SiCl_4$ as the chemical precursor was described. This latter approach led to a marked improvement in glass purity and served as the basis for the processes used in the 1990s to make synthetic vitreous silica.

Modern Manufacturing Techniques

Modern manufacturing processes of vitreous typically involve the fusion or viscous sintering of silica particles; the particles can be derived from sand crystals or are produced through a chemical process, e.g., flame hydrolysis or sol–gel. In one practice of the flame hydrolysis process, the powder is produced and fused into glass a single step, without the isolation of a porous body. Dopant and additive profiles are concentration are then controlled by the deposition conditions. When a process involving a discrete porous silica body as an intermediate is used, subsequent processing steps can be used to control dopant levels and in particular, the hydroxyl level of the final glass. The choice of fabrication method is often dictated by the end-use specifications. Flame hydrolysis or similar chemical techniques that allow for the production of very high purity glass are the methods of choice for optical applications but may be economically wasteful for less demanding applications.

Translucent Vitreous Silica. Translucent vitreous silica is produced by fusion of high purity quartz sand crystals. Sand is packed around a graphite rod through which a current is passed. The resistance heating produces a plastic mass that can be blown into molds, drawn into tubing, or shaped by rolling or pressing. Separation from the graphite rod is facilitated by gaseous products formed by interfacial reaction. Because the outside is sandy, the product is known as sand-surface ware. A matte finish is obtained by mechanical buffing. A glazed surface is produced by fusing the outside surface with an electric carbon arc or flame.

The Rotosil process employed by Heraeus and Heraeus-Amersil is used for the production of tubular or cylindrical shapes. It permits greater uniformity and dimensional control than the previous process. The quartz is washed in hydrofluoric acid and distilled water to remove impurities that can promote crystallization during manufacture. The sand is then placed in a rotating horizontal steel tube where it is held at the circumference by centrifugal force. A carbon arc is passed slowly down the center of the drum to fuse the sand. A modification, using open rotating molds on a vertical axis, allows formation of crucibles, beakers, and bowls.

For refractory applications, sand of moderate purity is fused by an electric arc into an ingot. The ingot is then crushed and ground to a size suitable for injection molding or slurry casting. A variety of shapes can be produced, including bricks, nozzles, and pouring tubes. After shaping, the pieces are dried slowly and then fired at 1150–1250 °C (2102–2282 °F) for 1–4 h. The materials have a white, opaque appearance.

Transparent Vitreous Silica. Clear, transparent, bubble-free vitreous silica may be obtained by melting natural quartz minerals by flame or plasma vapor deposition (synthetic fused silicas), and by sol–gel processing.

Uses

Chemical Applications. Because of its excellent chemical durability, high purity, thermal shock resistance, and usefulness at high temperature, vitreous silica has a wide range of applications in chemical analysis and preparations. Tubing, rods, crucibles, dishes, boats, and other containers and special apparatus are available in both transparent and nontransparent varieties. Because of its inertness, vitreous silica is used as a chromatographic substrate in the form of microparticles, capillary tubing, and open columns for high resolution gas chromatography. See also **Chromatography**.

Thermal Applications. The protection of precious-metal thermocouples in high temperature pyrometry is an important application of vitreous silica. Although satin tubing is usually employed, transparent tubes are superior for protecting couples when used in a reducing atmosphere.

Vitreous silica is used for gas- or electrically heated devices in various shapes, eg, as a tube or muffle because of its electrical resistivity, impermeability, and low expansion. In its simplest form, an electric-resistance furnace consists of a vitreous silica tube or pipe on which the resistance element is wound. Because of its indifference to temperature gradients, a tubular furnace of vitreous silica may be made to operate at different temperatures at various portions of the tube, either by arrangement of the heating elements or by cooling sections of the tube with water. Vitreous silica pipes may be employed in vacuum induction and gas-fired furnaces. See also **Vacuum**.

Radiant heaters employing resistance wire encased in vitreous silica tubes have the capability to modify the emitted radiation and furnish a higher proportion of shorter (1–2 μm) wavelengths that constitute the desirable radiations. Immersion heaters for use with acid solutions are of similar construction. An overhead heating unit consisting of a resistance wire sealed inside a vitreous silica container permits acid liquids to be concentrated or evaporated without ebullition or spattering. High efficiency radiators ~200-cm (~79 inches) long have been developed for power requirements up to 6 kW. These are used as energy sources in heat exchangers, high duty enamel drying equipment, polymerization processes, and copying devices.

Insulation having high thermal endurance has been made from vitreous silica fibers. See also **Ablative Materials**. Such material forms the basis for the 30,000 insulating tiles, 125-mm thick, that protect the aluminum skin of the space shuttle. The tiles add a minimum of weight because the density of the insulation is only 144 kg/m^3 (9 lb/ft^3), similar to balsa wood.

Optical Applications. Vitreous silica is ideal for many optical applications because of its excellent uv transmission, resistance to radiation darkening, optical polishing properties, and physical and chemical stability. It is used for prisms, lenses, cells, windows, and other optical components where uv transmission is critical. Cuvettes used in scatter and spectrophotometer cells are manufactured from fused silica and fused quartz because of the transmissive properties and high purity.

The development of high power laser systems at shorter UV wavelengths requires the transmissive and optical properties of fused silica. These high power lasers are utilized for commercial energy research and military applications. Excimer lasers are utilized in photoablation, photolithography, material processing, and medical applications. The optical beam delivery systems for these excimers can utilize fused silica lenses or optical fibers, as well as fluoride-based optics, eg, CaF_2 and MgF_2.

All higher energy laser systems throughout the world utilize a significant amount of high quality fused silica. Inertial confinement research laser systems, such as the Lawrence Livermore National Laboratory (LLNL) NIF (National Ignition Facility) laser that operates at 366 nm (frequency tripled Nd–YAG laser), require fused silica for the transport and cavity spatial filter lendes, Pockel cell windows, vacuum windows, final focal lens and the debris shield. Inertia confinement fusion research is also underway

using KrF (248-nm) laser systems, eg, the Los Alamos Aurora and Naval Research Laboratory NIKE. These utilize a fused silica (Corning Code 7980).

Mechanical Applications. The volume of vitreous silica used for fibers is a very small part of the total consumption. However, some interesting and significant applications have been developed in the laboratory, particularly in the area of measurements.

The sorption balance employs 15 small vitreous silica springs enclosed in glass tubes. The fiber is 2 mm (0.08 in)in diameter and the coils 1.25 cm (0.5 in) in diameter and 5.99 cm (2.4 inches) long. A platinum bucket, which weighs 202 mg, contains up to 0.5-g charcoal; the balance can be read to 0.2 mg. The sorption of gases is determined over a wide range of temperatures and pressures. This type of balance has been used for density determinations, measurements of heat loss and evaporation, study of chemical reactions between gas and solid phases, and weight determination of wet tissues of plant and animal origin. The advantages of vitreous silica are its resistance to corrosion, ease of cleaning and sterilization in an enclosed tube, and absence of damping from internal friction.

Because of its low and regular thermal expansion, vitreous silica is employed in apparatus used to measure the thermal expansion of solids. The most common form of dilatometer utilizes a vitreous silica tube closed at the bottom and containing the test sample. A movable rod of vitreous silica, resting on the sample, actuates a dial indicator resting on the top of the rod. The assembly containing the sample is placed in a furnace, bath, or cooling chamber to attain the desired temperature.

Lighting. An important application of clear fused quartz is as envelop material for mercury vapor lamps. In addition to resistance to deformation at operating temperatures and pressures, fused quartz offers uv transmission to permit color correction. Color is corrected by coating the inside of the outer envelope of the mercury vapor lamp with phosphor. Ultraviolet light from the arc passes through the fused quartz envelope and excites the phosphor, producing a color nearer the red end of the spectrum. A more recent improvement is the incorporation of metal halides in the lamp. See also **Illumination**.

Incandescent tungsten–halogen (F, Br, I) cycle lamps first became available in 1959 for general use. In this lamp, tungsten evaporating from the filament deposits on the envelope wall where it reacts with halogen vapor to form a volatile halide. The tungsten halide diffuses back to the filament where it dissociates to halogen vapor and tungsten. This permits a higher temperature operation, which affords higher efficiency and longer life than the conventional incandescent lamp. The wall temperature must be at least 250 °C (482 °F) and, if possible, ∼600 °C (∼1112 °F). Fused quartz has been essential for this development because it is one of the few readily available transparent materials that can be used in lamp envelopes. Improvements include the internal deposition of a barrier, eg, aluminum fluoride [CAS: 17949-86-9] or aluminosilicate [CAS: 1335-30-4], and reflective layers, eg, titanium silicate or zirconia. These protect the silica glass from vapor attack, slow the diffusion of deactivating impurities, and reflect heat onto the filament while transmitting visible light. These lamps are used in the illumination of airfields, sports arenas, buildings, streets, parking lots, and automobiles. They are also used in slide and film projectors and in specialized optical instruments.

Electronic Applications. In electronic systems, such as radar and computers, signal delay is sometimes necessary. A transducer converts electrical signals to ultrasonic elastic waves, which pass through a connecting medium to another transducer, where the waves are reconverted to electrical signals. Vitreous silica is an ideal connecting medium because it has excellent physical stability and low ultrasonic transmission losses. It transmits an ultrasonic signal almost 100,000 times more slowly than an electric signal in a wire.

By far the most significant electronic application, and perhaps the highest volume application for vitreous silica, is in semiconductors. This association began with silicon wafer technology, where vitreous silica was the principal high purity material for crucibles for silicon crystal growth. Both opaque sintered and transparent vitreous silica from tubing or boules are used. Crucible sizes have been increasing in response to the demand for ever-larger silicon wafers. See also **Semiconductors: Silicon-Based Semiconductors**.

Vitreous silica tubes are used for the subsequent high temperature diffusion, doping, and epitaxial growth treatments performed on wafers destined for large-scale integrated circuits. See also **Integrated Circuit (IC)**. Once again, the high purity of certain grades of vitreous silica, along with its high thermal endurance, make it the material of choice for diffusion tubes, wafer holders, boats, and associated hardware. Quartz manufacturers continue to push for higher purity, i.e., alkali content in tubing approaching <1 ppm.

Thin films of vitreous silica have been used extensively in semiconductor technology. These serve as insulating layers between conductor stripes and a semiconductor surface in integrated circuits, and as a surface passivation material in planar diodes, transistors, and injection lasers. They are also used for diffusion masking, as etchant surfaces, and for encapsulation and protection of completed electronic devices. Thin films serve an important function in multilayer conductor insulation technology where a variety of conducting paths are deposited in overlay patterns and insulating layers are required for separation. See also **Thin Films**.

Large-scale and very large-scale integration (VLSI) of electronic circuits requires the photoreduction of complex conductor and insulator patterns, which are reproduced on semiconductor devices by various photoresist processes. Vitreous silica is frequently used for the photomask substrate, ie, the transparent substrate for the image mask that contains the basis for conduction or insulator patterns. Because of the extremely high dimensional tolerances of VLSI, vitreous silica is a natural choice for the substrate. Its uv transmission properties allow fast exposure of the photoresists, and its very low thermal expansion prevents pattern distortions owing to temperature gradients encountered during processing. Perfectly flat and inclusion-free material is required. Another application for fused silica in the semiconductor field is as optical elements in microlithographic systems. In order to obtain smaller features on computer chips, ie, increasing the memory capacity, photolithographic stepper and scanner systems are moving to shorter wavelengths. Vitreous silica is used to make the excimer-based deep uv (248 and 193 nm) lithographic lens systems because of its superior uv transmission and radiation resistance characteristics. These lens systems are used to manufacture 256-Mb dynamic random-access memory computer chips(DRAM) and increasingly higher density NAND and NOR flash memory chips, whose growth rate is currently (2006) >30%/year. The refinement of silica properties for use at 193nm (particularly radiation resistance) is particularly important because 193-nm technology is being optimized further than previously thought possible. These systems are now being extended to manufacture circuit dimensions of <100 nm; this size was once intended to be manufactured using 157-nm lithography or other future technologies. In addition, titanium-doped silica (e.g., Corning Incorporated ULE) is being explored for its use in extreme UV (13 nm) lithography. Mirrors made from materials such as this offer the lultralow thermal expansion required for producing features in the 20-nm range.

Space and Astronomy. Vitreous silica is used in several space-based applications because of static fatigue (slow crack growth), thermal stability, and radiation resistance. Every U.S. space vehicle having service personnel, including Mercury, Gemini, Apollo, and space shuttle vehicles, has been equipped with windows made of high optical-quality vitreous silica (Corning Code 7940 or 7980) in order to have the clarity needed for visual, photographic, and television-based observations. The space shuttle utilizes triple-layer windows that have outer and central panes of vitreous silica with a tempered aluminosilicate inner pane. The outer pane is thinner for thermal endurance, whereas the two inner panes are thicker to supply strength. See also **Space Shuttle**.

The ability of vitreous silica to withstand dimensional changes with changing temperature has made it ideal for mirror blanks of telescopes. Vitreous silica is used in both space- and ground-based mirror applications because of the thermal stability and the ability to polish to ultrasmooth surface. See also **Telescope (Astronomical-Optical)**.

Space-based solar cells are covered with a very thin layer of vitreous silica to protect against the damaging environment of space such as atomic oxygen, micrometeorites, and radiation effects. Because the silica is transparent to damaging uv radiation, it is normally coated with a uv-reflective thin film. See also **Solar Energy**.

Optical Fibers. Pure and doped fused silica fibers have replaced copper lines in the telecommunication area. Fused silica fibers are used

in laser surgery, optical sensor application, and laser welding. Optical-fiber-tethered weapons, eg, fiber-optics-guided (FOG) missiles are another potential application for fused silica. Silica glass has also been used to fabricate microstructured air-core photonic band gap fibers. These fibers consist of an air core surrounded by a periodic lattice of air holes in glass. Light guidance in these fibers is based on the principle of interference to reflect radiation. Much of the success of silica in these applications can be related to its wide working range. See also **Optical Fiber Systems**.

SILICEOUS. Containing silicon dioxide or one of its compounds.

SILICIC. 1. Containing or pertaining to silicon. 2. Containing silicic acid (ortho) H_4SiO_4; or silicic acid (meta) H_2SiO_3; or silicic acids of a higher degree of hydration (disilicic acids, trisilicic acids, etc.).

SILICIFICATION. An important geochemical process by which certain sedimentary rocks such as limestones and dolomites, or calcareous fossils are partially or entirely replaced by silica, SiO_2. See also **Chert**; and **Flint**.

SILICON. [CAS: 7440-21-3]. Chemical element, symbol Si, at. no. 14, at. wt. 28.086, periodic table group 14, mp 1408–1,412 °C (2,566–2,574 °F), bp 2,355 °C (4,271 °F), density 2.242 g/cm^3 (solid crystalline, 20 °C (68 °F), 2.32 g/cm^3 (single crystal, 20 °C (68 °F). Elemental silicon has a face-centered cubic crystal structure (diamond structure). The existence of a hexagonal form of silicon with a wurtzite-type structure and with lattice parameters $a = 3.80$ Å and $c = 6.28$ Å was established in 1963 (Wentorf-Kasper). Claims to different parameters were made by Jennings-Richman (1976). These differences are discussed by Kasper-Wentorf (1977). Much new knowledge concerning the crystalline structures and phase transitions of silicon has been gained during the mid-1980s, notably from research under immensely high pressures and investigations involving the tunneling microscope, as described shortly.

The common form of silicon is a dark-gray, hard solid. It can be obtained as a brown microcrystalline powder, which is not an allotrope of the gray form. Both forms are unaffected by air at ordinary temperatures, but when heated in air to high temperatures a protective layer of oxide is formed. Silicon reacts with nitrogen [CAS: 7727-37-9] at high temperatures to form the nitride; with chlorine to form the chloride, with several metals to form silicides. Crystalline silicon is unattacked by HCl hydrochloric acid [CAS: 7647-01-0] or HNO_3, nitric acid [CAS: 7697-37-2] or H_2SO_4, sulfuric acid [CAS: 7664-93-9] but is attacked by hydrofluoric acid [CAS: 7664-39-3] FH to form silicon tetrafluoride gas [CAS: 7783-61-1]. Silicon is soluble in NaOH [CAS: 1310-73-2] sodium hydroxide solution forming sodium silicate [CAS: 1344-09-8] Na_4O_4SI and hydrogen gas. Silicon reacts with dry chlorine to form silicon tetrachloride [CAS: 10026-04-7] Cl_4SI.

There are three naturally occurring isotopes, ^{28}Si through ^{30}Si, and three radioactive isotopes have been identified, ^{27}Si, ^{31}Si, and ^{32}Si (Table 1). The latter isotope has a half-life of approximately 160 years, while the half-lives of the other two are short, measured in terms of seconds and hours.

TABLE 1. ISOTOPES OF SILICON

Isotope[a]	CAS Registry Number	Natural abundance, %	Half-life, s
^{24}Si	[15759-98-5]		0.10
^{25}Si	[15759-89-4]		0.22
^{26}Si	[14932-60-6]		2.23
^{27}Si	[14276-59-6]		4.14
^{28}Si	[14276-58-5]	92.23	
^{29}Si	[14304-87-1]	4.67	
^{30}Si	[13981-69-6]	3.10	
^{31}Si	[14276-49-4]		2.62[b]
^{32}Si	[15092-72-5]		160[c]
^{33}Si	[34809-98-8]		6.1
^{34}Si	[29675-19-2]		2.8
^{35}Si	[34809-99-9]		0.9
^{36}Si	[34810-00-9]		0.5

[a] Also known are ^{22}Si, ^{37}Si, ^{38}Si, and ^{39}Si.
[b] Value shown is in hours.
[c] Value shown is in years.

Lavoisier showed in 1787 that silicon (IV) dioxide SiO_2 [CAS: 14808-60-7] was not a single element and indicated that it was the oxide of a hitherto unknown element. In the early 1800s, Scheele, Davy, Gay-Lussac, and Thénard attempted to isolate the element, but were not successful. In 1871, Berzelius discovered silicon in a cast-iron melt and, in 1824, succeeded in isolating the element by reduction of potassium fluorosilicate with potassium. See also **Chemical Elements: History of the Origin**. Small laboratory amounts were produced by H.E. Sainte-Claire Deville in 1854 and by C. Winkler in 1864. It was not until 1900 that the effective properties of silicon as a deoxidizing agent for steel production were observed. Shortly thereafter, ferrosilicon alloys, using quartzite, coke, and iron pellets, were produced in electric refining furnaces of the type already in use for making calcium carbide. With this technique, it was possible to produce silicon of about 98% purity. It remained for the rigid purity requirements of semiconductors many years later before silicon of higher purities was produced.

Silicon is ranked second in the order of chemical elements appearing in the earth's crust, an average of 27.72% occurring in igneous rocks. In terms of seawater, it is estimated that a cubic mile of seawater contains about 15,000 tons of silicon (3240 metric tons per cubic kilometer). In terms of abundance throughout the universe, silicon is ranked seventh. First ionization potential 8.149 eV; second, 16.27 eV; third, 33.30 eV; fourth, 44.95 eV. Oxidation potentials $Si + 2H_2O \rightarrow SiO_2 + 4H^+ + 4e^-$, 0.86 V; $Si + 6OH^- \rightarrow SiO_3^{2-} + 3H_2O + 4e^-$, 1.73 V.

Other important physical properties of silicon are given under **Chemical Elements**.

Because of its chemical reactivity, silicon does not occur in elemental form in nature. The element is present in igneous rocks and clays as

alumino-silicate; as the oxide SiO_2 in quartz, sand. (Fig. 1), flint, and the gems amethyst, jasper, chalcedony, agate, onyx, tridymite, opal, crystobalite; as silicates in zircon (zirconium silicate, $ZrSiO_4$ [CAS: 10101-52-7]), in willemite (zinc silicate, Zn_2SiO_4), in wollastinite (calcium silicate, $CaSiO_3$ [CAS: 1344-95-2]), in serpentine (magnesium silicate, $Mg_3Si_2O_7$ [CAS: 133376-74-4]). Impure (up to 98% Si) silicon is obtained from the oxide (1) by igniting with aluminum powder, or (2) by reduction with carbon in an electric furnace. See also **Cancrinite**.

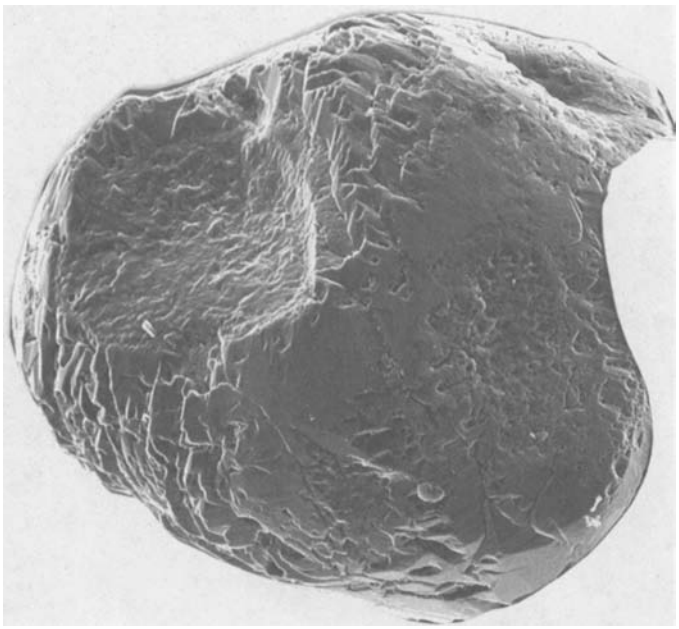

Fig. 1. Grain of sand, originally magnified 100×

Silicon Production for Alloys. production of raw steel requires about 1.6–1.7 kilograms of silicon per metric ton of steel. The silicon is used in the form of ferrosilicon [CAS: 8049-17-0], which contains about 20% silicon. It is estimated that about 3 million metric tons of ferrosilicon are consumed annually in steelmaking. The 20%-silicon-content ferrosilicon can be made in a conventional blast furnace. Ferrosilicons with higher silicon contents (45, 75, 90, and 98%) must be produced in electric furnaces. The raw materials are pure quartzites. The presence of impurities, such as aluminum oxide Al_2O_3 [CAS: 1344-28-1] and calcium oxide CaO [CAS: 1305-78-8], interfere with the melting process because of the formation of dross. The reducing agent used is chemical coke. For the very high concentrations of silicon (90–98%), ash-free petroleum coke or charcoal are used. Iron is added in the form of small pellets or chips in the production of the 45–75%-silicon alloys.

For certain metal alloys, a calcium silicon alloy is required. This alloy also is used as a steel deoxidizer and is favored because it forms a low-melting-point calcium silicate product. A representative composition of the alloy is: 30–33% Ca, 60–64% Si, 3–5% Fe, 1–2% Al, 0.3–0.6% C, and less than 0.15% S and P.

Silicon is used in the primary and secondary aluminum industry. The purity of silicon for metallurgical purposes ranges from 96.7 to 98.5% silicon; 0.10 to 0.75% aluminum; 0.03 to 0.04% calcium; with the remainder being principally iron.

Silicon Carbide. [CAS: 409-21-2]. This compound is an important industrial abrasive, having a hardness of 9.5 on the Mohs scale. In this compound, each silicon atom is surrounded tetrahedrally by four carbon atoms, and similarly, each carbon atom is surrounded by four silicon atoms. Silicon carbide is made by reducing pure quartz (glass-sand) with petroleum coke in an electric-resistance type furnace, known as the Acheson process. The product is hexagonal crystals ranging from light-green to black. It is used as a ceramic raw material for dross-repellent linings as well as for many abrasive applications.

Silicon carbide also has been recognized for many years because of its having a unique set of electronic material advantages over silicon and gallium arsenide. Not only can SiC withstand higher device operating temperatures (approximately 650 °C (1,202 °F) compared with silicon's 150 °C (302 °F), but SiC devices can operate with ten times the voltage capability and three times the thermal conductance capability. And, they are mechanically much more robust than traditional semiconductors.

The foregoing characteristics enable the configuration of a whole new family of high-power microwave and high-temperature electronics that can withstand high radiation for military and commercial systems.

Only recently has it been possible to produce uniform, centimeter-sized crystals. A high-purity vapor transport growth process has been developed (Westinghouse) to produce 1.5-inch (3.8-cm) device-grade SiC crystals and wafers. These comprised the building blocks for a demonstration of microwave transistors in the early 1990s. See Fig. 2.

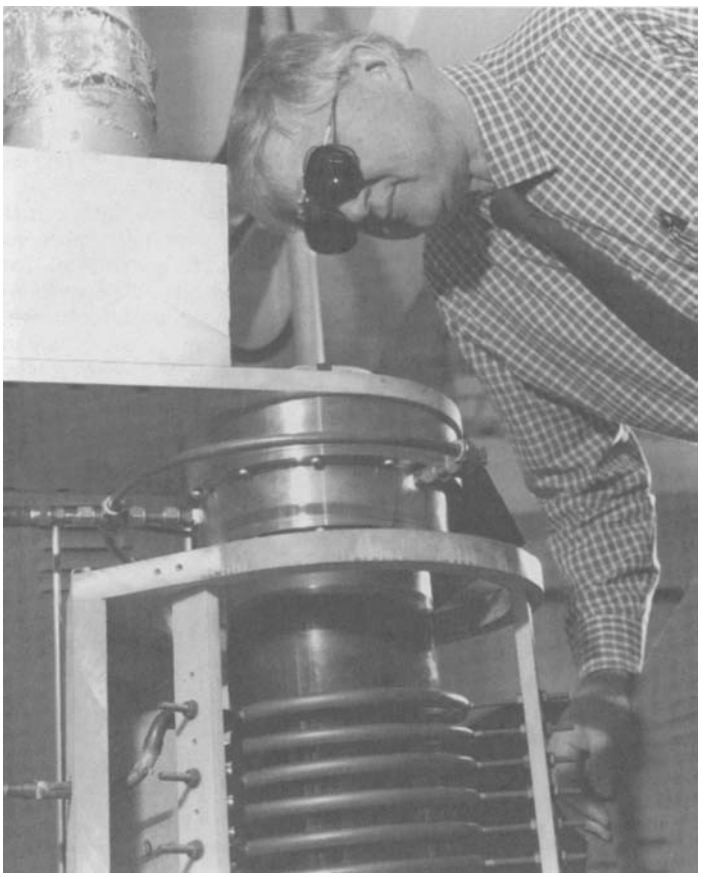

Fig. 2. Researcher Dan Barrett (Westinghouse Science & Technology Center) checks the hot (2400 °C) crystal growth furnace that he designed for physical vapor transport growth of single crystals of silicon carbide.

Super- or Hyperpure Silicon. For semiconductor use, there can be only one atom of impurity for every 100,000 silicon atoms! The starting material for the manufacture of hyperpure silicon is silicon tetrachloride, $SiCl_4$, or trichlorosilane, [CAS: 10025-78-2] $SiCl_3H$. Both of these materials can be reduced with hydrogen to yield a compact deposition of silicon on hot surfaces, ranging from 800–1,200 °C (1,472–2,192 °F). The starting compounds are purified of boron and phosphorus by fractional distillation and absorption techniques. The process hydrogen is purified by passing it through molecular sieves under high pressure, followed by absorption techniques at a low temperature (−190 °C (−310 °F). With the highly purified starting ingredients an excess of hydrogen is circulated through heated quartz tubes. Or, the gas mixture may be blown into quartz bell jars, whereupon the silicon is deposited on filaments of tantalum or tungsten or on thin rods of hyperpure silicon, which may be heated by electrical resistance or radiofrequency energy. This process yields polycrystalline rods of silicon which range up to about one meter in length and 150 millimeters (6 inches) in diameter.

To be used in semiconductor devices, the polycrystalline silicon must be converted to single crystals of a defined, predetermined type of

conductivity (*n* or *p* type). The crystals must be rigidly controlled as regards their resistivity, and possess the highest degree of crystallographic perfection. The two crystal-growing techniques used are: (1) crucible free vertical float zoning which removes all residual impurities, including phosphorus, arsenic, and oxygen, but boron is essentially irremovable by floating zoning, or (2) crucible pulling in which the crystals, particularly those of lower resistivity, are drawn out of a melt in a process known as the Czochralski technique. Both processes must be conducted under helium or argon, often under a vacuum of 10^{-5} torr.

Production of Ultrapure Silicon Crystal. In 1990, Westinghouse engineers reported the production of the purest crystal of silicon ever made — namely, four times purer than previously reported material. The crystal also is significantly larger, adding to its practicality in the manufacture of microelectronic circuits and devices.

The cylindrical structure, called a *boule*, weighs 22 pounds (10 kg) and is over a yard (meter) long, with a diameter of just over 3 inches (8 cm). Impurities are a few parts in 100 billion, compared with more than 10 parts in 100 billion previously reported for 1-inch (2.5-cm) diameter ultrapure crystals.

Crystal boules are sliced into wafers on which microelectronic circuits and power semiconductor devices are fabricated. An important use of the wafers is for infrared dectors for space, defense, and environmental applications.

Liquid-Solution Synthesis of Silicon Crystals. In late 1992, J.R. Heath (IBM Watson Research Laboratory) reported on a liquid-solution phase technique for preparing submicrometer-sized silicon single crystals. The synthesis is based on the reduction of $SiCl_4$ and $RSiCl_3$ (R=H, octyl) by sodium metal in a nonpolar organic solvent at high temperatures (385 °C (725 °F) and high pressure (above 100 atmospheres). For R=H, the synthesis produces hexagonal silicon single crystals ranging from 5 to 2000 nanometers. For R=octyl, the synthesis also produces hexagonal-shaped silicon single crystals.

Light Emission From Silicon. Because of silicon's successes in the electronic components field, research has been going on to find a form of Si that will produce luminous radiation. Because of former failures, numbers of scientists have given up this research. However, independently in French and British laboratories during 1990, some success has been achieved. These researchers have found that, if one etches Si into structures so tiny that the electronic behavior of the material is transformed, full-color emission from what are termed "silicon quantum wires." A British researcher L. Canham (Royal Signals and Radar Establishment, Malvern, England) has observed that, to make silicon quantum wires, a process for sculpting silicon, known for some 30 years, is the basis. A silicon wafer is immersed in an acid electrochemical bath, which bores into the disk to produce extremely small so-called "wormholes." The latter are etched chemically, enlarging them until they meet one another. The result is a columnar structure of silicon. The latter are about a micron high, and 50 of them, stacked end to end, would span an area about equivalent to a cross-section of a human hair and are only a few nanometers thick ($\frac{1}{15,000}$), smaller than a hair. The researchers have found that, when such a structure is bathed in ultraviolet light, light emission occurs. The emitted wavelength is determined by the porosity of the Si layer.

J.P. Harbison (Bellcore, Redbank, New Jersey) observes, "This is not the moment of the breakthrough for light-emitting silicon, but it is the moment when a lot of people are realizing its potential."

See also **Crystal**; and **Semiconductors: Silicon-Based Semiconductors**.

Research on Silicon Structure and Surface Properties. The rather unusual properties of silicon have intrigued scientists for many years. It possesses the physical properties of a *metalloid* (exhibits properties of both a metal and nonmetal). In several ways, silicon resembles germanium and, to a lesser extent, it resembles arsenic and boron. Silicon is a semiconductor of electricity, the conductivity rising with temperature. Silicon, in pure form, is intrinsically a semiconductor. The presence of impurities in very minute amounts markedly increases its conductivity. By introducing elements of group 13 (such as boron), which have a deficiency of electrons, the *p*-type silicon results. Therein, electricity is conducted by migration of electron vacancies or holes. On the other hand, introduction of elements of group 15, such as arsenic or phosphorus, in which there is no deficiency of electrons, the *n*-type silicon results, in which extra electrons carry an increased current because of their migration. Scientists have not been satisfied with oversimplified explanations such as that just given. As a key material in the microelectronics field, where the processing of silicon into chips and other configurations for electronic components is essentially effected at the surface of the silicon, particular interest concerns those crystalline structural details that play a role in the electronic nature of the element. However, prior to the emergence of solid-state technology, scientists were puzzled by what appeared to be crystal structure and surface anomalies and, consequently, research dates back many years, with progress largely determined by the instrumentation available to investigators. The *tunneling microscope*, the invention of which is accredited to G.K. Binnig and H. Rohrer and partially to E.W. Müller (who also invented the field-ion microscope in the 1950s), has contributed much toward an understanding of the surface of the silicon crystal, an understanding which is expected to be translated ultimately in manufacturing improvements and better final properties of silicon-based electronic components. See also **Scanning Tunneling Microscope**.

The relatively recent availability of means to create extremely high pressures (see also **Diamond Anvil High Pressure Cell**) has made it possible to gain further insights into the character of silicon. It has been learned from such experimentation that at a pressure of 110 kilobars (about 1.6 million pounds per square inch), silicon enters *truly metallic* phases. At the pressure stated, silicon abruptly assumes a structure similar to the beta form of tin. At this pressure and at a temperature of 6 degrees Kelvin (six Celsius degrees above absolute zero) the metal becomes superconducting, that is, it offers no resistance to the passage of electrons. At a pressure of 130 kilobars, the beta-tin form of silicon transforms into what has been designated as the *primitive hexagonal* phase, a phase first discovered in 1984. This research was conducted by Cohen, Chang, and Dacorogna (University of California, Berkeley). Prior to this experiment, it was not thought that such a phase would exist in the crystal of any chemical element. The researchers entered into theoretical calculations after the experiment to better understand the properties of the primitive hexagonal phase. The calculations were lengthy and required a CRAY/X-MP computer. A major finding was that the bonds linking the atoms in each of the planes defined by the hexagons should be weaker than the bonds linking the atoms in adjacent planes. This indicates that the electronic charge distribution should be inhomogeneous along one dimension. This inhomogeneity is an indication of a good superconductor because, in effect, it provides corridors through which electrons can move.

In their investigation, the researchers turned back to the much earlier hypotheses of quantum mechanics, including the properties of phonons (in quantum mechanics, a phonon can be treated as a particle, one that interacts with electrons). A strong interaction improves the opportunities for superconductivity. However, where the coupling is too strong, the integrity of the lattice may collapse and a structural phase transition may occur. Testing for superconductivity at such high pressures will be difficult. The Berkeley group predicts that the superconducting temperature will rise to a value greater than 10 degrees as the pressure nears the value required for the transition from the simple hexagonal phase to the hexagonal closed-packed phase. If expectations are proved, silicon could be the best superconductor of all chemical elements. Translating this to practical application, of course, may or may not be feasible at some future date. See also **Superconductivity**.

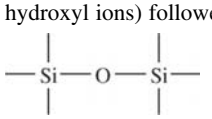
Silicon Chemistry and Compounds

Like carbon [CAS: 7440-44-0], silicon forms chiefly covalent bonds, but its greater atomic radius enables it to form positive ions more readily. Unlike carbon and tin, silicon is not allotropic, having only one elemental form, the diamond structure in which each atom is surrounded tetrahedrally by four others to which it is covalently bonded. An apparently amorphous brown powder, produced by combustion of silane, SiH_4, silicon tetrahydride [CAS: 7803-62-5] has been found to be a microcrystalline variety of this covalently-bonded structure. Much research has been conducted during the 1970s and 1980s pertaining to the more exotic silicon compounds, such as the *disilenes*, and to silicon-mediated organic synthesis. These topics are discussed later in this article. The following several paragraphs are devoted to the large number of traditional silicon compounds whose constitution and characteristics have been well established over the years.

Silicon Dioxide [CAS: 14808-60-7]. (SiO_2). This compound exists in at least eleven distinct crystalline forms. Several of them are obtained by heating α-quartz, which has a number of transition points, to produce β-quartz, and to give various forms of tridymite and crystobalite. The unit of structure is the tetrahedron in which each silicon atom is covalently bonded to four oxygen atoms, and the variation is in the ways these tetrahedra are interconnected (by oxygen atoms) to form a three-dimensional system.

Silicon dioxide is converted by hydrofluoric acid into silicon tetrafluoride, SiF_4, [CAS: 7783-61-1] a gas. SiF_4 can also be produced directly from the elements, as can the other tetrahalides, silicon tetrachloride, $SiCl_4$ (a liquid), silicon tetrabromide, $SiBr_4$ [CAS: 7789-66-4] (a liquid), and silicon tetraiodide, SiI_4 [CAS: 13465-84-4] (a solid). The silicon halides hydrolyze much more readily than the carbon halides, because the unoccupied silicon 3_d orbitals are energetically not far above its 3_s and 3_p orbitals. This fact also permits the formation of the sp^3d^2 hybrid bonds of the fluorosilicate ion, SiF_6^{2-}, and additional compounds of the halides, e.g., $SiX_4 \cdot 2$ pyridine. Silicon also is intermediate between carbon and the higher members of main group 4 of the periodic table in forming a dichloride, $SiCl_3$, by strong heating of silicon with silicon tetrachloride.

Quartz and other forms of silica react very slightly with water to form monosilicic acid, $(SiO_2)_n + 2nH_2O \rightarrow nSi(OH)_4$. As shown, this reaction is a depolymerization followed by a hydrolysis, and proceeds rapidly with hot alkalis or fused alkali metal carbonates, yielding soluble silicates containing the SiO_4^{4-} and $(SiO_3^{2-})_n$ ions. The hydrolysis reaction is geologically important, because it is considered to be the starting point in the formation of the innumerable silicate minerals that occur so widely in nature, just as many of the silica minerals may have originated by the reverse reaction. Many of the more complex silicic acids are considered to form by polymerization of $Si(OH)_4$ molecules by sharing of OH ions between two silicon ions (octahedrally coordinated by six hydroxyl ions) followed by condensation with the loss of water to produce



linkages. The polymerization of silicic acid is carried out industrially to produce silica gel, a stable sol of colloidal particles. The various methods involve careful removal of water [CAS: 7732-18-5] H_2O, the catalytic effect of acid or alkali (or fluoride ion) and controlled pH. Many varieties of silica gel have been made, including the zerogels and aerogels, in which the aqueous phase is displaced by a gaseous one. See also **Aerogels**.

In 1992, Yeganeh-Haeri, Weidner, and Parise (Center for High Pressure Research, State University of New York, Stony Brook) used laser Brillouin spectroscopy to determine the adiabatic single-crystal elastic stiffness coefficients of silicon dioxide in the alpha-cristobalite structure. This SiO_2 polymorph, unlike other silicas and silicates, was found to exhibit a negative Poisson's ratio. Alpha-cristobalite contracts laterally when compressed and expands laterally when stretched. Tensorial analysis of the elastic coefficients showed that Poisson's ratio reached a maximum value of -0.5 in some directions, whereas averaged values for the single-phased aggregate yielded a Poisson's ratio of -0.16.

Silicon Dioxide as a Chemical Intermediate. In 1992, R.M. Laine (University of Michigan, Ann Arbor) announced the development of a process that transforms sand and other forms of silica into reactive silicates that can be used to synthesize unusual silicon-based chemicals, polymers, glasses, and ceramics. The Laine procedure produces pentacoordinate silicates directly from low-cost raw materials — silicon dioxide, ethylene glycol, and an alkali base. The mixture is approximately a 60:1 ratio of silica gel, fused silica (or sand) to metal hydroxide and ethylene glycol. Heating the mixture slowly, the ethylene glycol and water (used to put the materials in solution) boils off. The resulting glycolatosilicates, unlike the hexa- and tetracoordinate forms, are reactive and offer potential for synthesizing a wide range of materials. Laine observes, "The new silicon chemistry could produce alternatives to many petrochemical-based products and could be competitive with or superior to present carbon-based materials." Thus far, a number of materials have been produced by the process:

1. A clear polymer capable of conducting electric current when spread in a thin layer across a flat surface. Potential includes applications in batteries, heated windshields, and electrochromic windshields.
2. A fire retardant polymer that is easily impregnated into wood to "petrify" the material, making it stronger and nonflammable.
3. Liquid-crystal polymers stable to about 425 °C (800 °F), with potential for uses in watch displays and aerospace instrumentation.
4. Silicate glasses capable of withstanding high temperatures.

Silicates. The great number of naturally occurring silicates result, as just indicated, from the polymerization and dehydration of monosilicic acid H_4SiO_4 to form, ultimately, such groups and ions as $(Si_2O_7)^{6-}$, $(Si_3O_9)^{6-}$, $(Si_4O_{12})^{8-}$, and $(Si_6O_{18})^{12-}$. Various cations, such as those of boron, B^{3+}, aluminum, Al^{3+}, etc., in the structure lie at the centers of anionic polyhedra having as anions the O^{2-} ions of neighboring SiO_4 tetrahedra, in which each *Si* O bond has an electrostatic bond strength of 1. Cations of lower charge density, on the other hand, like sodium, Na^+, potassium, K^+, calcium, Ca^{2+}, etc., are located interstitially. The great variety of the silicates is due to the considerable degree of isomorphism, exhibited not only by elements of the same group, but by elements of different groups, whereby they partly replace each other in the complex silicates, and by no means necessarily in stoichiometric proportions. Thus troosite may be represented by the formula $(Zn, Mn)_2SiO_4$, chrysolite by $6\ Mg_2SiO_4 \cdot Fe_2SiO_4$, and vermiculite by $(Mg, Fe)_3(AlSi)_4O_{10} \cdot (OH)_2 \cdot 4H_2O$, even the silicon in vermiculite being partly replaced (by aluminum). One plane of classification of the silicates is upon the basis of the linking of the SiO_4 tetrahedra:

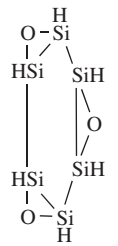
A. Discrete silicate radicals.
   1. Single tetrahedral (SiO_4^{4-}), e.g., phenacite, Be_2SiO_4.
   2. Two tetrahedra $(Si_2O_7)^{6-}$, e.g., hardystonite, $Ca_2ZnSi_2O_7$.
   3. Three tetrahedra $(Si_3O_9)^{6-}$, e.g., benitoite, $BaTiSi_3O_9$.
   4. Four tetrahedra $(Si_4O_{12})^{18-}$, e.g., axinite, (Fe, Mn) $Ca_2Al_2BO_3Si_4O_{12}$.
   5. Six tetrahedra $(Si_6O_{18})^{12-}$ e.g., beryl, $Be_3Al_2Si_6O_{18}$.

B. Silicon-oxygen chains of indefinite length.
   1. Single chains with one silicon atom to three oxygen atoms, e.g., diopside, $CaMg(SiO_3)_2$.
   2. Double chains (Si:O = 4 : 11), e.g., tremolite, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$.

C. Silicon-oxygen sheets. (Si:O = 2 : 5), e.g., talc, $Mg_3(SiO_5)_2(OH)_2$.

D. Silicon-oxygen spatial networks.
   1. Composition SiO_2 (composed of interlinked SiO_4 tetrahedral), e.g., quartz, SiO_2.
   2. Composition $M_n(Si, Al)_nO_{2n}$, e.g., feldspar, KSi_3AlO_8. These are probably based upon silicon and aluminum tetrahedra, variously linked.

Silanes. The increasingly large number of silicon compounds produced by industrial processes may be systematized about the silanes and their substitution products, just as the silicates are about the SiO_4 tetrahedron. Silicon, like carbon, forms a number of hydrides, though their number is much more limited. The silane series, analogous to the paraffin hydrocarbons, has at least six members, silane [CAS: 7803-62-5] (SiH_4), disilane [CAS: 1590-87-0] ($H_3Si-SiH_3$), hexasilane ($H_3Si-SiH_2-SiH_2-SiH_2SiH_2-SiH_3$). They are increasingly unstable, hexasilane dissociating at room temperature. They are halogenated with free halogens to form substituted silanes, and catalytically with the hydrogen halides. The halosilanes react with NH_3 to form silylamines or silazanes and are hydrolyzed by water to form siloxanes. Prosiloxane, H_2SiO, polymerizes readily but disiloxane, $H_3Si-O-SiO_3$, and the higher siloxanes, although they polymerize, can readily be studied. They have properties like the ethers and other analogous carbon compounds. Hydrogen-containing siloxanes, such as $HO_2Si-SiO_2H$ are also known and polymerize readily. There are also ring siloxanes, such as siloxen, which has a polymerized structure of epoxy form (a powerful reducing agent)



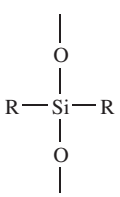
Silyl and polysilyl radicals also combine with nitrogen, arsenic, and other main group 5 elements, as with sulfur and selenium.

The silazanes are such compounds of silicon, nitrogen and hydrogen of the general formula $H_3Si(NHSiH_2)nNHSiH_3$, being called disilazane, trisilazane, etc., according to the number of silicon atoms present. (In disilazane, *n* in the above formula has a value of 0, in trisilazane it is 1, etc.)

The silthianes are sulfur compounds having the general formula $H_3Si(SSiH_2)_nSSiH_3$ which are called disilthiane, trisilthiane, etc., according to the number of silicon atoms present. They have the generic name *silthianes*. (In disilthiane, *n* in the above formula has a value of 0, in trisilthiane, a value of 1, etc.)

Silicones. These are semiorganic polymers with a quartz-like structure in which various organic groups are attached to the silicon atom. By varying the kind and number of organic groups, a variety of materials ranging from liquids through gels and elastomers to rigid solids (resins) can be produced.

The organosilicon compounds may be regarded as substituted silanes, although of course their preparation is not usually in this way. Thus, ethyl silicate, $Si(OC_2H_5)_4$, [CAS: 78-10-4] is prepared from silicon tetrachloride and ethyl alcohol, and tetraethyl silane, $Si(C_2H_5)_4$, [CAS: 631-36-7] is prepared from silicon tetrachloride and diethylzinc. The silicon-carbon bond, unlike the carbon-carbon bond, has about 12% of ionic character, varying somewhat with the atoms or groups attached to the two atoms. Other types of organosilicon compounds include the esters, the alkoxyhalosilanes, the higher tetra-alkylsilanes (prepared from silicon tetrachloride and Grignard reagents), the alkylsilanes (H partly replaced by R), the alkylhalosilanes, the alkylalkoxysilanes, the alkylsilylamines, some aryl compounds of the foregoing types, and many related derivatives of disilane and the polysilanes. Other types of compounds are those having silicon-carbon chains and the organosiloxane compounds, for which the name "silicones" is often used. These are essentially chains or networks of groups



joined by oxygen atoms attached to the silicon atoms as shown. There are many other groups of silicon compounds, as well as individual ones.

Aluminates. Many complex silico-aluminates or aluminosilicates are formed in nature. Of these, clay in more or less pure form (pure clay, kaolinite; kaolin, china clay, $H_4Si_2Al_2O_9$ or $Al_2O_3{\cdot}2SiO_2{\cdot}2H_2O$) is of great importance. Clay is formed by the weathering of igneous rocks, and is used in the manufacture of bricks, pottery, porcelain, Portland cement. Sodium aluminosilicate is used in water purification to remove dissolved calcium compounds.

Fluosilicate. Sodium fluosilicate, [CAS: 16893-85-9] Na_2SiF_6, white solid slightly soluble; magnesium fluosilicate, [CAS: 18972-56-0] $MgSiF_6$, white solid, soluble.

Sulfides. Silicon monosulfide, [CAS: 12504-41-5] SiS, yellow solid, somewhat volatile, formed by heating to redness crystalline silicon in sulfur vapor, reactive with water; silicon disulfide, [CAS: 13759-10-9] SiS_2, white crystals, formed by heating amorphous silicon and sulfur, and then subliming, reactive with water.

Nitrides. Trisilicon tetranitride, Si_3N_4, by heating silicon oxide plus carbon to 1,500 °C (2,732 °F) in a current of nitrogen gas.

Silicates. See also **Adhesives**.

Silicon-Silicon Double Bond. Of the chemical elements, Si is closest to carbon in terms of its chemical properties. Multiple bonds pervade carbon chemistry and thus it is no surprise that investigators, over a period of many years, have been seeking evidence of multiple bonding in silicon. As early as 1911, Kipping reported compounds exhibiting this bonding, but these substances were later shown to be polymers or cyclic oligomers. It was not until the 1960s that good evidence was reported for the existence of Si=C (silene) [CAS: 1344-95-2], Si=Si (disilene) [CAS: 15435-77-5], and Si=O (silanone) compounds. The full reality of such compounds, however, was not reported until 1981. At that time, a silene and a disilene, each of which is stable at room temperature, were reported by two separate groups. Brook, et al. reported on a silene; West, et al. reported on a disilene. It has since been concluded that many disilenes can be prepared, including compounds that are unexpectedly stable. Molecules containing Si=Si bonds can be synthesized by several routes. The key to stabilization of these compounds is to provide large substituents bonded to the Si atoms so that polymerization is blocked. It has been determined that disilenes react chemically by addition across the double bond, as do alkenes. Tetramesityldisilene, as reported by West, also undergoes a wide variety of addition reactions previously unestablished in organic chemistry. The result is several "new" and unusual types of molecules, the details of which are reported in the West paper listed under references.

Silicon-Mediated Organic Synthesis. As reported by Paquette (reference listed), since the late 1960s, organic chemists have used the chemical properties of tetracovalent silicon to achieve a variety of new synthetic transformations. Paquette (Ohio State University) summarizes, "In carbon-functional silanes, exceptional stabilization is provided to a carbocation center in the beta position when the carbon-silicon bond lies in plane. This phenomenon directs electrophilic attack to the silicon-substituted carbon in aryl-, vinyl-, and alkynylsilanes and to carbon-3 in allylsilanes. For different reasons, silicon also stabilizes a carbon-metal bond in the alpha position. Consequently, access to many silicon-containing organometallics is readily available. The exceptional strength of silicon-oxygen and silicon-fluorine bonds is yet another factor that controls the chemical reactivity of silicon reagents. In recent developments, preparative chemists have taken advantage of these properties in imaginative and useful ways." In the Paquette paper, these observations are developed in exceptional and illustrated detail.

Reactions of Elemental Silicon. In the late 1980s, E.A. Pugar and P.E.D. Morgan and a team of researchers at the Rockwell International Science Center, Thousand Oaks, California, conducted a thorough effort to understand "Low Temperature Direct Reactions Between Elemental Silicon and Liquid Ammonia or Amines for Ceramics and Chemical Intermediates." Details are given in reference cited.

Because of the important potential applications of silicon nitride, the use of low-cost starting materials, such as elemental silicon and liquid ammonia or amines, may be more effective than the existing chloride method. In earlier work, this process was found to form silicon di-imide ($Si(NH)_2$), but required purification steps to remove chloride.

Pugar and Morgan elucidate their research and include a summary of the work of other researchers over the years. The report concludes: "Through the use of modern sensitive probes, direct elemental silicon reactions with liquid ammonia, silicon-hydrazine and silicon-organic amines have been discovered. The reaction of elemental silicon with nitrogen-containing reagents, under rather benign conditions, can produce ceramic precursors and with further chemical treatments can produce fibers, films, and other commercial and industrial products."

Nomenclature of Silicon Compounds. The name of the compound SiH_4 is *silane*. Compounds having the general formula $H_3Si{\cdot}[SiH_2]_n{\cdot}SiH_3$ are called disilane, trisilane, etc., according to the number of silicon atoms present. Compounds of the general formula Si_nH_{2n+2} have the generic name *silanes*. Example: Trisilane, $H_3Si{\cdot}SiH_2{\cdot}SiH_3$.

Compounds having the formula $H_3Si{\cdot}[NH{\cdot}SiH_2]_n{\cdot}NH{\cdot}SiH_3$ are called disilazane, trisilazane, etc., according to the number of silicon atoms present; they have the generic name *silazanes*. Example: Trisilazaine, $H_3Si{\cdot}NH{\cdot}SiH_2{\cdot}NH{\cdot}SiH_3$.

Compounds having the formula $H_3Si\cdot[S\cdot SiH_2]_n\cdot S\cdot SiH_3$ are called disilthiane, trisilthiane, etc., according to the number of silicon atoms present; they have the generic name *silthianes*. Example: Trisilthiane, $H_3Si\cdot S\cdot SiH_2\cdot S\cdot SiH_3$.

Compounds having the formula $H_3Si\cdot[O\cdot SiH_2]_nO\cdot SiH_3$ are called disiloxane, trisiloxane, etc., according to the number of silicon atoms present; they have the generic name *siloxanes*. Example: Trisiloxane, $H_3Si\cdot O\cdot SiH_2\cdot O\cdot SiH_3$.

For designating the positions of substituents on compounds named as silanes, silazanes, silthianes, and siloxanes, each member of the fundamental chain is numbered from one terminal silicon atom to the other. When two or more possibilities for numbering occur, the same principles are followed as for carbon compounds. Examples:

1-Butyl-2,3-dichloro-2pentyltrisilane
$Cl\cdot SiH_2\cdot SiCl(C_5H_{11})\cdot SiH_2\cdot C_4H_9$

2-Methyl-3-pentyloxytrisilazane
$SiH_3\cdot N(CH_3)\cdot SiH(OC_5H_{11})\cdot H\cdot SiH_3$

1-Methoxytrisiloxane
$CH_3O\cdot SiH_2\cdot O\cdot SiH_2\cdot O\cdot SiH_3$

The names of representative radicals containing silicon are shown below. These illustrate the principles on which any further radical names should be formed.

Silicon, hydrogen	
silyl	H_3Si-
silylene [CAS: 13825-90-6]	$H_3Si=$
silylidyne [CAS: 13774-94-2]	$HSi\equiv$
disilanyl [CAS: 73151-72-1]	$H_3Si\cdot SiH_2-$
trisilanyl	$H_3Si\cdot SiH_2SiH_2-$
disilanylene	$-SiH_2\cdot SiH_2-$
trisilanylene	$-SiH_2\cdot SiH_2\cdot SiH_2-$
cyclohexasilanyl	$SiH_2\cdot SiH_2\cdot SiH\cdot OH$ (with $SiH_2\cdot SiH_2\cdot SiH_2$ bridge)
Silicon, hydrogen, oxygen	
siloxy	$H_3Si\cdot O-$
disiloxanyl	$H_3Si\cdot O\cdot SiH_2-$
disilanoxy	$H_3Si\cdot SiH_2\cdot O-$
disiloxanoxy	$H_3Si\cdot O\cdot SiH_2\cdot O-$
Silicon, hydrogen, sulfur	
silylthio	$H_3Si\cdot S-$
disilanylthio	$H_3Si\cdot SiH_2\cdot S-$
disilthianyl	$H_3Si\cdot S\cdot SiH_2-$
disilthianylthio	$H_3Si\cdot S\cdot SiH_2\cdot S-$
Silicon, hydrogen, sulfur, oxygen	
disilthianoxy	$H_3Si\cdot S\cdot SiH_2\cdot O-$
disiloxanylthio	$H_3Si\cdot O\cdot SiH_2\cdot S-$
Silicon, hydrogen, nitrogen	
silylamino	$H_3Si\cdot NH-$
disilanylamino	$H_3Si\cdot SiH_2\cdot NH-$
disilazanyl	$H_3Si\cdot NH\cdot SiH_2-$
disilazanylamino	$H_3Si\cdot NH\cdot SiH_2\cdot NH-$
Silicon, hydrogen, nitrogen, oxygen	
disilazanoxy	$H_3Si\cdot NH\cdot SiH_2\cdot O-$
disiloxanylamino	$H_3Si\cdot O\cdot SiH_2\cdot NH-$

Compound radical names may be formed in the usual manner. Examples:

silyldisilanyl	$(H_2Si)_2SiH-$
disilyldisilanyl	$(H_3Si)_3Si-$
triphenylsilyl	$(C_6H_5)_3Si-$

Open-chain compounds which have the requirements for more than one of the structures already defined are named, if possible, in terms of silane, silazane, silthiane, or siloxane containing the largest number of silicon atoms. Examples:

3-Siloxytrisilthiane
$H_3Si\cdot S\cdot SiH(O\cdot SiH_3)\cdot SiH_3$

1-Siloxy-3-(disilthianoxy)trisilthiane
$H_3Si\cdot S\cdot SiH(O\cdot SiH_2\cdot S\cdot SiH_3)\cdot S\cdot SiH_2\cdot OSiH_3$

When there is a choice between two parent compounds possessing the same number of silicon atoms, the order of precedence is siloxanes, silthianes, silazanes, and silanes. Examples:

1-Silylthiodisiloxane
$SiH_3\cdot O\cdot SiH_2\cdot S\cdot SiH_3$

1-Silylaminodisilthiane
$SiH_3\cdot S\cdot SiH_2\cdot NH\cdot SiH_3$

1-Phenyl-3-silyldisiloxane
$SiH_3\cdot SiH_2\cdot O\cdot SiH_2\cdot C_6H_5$

Cyclic silicon compounds having the formula $[SiH_2]_n$ are called cyclotrisilane, cyclotetrasilane, etc., according to the number of members in the ring; they have the generic name *cyclosilanes*. Example:

Cyclotrisilane $SiH_2\cdot SiH_2\cdot SiH_2$ (bridge)

Cyclic compounds having the formula $[SiH_2\cdot NH]_n$ are called cyclodisilazane, cyclotrisilazane, etc., according to the number of silicon atoms in the ring. They have the generic name *cyclosilazanes*. Example:

Cyclotrisilazane
$HN\cdot SiH_2\cdot NH\cdot SiH_2\cdot NH\cdot SiH_2$ (bridge)

Cyclic compounds having the formula $[SiH_2\cdot S]_n$ have the generic name *cyclosilthianes* and are named similarly to the cyclosilazanes. Example:

Cyclotrisilthiane
$S\cdot SiH_2\cdot S\cdot SiH_2\cdot O\cdot SiH_2$ (bridge)

Cyclic compounds having the formula $[SiH_2\cdot O]_n$ have the generic name *cyclosiloxanes* and are named similarly to the cyclosilazanes. Example:

Cyclotrisiloxane
$O\cdot SiH_2\cdot O\cdot SiH_2\cdot O\cdot SiH_2$ (bridge)

Cyclosilanes, cyclosilazanes, cyclosilthianes, and cyclosiloxanes are numbered in the same way as carbon compounds of similar nature. Examples:

2-Methoxycyclotrisilazane
$HN\cdot SiH_2\cdot NH\cdot SiH_2\cdot NH\cdot SiH(OCH_3)\cdot SiH_2$ (bridge)

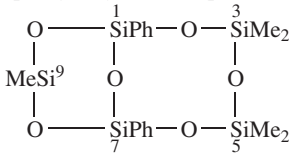
2-Methoxycyclorisilthiane
$S\cdot SiH_2\cdot S\cdot SiH_2\cdot S\cdot SiH(OCH_3)\cdot SiH_2$ (bridge)

2-Methoxycyclotrisiloxane
$O\cdot SiH_2\cdot O\cdot SiH_2\cdot O\cdot SiH(OCH_3)\cdot SiH_2$ (bridge)

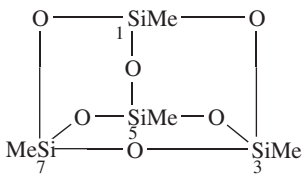
Polycyclic siloxanes (polycyclic compounds whose members consist entirely of alternating silicon and oxygen atoms) are named as bicyclosiloxanes, tricyclosiloxanes, etc., or as spirosiloxanes, and are numbered

according to methods in use for carbon compounds of similar nature. Polycyclic silthianes, silazanes, and silanes are treated similarly. Examples:

3,3,5,5,9,9-Hexamethyl-1,7-diphenylbicyclo[5,3,1]pentasiloxane



Tetramethyltricyclo[3,3,1,1[tetrasiloxane



The names of compounds containing silicon atoms as heteromembers (with or without other heteromembers) but not classifiable as (linear or cyclic) silanes, silazanes, silthianes or siloxanes are derived with the aid of the oxa-aza convention. Examples:

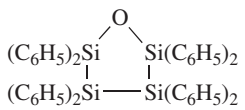
2,2,4,4,6,6-Hexamethyl-2,4,6-trisilaheptane

$(CH_3)_3Si{\cdot}CH_2{\cdot}Si(CH_3)_2{\cdot}CH_2{\cdot}Si(CH_3)_3$

2,4,6,8,-Tetraoxa-5-carbonsoilane

$SiH_3{\cdot}O{\cdot}SiH_2{\cdot}O{\cdot}CH_2{\cdot}O{\cdot}SiH_2{\cdot}O{\cdot}SiH_3$

Octaphenyloxacyclopentasilane

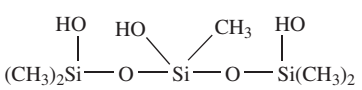


Hydroxy-derivatives in which the hydroxyl groups are attached to a silicon atom are named by adding the suffixes *ol, diol, triol*, etc., to the name of the parent compound. Examples:

Silanol	$H_3Si{\cdot}OH$
Silanediol	$H_2Si(OH)_2$
Silanetriol	$HSi(OH)_3$
Disilanehexaol	$(HO)_3Si{\cdot}Si(OH)_3$
Disiloxanol	$H_3Si{\cdot}O{\cdot}SiH_2{\cdot}OH$
Cyclohexasilanol	$SiH_2{\cdot}SiH_2{\cdot}SiH{\cdot}OH$ with SiH_2 and SiH_2 bridging, $SiH_2{\cdot}SiH_2{\cdot}SiH_2$

Polyhydroxy-derivatives in which hydroxyl group is attached to a silicon atom are named wherever possible in accordance with the principle of treating like things alike. Example:

1,13,5,5-Pentamethyltrisiloxane-1,3,5-trio



Otherwise they are named in accordance with the principle of the largest parent compound. Example:

2-Hydroxysilyltetrasilane-1,4-dio

$HO{\cdot}SiH_2{\cdot}SiH_2{\cdot}SiH(SiH_2{\cdot}OH){\cdot}SiH_2{\cdot}OH$

Substituents other than hydroxyl groups (functional atoms or groups and hydrocarbon radicals) attached to silicon are expressed by appropriate prefixes or suffixes. Examples:

Ethyldisilane
$CH_3{\cdot}CH_2{\cdot}SiH_2{\cdot}SiH_3$
Hexachlorodisiloxane
$Cl_3Si{\cdot}O{\cdot}SiCl_3$
Dibutyldichlorosilane
$(CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2)_2SiCl_2$
Silylamine
$H_3Si{\cdot}NH_2$
Silanediamine
$H_2Si(NH_2)_2$
Silanetriamine
$HSi(NH_2)_3$
N-Methylsilylamine
$H_3Si{\cdot}NH{\cdot}CH_3$
N,*N*-Dimethylsilylamine
$H_3Si{\cdot}N(CH_3)_2$
N,*N*′-Dimethylsilanediamine
$H_2Si(NH{\cdot}CH_3)_2$
N,*N*′,*N*″-Trimethylsilanetriamine
$HSi(NH{\cdot}CH_3)_3$
Acetoxytrimethylsilane
$(CH_3)_3Si{\cdot}O{\cdot}OC{\cdot}CH_3$
Diacetoxydimethylsilane
$(CH_3)_2Si(O{\cdot}OC{\cdot}CH_3)_2$

Compounds containing carbon as well as silicon and in which there is a "reactive group" in the carbon-containing portion of the molecule not shared by a silicon atom are named in terms of the organic parent compound wherever feasible. Examples:

α-Trimethylsilylacetanilide
$(CH_3)_3Si{\cdot}CH_2{\cdot}NH{\cdot}C_6H_5$
1-Trichlorosilylethanol
$Cl_3Si{\cdot}CH(OH){\cdot}CH_3$
2-Trimethylsilylethanol
$(CH_3)_3Si{\cdot}CH_2{\cdot}CH_2OH$
(Hydroxydimethylsilyl)methanol
$(CH_3)_2Si(OH){\cdot}CH_2OH$
α-(Hydroxydimethylsilyl)acetanilide
$(CH_3)_2Si(OH){\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_3$

(Silylmethyl)amine
$H_3Si{\cdot}CH_2{\cdot}NH_2$
But by rules 70.16 and 70.17:
(Methoxymethyl)silanol
$CH_3O{\cdot}CH_2{\cdot}SiH_2{\cdot}OH$
N-Methylsilylamine
$H_3Si{\cdot}NH{\cdot}CH_3$

Compounds in which metals are combined directly with silicon are, in general, named as derivatives of the metal. Example:

(Triphenylsilyl)lithium
$(C_6H_5)_3SiLi$

However, in exceptional cases, the metal may be named as a substituent. Example:

Sodium *p*-(sodiosilyl)benzoate
p-$NaO_2C{\cdot}C_6H_4{\cdot}SiH_2Na$

Metallic salts of hydroxy-derivatives may be named in the customary manner. Example:

Sodium salt of triphenylsilanol
$(C_6H_5)_3Si{\cdot}ONa$

Essentially Nonchemical Properties of Silicon

Were it not for the firm establishment of silicon as an indispensable material for modern electronics, the other exceptionally attractive properties of Si may have been overlooked for many years. Over the past few decades, electronics components manufacturers have mastered the skills required for manufacturing microminiature components, and this experience has given Si a head start for use in other subminiature structures. Si has been recognized as an outstanding material for making micromachined subminiature structures essentially just within the past decade, and it has become one of the key materials in the comparatively new field of *nanotechnology*.

As a mechanical material, silicon is stronger than steel, it does not show mechanical hysteresis, and it is highly sensitive to stress. This combination of properties qualifies Si as an excellent sensor for detecting acceleration, pressure, force, and other variables encountered in processing and manufacturing. One method of measuring fluid flow, for example, traditionally has depended upon sensing pressure differentials, as in the case of an orifice-type flowmeter. Thus, silicon sensors can be used. Silicon accelerometers can employ the same piezoresistive sensing technique used in pressure sensors.

In addition to sensors, Si can be used at the subminiature scale for the production of tiny pipe, nozzles, and valves required by automatic control systems. Thus, the weight and bulk of future control systems may be reduced by several orders of magnitude.

As of the early 1990s, engineers are working at the "edge" of a new kind of robotics — that is, subminiature handling devices that can master the handling requirements of the new nanomanufacturing technology. Such robots would be miniature, fully integrated silicon systems drawing heavily on the technologies of silicon-integrated electronics and micromachining. Semi-intelligent robots could be used in many manufacturing and control tasks. According to some researchers, such robots could have intelligence at the lowest possible system level, thus allowing them to function semiautonomously, with occasional input from a central control system.

Biological Applications of Silicon Technology. H.M. McConnell (Stanford University) and a team of researchers have developed a silicon-based device called a cytosensor (microphysiometer) that can be used to detect and monitor the response of cells to a variety of chemical substances, particularly ligands for specific plasma membrane receptors. As pointed out by McConnell, "The microphysiometer measures the rate of proton excretion from 10^4 to 10^6 cells. The instruments serves two distinct functions. In terms of detecting specific molecules, selected biological cells in this instrument serve as detectors and amplifiers. The microphysiometer can also investigate cell function and biochemistry. A major application of this instrument may prove to be screening for new receptor ligands. In this respect, the instrument appears to offer significant advantages over other techniques." More detail is given in the McConnell reference listed.

Health and Safety Factors

Elemental silicon is quite inert. In air, silicon is only classified as a nuisance particulate having a threshold limit value (TLV) of 10 mg/m^3; respirable fraction is 5 mg/m^3. However, SiO_2 dust, particularly that of crystalline quartz, is considered hazardous. Many silicon compounds are poisonous, and some, such as the silanes, are highly explosive as well. Compounds such as $SiCl_4$, $SiHCl_3$, and $SiBr_4$ decompose in the presence of moisture, forming SiO_2 and the corresponding acid. If such compounds are breathed, the acid-forming reaction takes place in the moist respiratory tract and the result is similar to that of directly breathing the acid fumes.

SILICON CHIP (FABRICATION). See **Semiconductors: Silicon Semiconductors**.

SILICON CONTROLLED RECTIFIER (or SCR). A semiconductor device consisting of four alternate layers of *n* and *p* type silicon, which functions as a current controlled switch. The schematic symbol and its correspondence to the four layers is shown in Fig. 1. Two outstanding features are associated with the SCR, namely, the speed of switching and ratio of controlled to controlling currents. Load currents of tens to hundreds of amperes may be turned on in a few microseconds and turned off in about ten times as long a time. Typically, the controlling current is several orders of magnitude less than the controlled current.

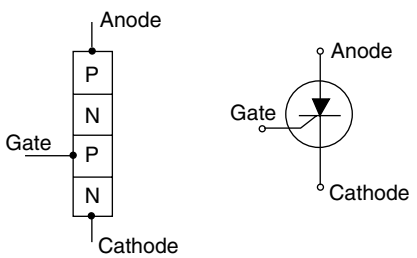

Fig. 1. Diagrammatic representation of silicon-controlled rectifier and schematic symbol.

In operation, a comparatively small anode current flows when the gate current is zero and the anode-to-cathode voltage is held below a critical value known as the *forward breakover voltage*. A positive pulse of gate current of suitable magnitude triggers the device into a high conduction mode. At this time the anode current is determined almost entirely by the characteristics of the external circuit in series with the anode-cathode path, providing this current exceeds a small minimum value called the *holding current*. Once the high conduction mode is achieved, the gate current has no further control over the anode current. To turn off the anode current, the anode-to-cathode voltage must be reduced substantially (so that the anode current falls below the holding current). For turn-off in minimum time, it is necessary to reverse the polarity of the anode voltage.

SILICON CONTROLLED SWITCH (or SCS). An electronic device consisting of four layers of semiconductor material alternately doped with *p* and *n* type impurities. It differs from the silicon controlled rectifier in that external connections are made to all four layers rather than to only three, as in the case of the latter. The schematic symbol and an indication of the equivalence of the device to a combination of two junction transistors are shown in Fig. 1. It is primarily used for switching and control applications.

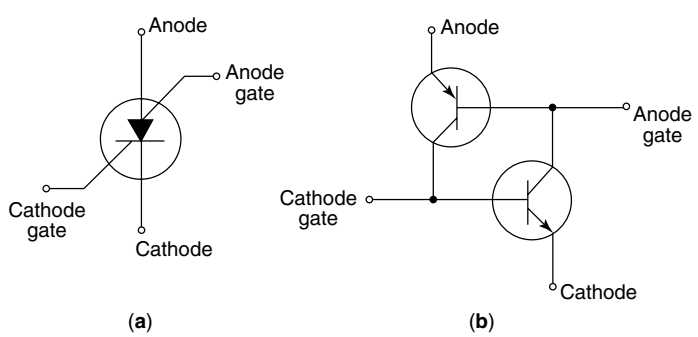

Fig. 1. Schematic symbol of silicon controlled switch (**a**) and equivalence to interconnection of two transistors (**b**).

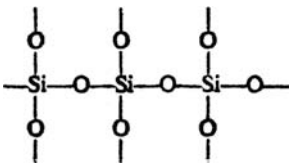
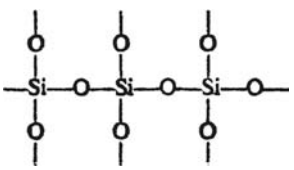
SILICONE RESINS. The chemistry of the silicones is based on the hydrides, or silanes, the halides, the esters, and the alkyls or aryls. The silicon oxides are composed of networks of alternate atoms of silicon and oxygen so arranged that each silicon atom is surrounded by four oxygen atoms and each oxygen atom is attached to two independent silicon atoms:



Such a network can be described as a series of spiral silicon-oxygen chains crosslinked with each other by oxygen bonds. If some of the oxygen atoms are replaced with organic substituents, a linear polymer will result:



Taking into consideration the stability of structures involving C−Si bonds, it is evident that the basic chain itself must be comparable in its stability to that of silica and the silicate minerals, and if the R substituents contain no carbon-to-carbon bonds, as for example with methyl groups, the combination should have excellent thermal stability and chemical resistance.

Among the most efficient of silicone monomers in early use as building blocks in the preparation of silicone resins are the halogen alkyl or aryl silanes. Compounds of the type represented by the formula R_2SiCl_2 are capable of undergoing hydrolysis to form long-chain polymers of varying consistencies and viscosities with a predetermined number of molecules of R_3SiCl as chain stoppers. If cross links are desired, tri-functional compounds such as $RSiCl_3$ can be used.

Many silicone resins have been prepared through the use of silazine monomers, that is, compounds with amino groups attached directly to silicon. Di-2-pyridyldichlorosilane has also been described as an intermediate in the preparation of oils, emulsifying agents and resins. Fluorinated aromatic rings are found in many silicone resins. The esterification of dimethylbis-(*p*-carboxylatophenyl)-silane with glycol [CAS: 107-21-1] or glycerol yields thermoplastic materials. Trimethyl-*p*-hydroxyphenylsilane is acceptable as a monomer in resin formation when compounded with hexamethylenetetramine. Trichlorosilane is often a constituent of cohydrolysis monomeric mixtures.

Emulsifying agents have been prepared from quaternary ammonium salts with silicon in the cation. There are a large number of alkyd-silicone resins.

Water-soluble metal salts of alkyltrisilanols are efficient in the reduction of surface tension. Silicone putty is made by compounding a benzene-soluble silicone polymer with silica powder and an inorganic filler.

Chlorinated alkyl or aryl groups are often found in polysiloxane resins. One of the chief advantages of this type of halogenated product lies in its reduced tendency to burn. Whereas diphenyloxosilane polymer burns readily in a flame, the introduction of one, two or three chlorines in each benzene ring progressively reduces this tendency. Physically, these resins appear in many different forms, from horny through sticky-resinous to rubber-like, depending on the conditions of combination and composition.

Some of the most important types of silicone resins, useful as coating preparations, are analogous to the alkyds. Glycerol, for instance, is allowed to react with trialkylethoxysilanes, by which reaction one or more hydroxyls of the glycerol are replaced by R_3SiO. Polysiloxane resins with terminal ethoxyl groups can be used. Synthesis of silicone resins with terminal halogen or hydroxyl is also possible, though generally the halogen disappears in hydrolysis of further processing.

Ethyl silicate [CAS: 78-10-4] (tetraethoxysilane) is often used without modification as a water-repellent material for concrete and masonry in general. All, or nearly all, the ethoxyl groups are hydrolyzed by the

moisture of the air to form cross-linked water-repellent polymers. The material is applied in desirable thickness, dissolved in some volatile solvent which soon evaporates. Silicone resins which are partially condensed before application, or even fully condensed, can also be used here. In the latter case, hardness is achieved on evaporation of the solvent. Certain silicone resins are useful as hydrophobic agents for the impregnation of paper and fabrics.

The simplest silicone resins are formed by the almost simultaneous hydrolysis and condensation (by dehydration) of various mixtures of methylchlorosilanes. Ice water often suffices for the first step, but advanced condensation to resinous materials of satisfactory thermosetting properties generally comes about on heating. As far as solvents are concerned, water alone has its disadvantages in that the organic materials are so slightly soluble therein. Mixed solvents are commonly used, generally water with such compounds as dioxane, one of the amyl alcohols, dibutyl ether or even an aromatic hydrocarbon. Warm water hydrolysis of di-*t*-butyldiaminosilane forms noncrystallizable liquids or resinous products, and this resinification can be controlled. Among catalysts for these condensations may be found ferric chloride, the hydroxyl ion, triethyl borate, stannic chloride and sulfuric acid.

A water-methylene dichloride mixture is satisfactory as a hydrolyzing agent on groups of compounds such as phenyltrichlorosilane, dimethyldichlorosilane and methyltrichlorosilane. The value of higher-boiling ethers lies in their ability to provide higher-boiling reaction systems.

Ferric chloride [CAS: 7705-08-0] is sometimes an important constituent of the hydrolyzing mixture. The formation of gels during polymerization can be controlled. Patents are in existence covering the hydrolysis of chlorosilanes by pouring their solutions onto the surface of a swirling solution of the active electrolyte.

Alkaline hydrolysis of dialkyldialkoxysilanes can sometimes be used for the purpose of preparing silicone resins.

Triethyl orthoborate affects polymerization by dehydration, probably reacting with the water which it abstracts, to form boric acid [CAS: 11113-50-1] and alcohol [CAS: 67-63-0]. This principle is commonly used. Antimony pentachloride [CAS: 7647-18-9] is used on occasion and also sulfuric acid [CAS: 7664-93-9], but there is always danger that the latter will split off an alkyl or an aryl group. Sulfuric acid also sometimes induces equilibration. This *tendency* on the part of the acid *reacts* sometimes with the opposite effect.

Some polysiloxanes are curable with lead monoxide, with a consequent reduction in both curing time and temperature. High-frequency electrical energy vulcanizes in one case at least. Zirconium naphthenate imparts improved resistance to high temperatures. Barium salts are said to prevent "blooming." Sulfur dichloride [CAS: 10545-99-0] is also used. Some resins are solidified by pressure vulcanization, using di-*t*-butyl peroxide. Improvements are to be found in lower condensation temperatures and shorter times of treatment.

Viscosity is often regulated by bubbling air through solutions of polysiloxanes or the liquid material itself. In this manner, alkyl side chains are oxidized and oxygen bridges set up between silicon atoms. Obviously, the greater the number of such cross links, other influences constant, the greater will be the viscosity.

Addition of glycerol, phthalic anhydride and "butylated melamine formaldehyde resins" is sometimes found to improve the thermosetting properties of silicone resins. Methylsilyl triacetate has the same effect in certain cases. Some silicone resins can be advantageously modified by the addition of polyvinyl acetyl resins or nitroparaffins.

A solution of cellulose nitrate [CAS: 9004-70-0] in butyl acetate [CAS: 123-86-4], diluted with toluene [CAS: 108-88-3], can be plasticized with dibutyl phthalate [CAS: 84-74-2] and tetraethoxysilane [CAS: 78-10-4]. After application to glass, the lacquer cannot be stripped from the surface even after soaking in boiling water. It has been stated, however, that tetraethoxysilane sometimes decreases the tensile strength of a lacquer in spite of its effect in increasing adhesive properties. A uniformly lustrous appearance is imparted to compounds containing plasticized ethylcellulose [CAS: 9004-57-3], cellulose fibers and pigment, by applying liquid polymerized alkyl polysiloxanes with an average radical/silicon ratio of between 1185 and 2.20. Several resinous materials are known which contain sulfur connected to carbon but not directly to silicon.

Inorganic fillers include titanium dioxide [CAS: 13463-67-7], "Celite" and zinc oxide [CAS: 1314-13-2]. Lithium [CAS: 7439-93-2] or lead salts of acetic acid [CAS: 64-19-7], stearic acid [CAS: 57-11-4] or phenol are sometimes used as fillers. Silica [CAS: 7631-86-9] and alumina [CAS: 1344-28-1] are also feasible. Trimethyl-β-hydroxyethylammonium bicarbonate has been used as a curing agent.

There are any number of review articles and patents covering the increase in serviceability of paints and varnishes which are admixed with silicone resins. Products suitable for use as plasticizers, paint vehicles, etc., are sometimes prepared from mixtures which include phthalic anhydride. Silicone paints, in general, show high adhesion and permit greater retention of color and tint. Of special importance here is the absence of color in the resin and the freedom from discoloration during baking and curing. At high temperatures, silicone varnishes show much higher electrical resistance than others. Paints admixed with silicone resins generally show increased resistance to alkalies and to the elevated temperatures involved in baking processes. See also **Paints and Coatings**.

Treating spinnarets with silicon resins eliminates much of the plugging.

Aluminum alkoxides are successful as hardening agents.

Copolymers of adipic acid [CAS: 124-04-9], glycerol [CAS: 56-81-5], and 1,3-diacetoxy-methyltetramethyldisiloxane, or similar compound, are sometimes used. The silicon adaptation of the alkyd resin possesses, in general, increased hardness and flexibility. In addition, there is greater stability at higher temperatures. Copolymers can also be prepared using amyldibutoxyboron. Antiknock properties are claimed for this type of product as well as increased heat resistance.

The most important development in the chemistry of silicone resins embodies the preparation of monomeric silanes with at least one alkenyl group attached to silicon. Hydrolyzable groups are also present, so that polymerization can take place in two ways — by the conventional hydrolytic processes followed by condensation and by addition polymerization on the double bond, usually through the catalytic activity of benzoyl peroxide [CAS: 94-36-0] or similar agent. Some of the products find use as textile finishes, lubricating oils, additives or molding compounds. Vinyl and allyl groups are most common, with an occasional methallyl.

Triethylsilyl acrylate can be induced to undergo hydrolysis of the ethoxyl radicals to a desired extent forming linear or cross linked polymers. Addition polymerization will also take place on the double bond of the acrylate radical. More stable monomers result from the use of allyl or vinyl groups instead of acrylates. The latter contain a silicon-oxygen-carbon linkage which is always more or less susceptible to hydrolysis.

Other copolymers of this type with vinyl acetate [CAS: 108-05-4] or vinyl butyral resins have been found satisfactory for use in the lamination of wood, glass and metals. Glass-resin adhesives are also known.

General resistance to external influences constitutes the most outstanding property of silicone resins. Ultimate failure and breakdown is probably attributable, more than do anything else, to eventual oxidation of the radicals.

Among the more recent developments in this field may be mentioned the use of certain silicone resins, particularly those containing vinyl groups, as adhesives. Others find value as woodsealing products. A silicone-glycol copolymer has been reported with curing properties, and alkyd resins are now modified with silicones. Combination epoxide-silicone resins have been investigated. A harder type of silicone resins sometimes results from the processing of monomers containing H or olefinic group attached to silicon. Dental impression materials are coming more to the front from this source as well. Finally, more attention is being devoted to studies of the relation between chemical structure and thermodynamic properties.

Resistance to γ-radiation is especially valuable. "Mouth-tissue-simulating molding compositions" for dentures are on the market. Optical lenses prepared from silicone resins are not affected by hot climates. Mold release agents are still the subject of research, as are resins with long storage capabilities. Coating bananas with silicone resins reduces the possibility of bruising. Heat-transfer compositions must have high molecular weights. In oil wells, a new use has come to the fore in the prevention of sand flow. Transparent resins are still in demand, some of which are porous.

Compounding silicone resins with phenyl formaldehyde or melamine polymers seems to produce good results. Sulfur in the resin makes a product suitable for use as fuel hose, gaskets and gas tanks. Phosphorus [CAS: 7723-14-0] is found in silicone resin coatings but the product

is liable to be toxic. Titanium is found in waterproof coatings. Tin compositions have low toxicity. Some resins of high viscosity contain Si–O–N units. Crosslinking, however, is not recommended. The tendency to become brittle is ever present although a few instances are known to be contrary.

HOWARD W. POST, Williamsville, NY

SILK. Silks can be defined as externally spun fibrous protein secretions. Of all the natural fibers, silks represent the only ones that are spun. Silk fibers have been used in textiles for thousands of years, owing to their unique visual luster, tactile properties, and durability. These fibers are remarkable materials displaying unusual mechanical properties. Strong, extensible, and compressible, silks display interesting electromagnetic responses, particularly in the uv range for insect entrapment; form liquid crystalline phases related to processing; and exhibit piezoelectric properties. Silks were used in optical instruments as late as the mid-1900s because of their fine diameter and high strength and stability over a range of temperatures. Spider silks are reportedly used in the South Pacific for gill nets, dip nets, and fishing lures as well as in weaving and ceremonial dress.

Silks are synthesized by a variety of organisms, including silkworms, spiders, scorpions, mites, and flies. Few of these silks have been characterized. Silks differ in properties, composition, and morphology, depending on the source. Silkworm cocoon silk from *Bombyx mori* is the most well characterized, owing to the extensive use of these fibers in the textile industry for over 5000 years in a practice originating in China. The dragline silk from the orb-weaving spider, *Nephila clavipes*, is the most well characterized of the different spider silks. Spider silk has not been domesticated for textile applications because spiders are more difficult to raise in large numbers owing to their solitary and predatory nature. Unlike the cocoon silk from the silkworm, orb webs are not reelable as a single fiber.

The cocoon silk from *B. mori* contains two structural fibroin filaments coated with a family of glue-like sericin proteins, resulting in a single thread having a diameter of 10 to 25 μm. Wild silkworms generally have larger-diameter threads, ranging up to 65 μm and displaying a variety of different cross-sectional morphologies. The life cycle of *B. mori* runs for 55 to 60 days, and the organism passes through a series of developmental stages or molts. Silk production occurs during cocoon formation around day 26 in the cycle during the fifth larval instar just before molt to the pupa. The silkworm passes through four different metamorphosizing phases: egg or embryo, larva, pupa, and moth (adult). Smaller quantities of silk are produced at all larval stages except during molts.

Spider silks function in prey capture, reproduction, and as vibration receptors, safety lines, and dispersion tools. Spider silks are synthesized in glands located in the abdomen and spun through a series of orifices (spinnerets). The types and nature of the various silks are diverse and depend on the type of spider. Methods and apparatus for spinning spider silk protein have been patented (U.S. Pat. Appl. 20040102614 (May 27, 2004), S. Islam and co-workers).

Structure

Composition. The silkworm cocoon silk contains two structural proteins, the fibroin heavy chain (mol wt ca 325,000) and fibroin light chain (mol wt ca 25,000), plus the family of sericin proteins (mol wt 20,000–310,000) to hold the fibroin chains together in the final cocoon fiber. See also **Amino Acids**; and **Proteins**. Other silks, such as the caddis fly and aquatic midge, which spin silks underwater to form sheltered tubes, have also been characterized and consist of a family of proteins having high cysteine content and running from low to very high ($>10^6$) molecular weights. Some silkworm silks from wild strains have been reported to contain up to 95% alanine.

The consensus crystalline amino acid repeat in the B. mori silkworm cocoon silk fibroin heavy chain is the 59mer: GAGAGSGAAG $[SGAGAG]_8$Y. More detailed analysis of these repeats indicates that the fibroin contains alternate arrays of repeating GAGAGS and GAGAGY. Valine or tyrosine replacements for alanine exist in the second repeat. These core repeats are surrounded by homogenous nonrepetitive amorphous domains. The repetitive structures in the protein are thought to be the result of genetic level continuous unequal crossovers or genetic recombination events during evolution.

The spider dragline silk from the principal ampullate gland contains at least one protein, called MaSp1, for major ampullate silk protein, previously termed spidroin 1; mol wt is around 275,000. It remains unclear whether additional proteins play a significant role in the dragline silk fiber. There is no sericin or glue-like protein associated with the dragline fiber. MaSp1 contains amino acid repeats considerably shorter than those found in the silkworm fibroin and not as highly conserved. The repeats contain polyalanine domains consisting of from six to nine residues, and a 15-amino acid region showing a GGX repeat motif, where X = alanine, tyrosine, leucine, or glutamine.

Secondary Structure. The silkworm cocoon and spider dragline silks are characterized as an antiparallel β-pleated sheet wherein the polymer chain axis is parallel to the fiber axis. Other silks are known to form α-helical (bees, wasps, ants) or cross- β-sheet (many insects) structures. The cross- β-sheets are characterized by a polymer chain axis perpendicular to the fiber axis and a higher serine content. Most silks assume a range of different secondary structures during processing from soluble protein in the glands to insoluble spun fibers.

The crystalline structure of silk was first described in the 1950s as an antiparallel, hydrogen-bonded β-sheet based on the characterization of *B. mori* fibroin, and further modifications to this early model have been made over the years. Two crystalline forms for silk have been characterized based on x-ray diffraction and ^{13}C-cross-polarization magic angle spinning (cp/mas) nmr spectroscopy. The random coil or silk I, ie, the prespun pseudocrystalline form of silk present in the gland in a water-soluble state, is predominant in the gland; silk II, ie, the spun form of silk which is insoluble in water, becomes predominant once the protein is spun into fiber. The unit cell parameters in the silk II structure are 940 pm (*a*, interchain), 697 pm (*b*, fiber axis), and 920 pm (*c*, intersheet). The chains run antiparallel with interchain hydrogen bonds roughly perpendicular to the chain axis between carbonyl and amine groups. Van der Waal forces stabilize intersheet interactions owing to the predominance of short side-chain amino acids (glycine, alanine, serine) in these crystalline regions. Solid-state ^{13}C-nmr studies of *N. clavipes* dragline silk have concluded that the polyalanine runs in the MaSp1 are in a β-sheet conformation.

The structure of silk I remains incompletely understood. This structure is unstable and upon shearing, drawing, heating, spinning, or exposure in an electric field or exposure to polar solvents, such as methanol or acetone, converts to silk II. The change in unit cell dimensions during the transition from silk I to silk II during fiber spinning is most significant in the intersheet plane, where an 18.3% decrease in distance occurs between overlying sheets. This change results in the exclusion of water, thus reducing solubility of the protein. Silk II is more energetically stable than silk I and the energy barrier for the transition is low, whereas the return barrier is high and considered essentially irreversible. Because the instability or metastable nature of the silk I conformation leads to difficulty in obtaining an orientated sample for fiber diffraction analysis and detailed structural characterization, different models have been proposed to describe the silk I structure.

Crystallinity. Generally, spider dragline and silkworm cocoon silks are considered semicrystalline materials having amorphous flexible chains reinforced by strong stiff crystals. The orb web fibers are composite materials (qv) in the sense that they are composed of crystalline regions immersed in less crystalline regions, which have estimates of 30–50% crystallinity. Earlier studies by x-ray diffraction analysis indicated 62–65% crystallinity in cocoon silk fibroin from the silkworm, 50–63% in wild-type silkworm cocoons, and lesser amounts in spider silk.

Structure of the Spider Orb Web. The construction of the orb web is a feat of engineering involving material tailoring, optimization of material interfaces, and conservation of resources to promote survival of the spider. In addition, the web absorbs water from the atmosphere and ingestion by the spider may provide a significant contribution to water intake needs. Around 70% of the energy is dissipated through viscoelastic processes upon impact by a flying insect into the web. Thus the web balances stiffness and strength against extensibility, both to keep the web from breaking and to keep the insect from being ejected from the web by elastic recoil. The ability to dissipate the kinetic energy of a flying insect impacting the web is

based on the hysteresis of radial threads and also aerodynamic damping by the web. Some orb webs appear to be at least in part recycled by ingestion as a conservation tool, and some of the amino acids are reused in new webs.

Processing

In Vivo Processing. Silks are synthesized in specialized glands within the organism. Initially, some degree of self-organization or assembly occurs as a result of protein–protein interactions among the crystalline repeats in the protein chains. In the spider gland, changes in physiological conditions such as pH and salt concentrations accompany the processing and, presumably, help maintain solubility, despite increasing protein concentration during passage through the various regions of the gland. In silkworm there are three distinct regions to the glands and two sets of these organs feeding into one final thread. The fibroin is synthesized in the posterior region of the gland and the protein moves by peristalsis to the middle region of the gland where it is stored as a viscous aqueous solution until needed for spinning. The protein concentration is 12–15% in the posterior region of the gland where fibroin chain synthesis occurs, increases to around 20–30% in the middle region of the gland where the fibroin is stored and sericin is synthesized, and is significantly higher in the anterior region of the gland where spinning is initiated. The two lobes of the gland join just before the spinnerets in the anterior region and the fiber is spun into air. Aside from binding together the fibroin chains in the final spun fiber, sericin in this process may function in plasticization to ease the flow through the spinneret, as a reservoir for divalent cations, or as a water-holding medium to promote plasticization of the fiber after spinning.

Rheological experiments indicate that crystallinity in the fiber correlates positively with shear and draw rates, and an extrusion rate of around 50 cm/min was found to be a minimum threshold for the appearance of birefringence and the conversion of the soluble silk solution in the gland to the β-sheet found in the spun fiber. In the posterior region of the gland, 0.4–0.8 mm in diameter, the silk solution is optically featureless, a range of secondary structures are present, including random coil and silk I, and the shear rate is low. In the middle region of the gland, the diameter is 1.2–2.5 mm, streaming birefringence is observed, and the shear rate is also low. In the anterior region of the gland, the diameter is narrow, 0.05–0.3 mm, the shear rate is high, water appears to be actively transported out of the gland, the pH decreases, and active ion exchange occurs. Viscosity also increases but presumably decreases prior to spinning as a result of the liquid crystalline phase. At this point the characteristic silk II structure forms. In the pair of major ampullate glands in the spider, which are the location of dragline protein synthesis, a similar process occurs as summarized for the silkworm. This gland is smaller, however, and there is no sericin contribution in the middle region of the gland. A lyotropic nematic liquid crystalline phase of the protein forms prior to spinning in both the spider and the silkworm, as well as in many of the different glands of the spider responsible for the different silks.

Commercial and Artificial Processing. Commercially, silkworm cocoons are extracted in hot soapy water to remove the sticky sericin protein. The remaining fibroin or structural silk is reeled onto spools, yielding approximately 300–1,200 m (984–3,937 ft) of usable thread per cocoon. These threads can be dyed or modified for textile applications.

Most solvents used to solubilize globular proteins do not suffice for silks owing to extensive hydrogen bonding and van der Waals interactions, and the exclusion of water from the intersheet regions. Silks are insoluble in water, dilute acids and alkali, and most organic solvents; they are resistant to most proteolytic enzymes. Silkworm fibroin can be solubilized by first degumming or removing the sericin using boiling soap solution or boiling dilute sodium bicarbonate solution, followed by immersion of the fibroin in high concentration salt solutions such as lithium bromide, lithium thiocyanate, or calcium chloride. These salt solutions can also be used to solubilize spider silk, as can high concentrations of propionic acid–hydrochloric acid mixtures and formic acid. After solubilization in these aggressive solvents, dialysis into water or buffers can be used to remove the salts or acids, although premature reprecipitation is a common problem. Ternary-phase diagrams of silk, water, and chaotropic salt for processing windows have been published for native silkworm silks and for genetically engineered versions of silkworm silk.

Films or membranes of silkworm silk have been produced by air-drying aqueous solutions prepared from the concentrated salts, followed by dialysis. The films, which are water soluble, generally contain silk in the silk I conformation with a significant content of random coil. Many different treatments have been used to modify these films to decrease their water solubility by converting silk I to silk II in a process found useful for enzyme entrapment. Silk membranes have also been cast from fibroin solutions and characterized for permeation properties. Oxygen and water vapor transmission rates were dependent on the exposure conditions to methanol to facilitate the conversion to silk II. Thin monolayer films have been formed from solubilized silkworm silk using Langmuir techniques to facilitate structural characterization of the protein. Resolubilized silkworm cocoon silk has been spun into fibers, as have recombinant silkworm silks.

Properties

Mechanical Properties. The mechanical properties of silks are an intriguing combination of high strength, extensibility, and compressibility (Table 1).

TABLE 1. MECHANICAL PROPERTIES OF SILKS AND OTHER FIBERS

Fiber	Elongation, %	Modulus, GPa[a]	Strength, GPa[a]	Energy to Break, J/kg[b]
		Fibroins		
B. mori	15–35	5	0.6	7×10^4
Other silkworms	12–50	2–4	0.1–0.6	$(3–6)\times10^4$
		Draglines		
N. clavipes				
quasistatic[c]	9–11	22–60	1.1–2.9	$(3.7–12)\times10^4$
high strain[d]	10	20		
Other spiders	10–39	2–24	0.2–1.8	$(1–10)\times10^4$
		Other fibers		
Nylon	18–26	3	0.5	8×10^4
Cotton	5–7	6–11	0.3–0.7	$(5–15)\times10^3$
Kevlar	4	100	4	3×10^4
Steel	8	200	2	2×10^3

[a] 1 GPa = 10^9 N/m^2. To convert GPa to psi, multiply by 145,000.
[b] To convert J to cal, divide by 4.184.
[c] Instron tensile test rates of 10%/s.
[d] Rates of >500,000%/s.

Resistance to axial compressive deformation is another interesting property of the silk fibers. Based on microscopic evaluations of knotted single fibers, no evidence of kink-band failure on the compressive side of a knot curve has been observed. Synthetic high performance fibers fail by this mode even at relatively low strain levels. This is a principal limitation of synthetic fibers in some structural applications.

B. mori cocoon silk ranges from 10 to 25 μm diameter; dragline silk from *N. clavipes* from 2.5 to 4.5 μm in diameter. Web fibers from some spiders have diameters as low as 0.01 μm. A silking rate of around 1 cm/s is considered equivalent to natural spinning rates for the spider. Some spider silks have been observed to supercontact up to around 50% when unconstrained and exposed to high moisture; other silks such as the silkworm cocoon silk do not contract under similar experimental conditions. A skin core has been reported using light microscopy and electron microscopy. However, more recent data using dragline silk from *N. clavipes* refute this finding.

Thermal Properties. Spider dragline silk was thermally stable to about 230 °C (446 °F) based on thermal gravimetric analysis (tga). Two thermal transitions were observed by dynamic mechanical analysis (dma), one at −75 °C (−103 °F), presumed to represent localized mobility in the noncrystalline regions of the silk fiber, and the other at 210 °C (410 °F), indicative of a partial melt or a glass transition. Data from thermal studies on *B. mori* silkworm cocoon silk indicate a glass-transition temperature, T_g, of 175 °C (347 °F) and stability to around 250 °C (482 °F). The T_g for wild silkworm cocoon silks were slightly higher, from 160 to 210 °C (320 to 410 °F).

Genetic Engineering

An understanding of the genetics of silk production in silkworms and spiders should help in developing processes for higher levels of silk expression generated by recombinant deoxyribonucleic acid (DNA) methods. The ability of the silkworm to produce large amounts of protein, around 300 μg of fibroin per epithelial cell lining the silk producing gland, has generated a great amount of interest from molecular biologists and developmental biologists in elucidating the genetic regulation of this system. Genetically engineered or recombinant DNA silkworm and spider silks have been produced using either native genes or synthetic genes. It is interesting to note that studies of variations in native silkworm populations indicate differences in sizes of the crystalline-encoding domains resulting from a high degree of polymorphism in length and organization of the fibroin gene and thus the encoded proteins. A significant degree of variation in protein size apparently can be tolerated in native populations of silkworms and possibly spiders. Owing to the highly repetitive nature of the genes and the encoded proteins, the deletion or addition of repeats has little impact on secondary structure and functional performance within a certain window of sizes.

Applications

Because of the advent of improved analytical techniques, together with the tools of biotechnology, a new generation of products is envisioned with silk. The ability to tailor polymer structure to a precise degree leads to interesting possibilities in the control of macroscopic functional properties of fibers, membranes, and coatings, as well as improved control of processing windows. Biotechnology offers the tools with which to solve limitations in spider silk production that have not been overcome with traditional domestication and breeding approaches, such as those used successfully with the silkworm. This is of interest because of the variety of silk structures available and the higher modulus and strength as compared to silkworm silk.

Hybrid silk fibers containing synthetic fiber cores having silk coextruded or grafted have been synthesized. Cosmetics and consumer products such as hair replacements and shampoos containing silk have also been marketed. Sutures, biomaterials for tissue repairs, wound coatings, artificial tendons, bone repair, and related needs may be possible applications, assuming immunological responses to the silks are controllable. See also **Biomaterials, Prosthetics, and Biomedical Devices**. A thin-layered, endovascular silk-covered stent device has been reported. It is also reasonable to speculate on the use of silk webbing for tissue cell growth, nerve cell growth, and brain repair applications as temporary scaffolding during regrowth and reinfusion after surgery. Cell culture Petri plates having genetically engineered silkworm silks containing cell binding or adhesive domains have already been produced and are sold commercially. These recombinant silks are stable during injection molding with polystyrene. The demonstration of fiber spinning from resolubilized silkworm silk provides further opportunities in material fabrication using native and genetically engineered silk proteins.

SILK COTTON TREES. Of the family *Bombaceceae* (silk cotton family), there are several genera of these trees from which valuable commercial fibers and oils are obtained. The silk cotton tree (*Ceiba pentandra*), also called the ceiba or kapok tree is a tropical tree with a large trunk that may reach a height of about 100 feet (30.5 meters) and diameter of 10 feet (0.3 meter). The tree is found in Brazil, Java, India, Central America, and Ecuador. The trunk has large roots that stabilize the tree and taper from underground to buttress the natural trunk. The tree produces large pods, which yield silk cotton called *kapok*. This material is used for filling mattresses and in padding cushions and furniture. Kapok is very light and resilient and also can be used as an insulating material. Most of the kapok used in the United States comes from Java. The Javanese tree was introduced from Brazil where the tree is referred to locally as the samaúma. The long, silky, and white fibers appear much like cotton. However, the fibers cannot be spun because of their brittleness. Kapok is also sometimes referred to as Illiani silk and Java cotton. Chemically, kapok is similar to jute, but with different proportions of the constituents, kapok being lower in alpha cellulose and higher in pentosans and lignin.

Other important genera of the silk cotton family include: *Calotropis gigantea*, a shrub grown in the East Indies and India and which produces a silky cotton known as *madar*, of an inferior quality to kapok. *Calotropis procera*, found in the same region, produces *akund*. Sometimes these inferior fibers are mixed with kapok. The species *Bombax ceiba* and *B. malabaricum*, grown in India, yield a red silk cotton called *simal*. A fiber known as *shilo* is obtained from *B. ellipticum*. The Indian tree *Cochlospermum gossypium* yields a white silk cotton similar to kapok. Mexican kapok is produced from *Bombax palmeri* and from *Ceiba schottii* and *C. acuminata*. Ecuadoran kapok comes from the genus *Chorisia*. Balsa fiber from the genus *Ochroma*, produced in Colombia, Ecuador, and Central America, is of a darker color.

The seeds of the kapok tree yields a semidrying oil which finds use in the manufacture of margarine and soaps.

SILKWORM *(Insecta, Lepidoptera).* The caterpillar of the moth, *Bombyx mori*, which produces the silk of commerce. Caterpillars of the family *Saturniidae* also spin cocoons of silk, and are known as the giant silkworms. This family includes the common luna, cecropia, and polyphemus moths of North America, as well as many other species.

SILL. A tabular mass of igneous rock that has been intruded laterally between layers of sedimentary rock, beds of volcanic lava or ejectmenta, or even along the direction of the foliation in metamorphic rock. The term sill is synonymous with intrusive sheet.

SILLIMANITE. The mineral sillimanite is an aluminum silicate, the formula Al_2SiO_5 being like that of andalusite and kyanite. It is orthorhombic, usually in slender prisms, but may be fibrous or massive. Its hardness is 6.5–7.5; specific gravity, 3.23–3.27; luster, vitreous to silky; color, various shades of gray, grayish-green, and grayish-brown; transparent to translucent. It occurs in granites and gneisses as tiny prisms and aggregates, and is often associated with andalusite, cordierite and corundum. Sillimanite has been found in Bavaria, the Czech Republic and Slovakia, France, India, the Malagasy Republic, Myanmar and Ceylon, the latter two localities furnishing transparent sapphire-blue gem stones. In the United States sillimanite has been found in Connecticut, New York, Pennsylvania, Delaware, North Carolina, and in California, where in Inyo County is the largest deposit in the world. This mineral was named in honor of Benjamin Silliman for many years professor of chemistry and natural science at Yale University. Sillimanite is used in the manufacture of spark plug "porcelains" and laboratory ware.

SILOXANES. See **Silicon**.

SILTHIANES. See **Silicon**.

SILTSTONE. A term signifying a clastic sedimentary rock in which the particles are of silt grade.

SILURIAN PERIOD. A major subdivision of the Paleozoic Era. Type locality, Wales and Shropshire, England. The formations of this system were first studied and described by R.I. Murchison in 1835. The Silurian Period began 380 million years ago and lasted for 50 million years. In

Murchison's time, and for some time afterward, the Paleozoic Era, below the Devonian, was divided into the Cambrian and Silurian. This practice still holds in parts of Europe. The Silurian formations are well exposed in Eastern North America, especially in New York State, and the length of the Appalachian geosyncline where the sediments are principally red sandstones and shales of delta origin. There was little or no volcanic activity except in southeastern Maine. The Silurian is also well exposed in nearly all of Western Europe, Northern Siberia, Myanmar, Central Asia, Himalayas, Morocco, Australia, Peru and Bolivia. The system is characterized by all types of sediments, with evidence in certain areas of an arid climate, including thick deposits of salt and gypsum. The maximum thickness of sediments is 15,000 feet (4,500 meters) in Britain.

SILVER. [CAS: 7440-22-4] Chemical element, symbol Ag (from Latin *argentum*), at. no. 47, at. wt. 107.868 ± 0.003, periodic table group 11, mp 961.93 °C, bp approximately 2,212 °C, density 10.50 g/cm^3 (20 °C). Elemental silver has a face-centered cubic crystal structure.

Silver is a white metal, softer than copper and harder than gold. When molten, silver is luminescent and occludes oxygen, but the oxygen is released upon solidification. As a conductor of heat and electricity, silver is superior to all other metals. Silver is soluble in HNO_3 containing a trace of nitrate; soluble in hot 80% H_2SO_4; insoluble in HCl or acetic acid; tarnished by H_2S, soluble sulfides and many sulfur-containing organic substances (e.g., proteins); not affected by air or H_2O at ordinary temperatures, but at 200 °C, a slight film of silver oxide is formed; not affected by alkalis, either in solution or fused. There are two stable, naturally occurring isotopes, ^{107}Ag and ^{109}Ag. In addition, there are reported to be 25 less stable isotopes, ranging in half-life from 5 seconds to 253 days.

In terms of cosmic abundance, the estimate of Harold C. Urey (1952), using silicon as a base with a figure of 10,000, silver was assigned an abundance figure of 0.023. In terms of abundance in sea water, silver is ranked number 43 among the elements, with an estimated content of 1.5 tons per cubic mile (0.324 metric ton per cubic kilometer) of sea water.

Electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 5s^1$. First ionization potential is 7.574 eV; second, 21.4 eV; third, 35.9 eV. Oxidation potentials: $Ag \rightarrow Ag^+ + e^-$, $E^0 = -0.7995$ V; $Ag^+ \rightarrow Ag^{2+} + e^-$, -1.98 V; $2Ag^+ \quad OH^- \rightarrow Ag_2O + H_2O + 2e^-$, -0.344 V; $Ag_2O + 2OH^- \rightarrow 2AgO + H_2O + 2e^-$, -0.57 V; $2AgO + 2OH^- \rightarrow Ag_2O_3 + H_2O + 2e^-$, -0.74 V. Other important physical properties of silver are given under **Chemical Elements**.

Occurrence and Processing. Silver is widely distributed throughout the world. It rarely occurs in native form, but is found in ore bodies as silver chloride, or more frequently, as simple and complex sulfides. In former years, simple silver and gold-silver ores were processed by amalgamation or cyanidation processes. The availability of ores amenable to treatment by these means has declined. Most silver is now obtained as a byproduct or coproduct from base metal ores, particularly those of copper, lead, and zinc. Although these ores are different in mineral complexity and grade, processing is similar.

All the ores are concentrated in complex mills by selective froth flotation to produce individual copper, zinc, lead, and, infrequently, silver concentrates. The copper and lead concentrates are smelted to produce lead and copper bullions from which silver is recovered by electrolytic or fine refining. The silver bearing zinc concentrates are commonly processed by leaching and electrolytic methods. Silver is ultimately recovered as a byproduct from zinc plant residues. Canada is a leading silver mining country. Other important sources of silver are Mexico, the United States, Peru, the former U.S.S.R., and Australia. See also **Mineralogy**.

A substantial portion of the total world silver supply is obtained from recycled scrap. Much of this scrap comes from photographic film, jewelry and the electrical field. The high value of the scrap dictates accurate sampling and careful feed preparation. Efficient and fast processing is required to minimize metal losses and a tie-up of high-value materials. The highly complex nature of plant feed, with respect to physical form, chemical composition, and grade, requires use of complex and highly flexible processing procedures.

Uses of Silver: Silver in the twentieth century can be classified an industrial commodity. For most of the 19th century, silver was a monetary metal. Industrial consumption of silver is principally in photographic film, electrical contacts, batteries and brazing alloys. Sterling silver and silver plated copper alloys are used extensively for tableware and for jewelry and other decorative art. Recently, the field of commemorative and collector arts has become a substantial market for silver alloys, particularly sterling silver.

The predominant place of silver salts as photographic receptors is not the result of any unusual primary sensitivity to illumination, but is due to the fact that they undergo an unusual secondary amplification process called "development." Silver salts, like the salts of many metals, when immersed in solutions of many reducing agents, are changed to metallic silver. The photographic system depends upon the fact that when certain mild reducing agents (called "photographic developers") are chosen, the rate of reduction is increased many fold if the silver salt crystals carry very small amounts of metallic silver at the developer-crystal interface. The effect produced by the original light exposure is amplified in the development process by a factor of 100 billion. Whereas new photographic or recording devices are being developed not involving silver, none yet approach the packing density of a fine-grained image possible using silver. Thus, it appears that silver will be used in photographic recording for many years to come.

Among the electrical uses for silver are electrical contacts, printed circuits, and batteries. By far, the primary use is in electrical contacts where the high electrical and thermal conductivities, as well as corrosion and oxidation resistances, of silver are major reasons for its selection. Although silver has a strong tendency to weld under heavy currents, this is counteracted by alloying or by adding nonmetallic substances (such as cadmium oxide) to the silver matrix. The use of silver-cadmium oxide and silver-tungsten materials in electrical contact applications is widespread. The alloys used to improve the wear resistance and to reduce the sticking tendency of silver include silver-gold, silver-copper, silver-palladium, and silver-platinum. More complex alloys include silver-copper-nickel, silver-magnesium-nickel, silver-gold-cadmium-copper, and silver-cadmium-copper-nickel. Silver-cadmium oxide alloys are unique materials and are prepared either by combining silver and cadmium oxide by powder metal techniques or by the internal oxidation of a silver-cadmium alloy. Electrical alloys, which are impossible to combine by conventional melting, lend themselves to powder metal fabrication. Such composite structures as silver-graphite, silver-iron, and silver-tungsten are good examples of these types of materials.

In silver batteries, the silver oxide-zinc secondary battery has found its place in applications where energy delivered per unit of weight and space is of prime importance. The major disadvantages lie in their high cost and relatively short life. Consequently, a large part of the silver battery market is concerned with defense and space components. See also **Battery**.

Prior to World War II, consumption of silver in silverware and jewelry was the largest industrial use of silver. Competition from stainless steel in flatware and holloware has contributed to a decline in overall use. Most consumption of silver in silverware and jewelry is in the form of sterling silver, an alloy of silver with approximately 7.5 weight percent copper. Silver plate, which is silver electroplated on a base metal, varies widely in specification. The thickness, expressed for example in penny-weights of pure silver per gross of teaspoons can range from a low of 1 to as high as 200.

In the 1920s and 1930s, low-temperature silver-copper brazing alloys were found to be useful on copper and its alloys and iron and its alloys (including stainless steel). Silver and copper form a simple eutectic system with limited solid solubility. This system can absorb elements such as zinc, cadmium, tin, and indium. These additions lower its melting temperature. It also can absorb higher melting elements such as nickel or palladium. These raise its melting temperature, but may improve its wetting characteristics, corrosion resistance, and strength at elevated temperatures. Silver solders or brazing alloys have the ability of making joints far stronger and more durable than common soft-solder (such as lead-tin) alloys. They are used in most refrigeration systems to join copper tubing. Also, extensive use is found in the assembly of automotive parts, military components, aircraft assemblies, and other hard goods manufacture. The nominal composition of a popular brazing alloy, ASTM Classification BAg-1 is silver 45%, copper-15%, zinc-16%, cadmium-24%.

One silver alloy containing about 70% silver, 26% tin, 3% copper, and 1% zinc is unique in that it is used extensively by dentists in combination

with mercury to fill cavities in teeth. The "amalgam" manufacturers supply dentists with the alloy in the form of powder (filed, or more recently, atomized). This is mixed with mercury, using from 8 to 5 parts of mercury to 5 of alloy, and the cavity is packed. In the cavity, a metallurgical reaction takes place in which the silver-tin compound in the alloy becomes a durable silver-tin-mercury compound.

Silver, its oxides, halides and other salts play important roles in chemistry. Silver is an excellent catalyst in oxidizing reactions such as in the production of formaldehyde from methanol and oxygen, ethylene oxide from ethylene and oxygen, and glyoxal from ethylene glycol and oxygen. Silver has oligodynamic properties, that is, the ability of minute amounts of silver in solution to kill bacteria. Modern technology has made use of this property in various ways, mainly as a means of purifying water.

Small amounts of silver are used annually in such diverse applications as a backing for mirrors, and in control rods for pressurized water nuclear reactors. Miscellaneous uses like this account for only a small fraction of total silver consumption.

Chemistry of Silver. [CAS: 20667-12-3] Silver(I) oxide, Ag_2O, is made by action of oxygen under pressure on silver at 300 °C, or by precipitation of a silver salt with carbonate-free alkali metal hydroxide; it is covalent, each silver atom (in solid Ag_2O) having two collinear bonds and each oxygen atom four tetrahedral ones; two such interpenetrating lattices constitute the structure. Silver(I) oxide is the normal oxide of silver. Silver(II) oxide, AgO, is formed when ozone reacts with silver, and thus was once considered to be a peroxide. Silver(III) oxide, Ag_2O_3, has been obtained in impure state by anodic oxidation of silver.

All of the silver(I) halides of the four common halogens are well known. The fluoride may be prepared from the elements, the chloride by action of hydrogen chloride gas at 150 °C, upon silver, and the bromide and iodide by ionic reactions in solution. The chloride, bromide, and iodide are essentially insoluble in H_2O, but the fluoride is soluble. There is also a subfluoride, Ag_2F, which may be prepared as a cathodic deposit by electrolysis of silver(I) fluoride AgF, or by evaporation of finely divided silver with silver(I) fluoride in dilute hydrofluoric acid. It is an anisotropically conducting solid and is considered to be made up in the solid state of two silver layers, metallic-bonded to each other, and ionic-covalent bonded to a single fluorine layer. It has reverse cadmium iodide structure. Silver subchloride, Ag_2Cl is made by reaction of Ag_2F and phosphorus trichloride. Silver(II) fluoride, AgF_2, made by action of fluorine upon a silver(I) halide, is a fluorinating agent or catalyst for fluorinations. The silver(I) halides vary markedly in ionicity, the values given by Pauling being AgF 70%, AgCl 30%, AgBr 23% and AgI 11%. This is reflected in their crystal structures and in their solubility in water (or rather, their relative insolubility). The first three have sodium chloride structure, AgI has wurtzite structure; AgF has a molal solubility of 14, and the pK_{sp} values of the others are 9.75, 12. 27 and 16.08, respectively.

Silver differs markedly from copper in forming few oxy compounds. One of these is silver oxynitrate or silver(II, III) nitrate which has the empirical formula $AgO_{1.148}(NO_3)_{0.453}$, in which the average oxidation number of silver is 2.448. It is prepared by action of fluorine upon aqueous silver nitrate or is obtained as an anodic deposit by electrolysis of silver nitrate in dilute HNO_3.

Silver enters into complex formation with many ions and molecules. With halogens, the silver complexes are fewer than the copper ones. Silver chloride dissolves in HCl with the formation of such chloroargentate ions as $(AgCl_2)^-$, $(AgCl_3)^{2-}$, and possibly $(AgCl_4)^{3-}$. Complex ions with bromide, $(AgBr_2)^-$ and $(AgBr_3)^{2-}$ are more stable, as are those with iodide, than those with chloride. Complexes of the type Ag_2Cl^+, Ag_3Cl^{2+}, Ag_2Br^+, Ag_3Br^{2+}, Ag_4Br^{3+}, $Ag_2Br_6{}^{2-}$, Ag_2I^+, Ag_3I^{2+}, Ag_4I^{3+}, $Ag_2I_6{}^{4-}$, $Ag_2I_7{}^{5-}$ and $Ag_3I_8{}^{5-}$ are also known. With ammonia the ions $(Ag(NH_3)_2)^+$ and $(Ag(NH_3)_3)^+$ are definitely known and others may exist. Similar complexes are formed with amines and diamines. With cyanides, silver forms very stable complexes, the number of CN- ions in the complex depending somewhat upon the excess of cyanide, so that $(Ag(CN)_2)^-$, $(Ag(CN)_3)^{2-}$, and $(Ag(CN)_4)^{3-}$ are definitely known. With thiosulfates, silver forms various complexes. In dilute solution, $(Ag_2(S_2O_3)_2)^{2-}$ exists, while in high concentration of $S_2O_3{}^{2-}$ ion, the complex $(Ag_2(S_2O_3)_6)^{10-}$ has been identified. In HNO_3 solution Ag^+ is easily oxidized to Ag^{2+} by peroxydisulfate. From this solution complex compounds of dipositive silver can be prepared, which are stable because coordination radically alters the oxidation potential of Ag(I) to Ag(II). They include pyridine complexes such as $(Ag(py)_4) \times (NO_3)_2$. 8-Hydroxyquinoline complexes containing the ions $(Ag(oxin)_2)^{2+}$, and o-phenanthroline complexes containing the ion $(Ag(o\text{-}phen)_2)^{2+}$. Silver(III) is known in the square, planar complex $AgF_4{}^-$, which has been prepared as $KAgF_4$ by direct fluorination of a mixture of potassium chloride and silver chloride. Silver(III), like Cu(III), also occurs in tellurate and periodate complexes.

Other silver compounds include: Silver chromate (Ag_2CrO_4), yellow to red to brown precipitate by reaction of silver nitrate solution and potassium chromate solution.

Silver dichromate ($Ag_2Cr_2O_7$), red precipitate by reaction of silver nitrate solution and potassium dichromate solution, changing to silver chromate upon boiling with H_2O.

Silver phosphate (Ag_3PO_4), yellow precipitate, by reaction of silver nitrate solution and disodium hydrogen phosphate solution, soluble in HNO_3 and in NH_4OH, turns dark on exposure to light.

Silver sulfate (Ag_2SO_4), white precipitate, by the action of silver nitrate solution and potassium sodium or ammonium sulfate solution or H_2SO_4, mp of silver sulfate 652 °C.

Silver sulfide (Ag_2S), black precipitate, by the reaction of silver nitrate solution and hydrogen sulfide.

Silver forms several compounds or complexes with proteins by the action of silver oxide with gelatin in alkali solution, or with albumin, or by suspension in casein solution and by other methods. Such silver-protein complexes containing from 19 to 23% of silver are known as "mild silver protein" and are used as antiseptic solutions. They are readily soluble in H_2O.

SILVER-CELL BATTERY. A type of short-duration, high-power-density battery of light weight used for single-time, high-power applications in vehicles where weight is critical.

SILVER FIRS. See **Fir Trees**.

SILVERFISH *(Insecta, Thysanura. Lepisma)*. One of the primitive wingless insects. It is about $\frac{1}{2}$ inch (12 millimeters) long, broad in front and tapering behind, with two long slender antennae and three similar

processes at the caudal end of the body. It is covered with lustrous grayish scales, hence the common name. The insect eats starchy materials and sometimes defaces book bindings, wall paper, and laundry, but as a rule it is not sufficiently abundant to be a pest. It is often found in damp buildings. It is also called the fish moth.

SILVERSIDES *(Osteichthyes)*. Of the suborder *Mugiloidea*, family *Atherinidae*, the silversides are related to barracudas and mullet. They also are termed antherinid smelts, but should not be confused with the true smelts. See also **Smelts**. There are numerous species, ranging up to a length somewhat in excess of 20 inches (51 centimeters). The *Antherinopsis californiensis* (jack smelt) is a silvery fish found in the waters off the California coast. Fresh and brackish-water silversides are found in the Great Lakes and in inland waters as far south as Florida and as far west as Texas. Mexican freshwaters support the *Chirostoma*, a rather abundant fish reaching a length of about 20 inches (51 centimeters) and well regarded as a food fish. Several species occur in the Mediterranean, only a few of which are found in the more northern waters off the British Isles.

Occurring in the waters of Lower California and as far northward as southern California, the *Leuresthes tenuis* (grunion) attains a length of 5 to 7 inches (12.5 to 18 centimeters) and is well known for its spawning habits. The female grunion lays her eggs in a shallow indentation in the beach and always at night during a high tide. The male fertilizes the eggs immediately, whereupon the grunion "flop" back to sea, aided by the waves. Within just a few minutes after they are touched by the waters of the subsequent high tide, the eggs are hatched. Spawning normally occurs within one or two days after a full or new moon. The *Hubbsiella sardina* has habits similar to the grunion, but will spawn during daylight hours. Grunions mature at 1 year and live about 3 years.

SILVERY POUT. See **Codfishes**.

SIMOON. See **Winds and Air Movement**.

SIMPLE DISTILLATION. Distillation in which no appreciable rectification of the vapor occurs, i.e., the vapor formed from the liquid in the still is completely condensed in the distillate receiver and does not undergo change in composition due to partial condensation or contact with previously condensed vapor.

SIMPLEX OPERATION (Communication System). A method of operation in which communication between two stations takes place in one direction at a time. This includes ordinary transmit-receive operation, press-to-talk operation, voice-operated carrier, and other forms of manual or automatic switching from transmit to receive.

SIMPSON, GEORGE GAYLORD (1902–1984). George Simpson was an American paleontologist whose research on evolutionary processes, systematics and historical biogeography helped transform biological theory in the twentieth century.

Simpson was born in Chicago, Illinois, and raised around Denver, Colorado. After several years in humanities and journalism at the University of Colorado in Boulder (from 1918), Simpson transferred to Yale University in 1922, following an emerging passion for geology and paleontology. He earned a PhB in 1923 and PhD in 1926. Simpson's dissertation studied the evolutionary relationships and taxonomy of mammals alive during the Mesozoic era. It surveyed fossils in major American museums. A postdoctoral fellowship at the British Museum (Natural History) in 1926–1927 repeated this task for European collections. By all accounts, these studies were widely respected, and Simpson was a rising star in the profession when returning to America in 1927.

Simpson's career was anchored in superb institutions. Hired to replace his mentor, William Diller Matthew, Simpson moved through the curatorial ranks at the American Museum of Natural History between 1927 and 1959. The American Museum held one of the largest libraries and collections of vertebrate fossils (especially mammals) in the world. Simpson flourished through the 1930s and 1940s despite harsh economic realities around him and occasionally hostile administration. Through patronage from philanthropists, especially Horace Scarritt, Simpson funded major collecting expeditions. Contrary to his later bookish reputation, Simpson was a devoted field paleontologist while employed by the American Museum. Combining energetic collecting and adventure, he led major expeditions to Florida and Montana, plus two to Patagonia (one is chronicled in (1934) *Attending Marvels*). A planned expedition to Mongolia was refused permission by Stalin's government, despite strenuous efforts in Moscow by Simpson and various diplomats. To these, Simpson added many smaller collecting projects (lasting weeks to a few months) across North America. He was a proud member of the Explorers Club, which promoted scientific exploration.

Simpson volunteered for military service in 1942, serving as an intelligence officer in front lines of the North African, Sicilian and Italian campaigns. A lifelong interest in languages meant he spoke French, German, Spanish and Italian fluently before the war (he also read hieroglyphics), making him ideal for intelligence collection. While in North Africa, he learned Arabic. Simpson's volunteering came at a time of crisis for paleontology at the American Museum. Its new director, Albert Parr, dissolved Simpson's department arguing paleontology was old-fashioned. Parr, an oceanographer hoping to lead the museum towards 'modern' approaches in experimental biology, provoked Simpson sufficiently that he accepted a professorship at Yale University in 1942. The war intervened, however, and Simpson delayed his final resignation. When he returned in 1944, cooler heads prevailed, and Simpson convinced Parr to reconstitute the department with him as chairman. He also became professor at Columbia University in 1945.

After the war, Simpson's fieldwork concentrated on the American southwest and the earliest stages of the Tertiary period to study the adaptive radiation of placental mammals and the migration of mammals between North and South America. Simpson referred to 1944–1956 as his "halcyon period," as it included a wide variety of projects: fossil penguins, diverse activities in professional organizations, and many publishing ventures. In 1947, Simpson and his wife built a house in the La Jara Valley of New Mexico. Los Piñavetes, as they called it, overlooked the San Juan Basin, where Simpson regularly collected fossil mammals. Though equally comfortable in cosmopolitan Manhattan, their move back west was a return to their roots.

On a 1956 expedition through Brazil to understand faunal interchange from the southern perspective, Simpson was struck by a falling tree, suffering life-threatening injuries. The accident left him severely disabled for several years and permanently lame. Long time friends noted psychological changes, too. He never returned to sustained fieldwork. None of his writing afterwards matched his earlier brilliance. His long incapacity soured relations with colleagues at the American Museum. Right or wrong, Simpson felt abandoned at his time of greatest need.

In 1959, Simpson moved to Harvard University, accepting an Alexander Agassiz Professorship at the Museum of Comparative Zoology (MCZ). Expertise at the MCZ included some of the most prominent evolutionists of the century, such as Alfred Romer, Ernst Mayr, Bryan Patterson and Simpson in one generation, Arthur Crompton and E. O. Wilson in the next. Though each continued important work, synergy was minimal and conflict was high between Simpson and his colleagues. Simpson expanded his teaching (which he rarely enjoyed) and broadened his range of writing, including many more essays, general books and textbooks. A 1964 article proposing the extremely low likelihood of finding humanoid life on other planets earned him intense critical attention from a wide audience. See also **Mayr, Ernst Walter (1904–2005)**; and **Romer, Alfred Sherwood (1894–1973)**.

During his MCZ years, Simpson also became involved in several kinds of professional disputes. First, new approaches to systematics (numerical taxonomy, then Hennigian cladism) attacked the kind of evolutionary taxonomy Simpson had spent his career developing, such as *Principles of Animal Taxonomy* published in 1961. Second, the rapid growth of biochemistry and molecular biology threatened to marginalize systematics and paleontology. At Harvard, this led to a formal split of the biology department into two groups, with "organismic" and "evolutionary" biologists, as they called themselves, concentrating at the MCZ and launching numerous attacks within the biology profession against their marginalization by "molecular" biologists. Simpson's 1961 essay "One hundred years without Darwin are enough" is an early salvo in this

struggle. Later, Simpson had a bitter row with proponents of "punctuated equilibrium," such as Stephen Jay Gould and Niles Eldredge, over the novelty of their view and their representation of his work.

After moving to Harvard in 1959, Simpson and his wife traveled and cruised extensively, eventually reaching all parts of the globe (including Antarctica). Meticulous diary and photographic collections document these adventures. Because he religiously avoided university administration, Simpson's colleagues complained he was more likely met at a conference on another continent than at a committee meeting elsewhere on campus. More tours than expeditions, these travels kept the restless Simpson not only active and engaged but also seemingly in control of his fragility. He was determined not to be slowed down. Regardless, serious health problems for both Simpson and his wife led to a move to Tucson, Arizona, in 1967, also giving up Los Piñavetes. Simpson continued his Harvard professorship until 1970 and launched a concurrent appointment at the University of Arizona in 1967. Despite unstable health, Simpson kept traveling and writing as central aspects of his life. His writing focused on general audience essays and books, attempting to connect his audiences with the subjects he loved. He formally retired in 1982, working thereafter in a custom-built library at home.

While on a Pacific cruise in 1984, Simpson caught pneumonia. He never recovered from its complications. He died in October 1984, survived by his wife and three of his children. His extensive technical library was donated to the University of Florida at Gainesville.

By all accounts Simpson was a restless genius, with a near-photographic memory and intimidating analytic abilities. His bibliography includes over 750 items, including technical papers and monographs, books, essays and commentaries. Simpson's research included several core themes: systematics, historical biogeography and evolution. See also **Systematics: Historical Overview**.

Combining studies using the impressive collection at the American Museum with those made during travels to most of the world's great museums, Simpson's 1945 classification of mammals was a long anticipated synthesis. The scope and detail of his classification was immediately recognized as a major success, with information from around the world (both published and from his first-hand studies) masterfully brought together. Simpson included a short introduction prescribing methods for taxonomic practice. First, he presented systematics as the most interdisciplinary activity in zoology, combining information from every discipline when reaching its conclusions. Second, he argued classification must reflect evolutionary history. Subspecies evolved into species, species into genera, and genera evolved into higher categories. Simpson insisted taxonomic schemes reflect this dynamic. (Other taxonomists argued this approach made taxonomic names and arrangements too dependent upon ever-changing ideas about evolutionary relationships; they wanted names and arrangements to be stable, lasting, and independent of evolutionary facts.) Simpson's 1961 *Principles of Animal Taxonomy* explains his approach. See also **Taxonomy (The History)**.

Simpson was trained at a time when paleontologists understood evolution to include three kinds of phenomena: change in form, change in distribution or range, and change in the composition of a community. For each, Simpson developed extensive research programs. See also **Evolution (History)**.

Biogeographers study changes in distribution and range. Learning from his mentors, Simpson added a historical dimension by tracing those changes over long periods of time and seeking patterns and explanations for those long-term changes. Early in his career, Simpson focused on migrations of mammals across the northern hemisphere, then within North America, caused by climate changes in recent ice ages. Later, he focused on interchanges between North and South America. Throughout, Simpson sought general mechanisms for explaining migration patterns. For example, what made some mammals good travelers? What patterns were mammals likely to follow in moving from one continent to the next? What pushes a species into moving from place to place? By 1940, Simpson developed general theories about biogeography and spent the next 30 years developing new methods for their study. In the 1930s Simpson severely criticized proponents of continental drift, saying the fossil record for mammals could be explained better by migration across land bridges. Only after evidence for sea-floor spreading became clear in the 1960s did Simpson accept drift. See also **Biogeography (The History)**; and **Continental Drift**.

Simpson's studies of faunal composition made use of his superb memory and encyclopedic knowledge about mammal distribution. He summarized this research in *Splendid Isolation*, published in 1980. On one hand, Simpson brought to this topic quantitative and graphical methods for measuring degrees of similarity between faunas separated in space or time. This allowed for quick statistical comparisons and simplified the process of pattern recognition. On the other hand, Simpson again sought general theories to explain how faunal compositions changed over time. Why were placental mammals so successful against marsupials? How do ecology and evolution combine in structuring faunas? How do whole faunas respond to mass migration inward or outward? Simpson's best-known research focused on mechanisms for the evolution of form. Integrating recent developments in genetics, biogeography, ecology and mathematical modeling of populations, Simpson constructed a general theory to explain the different rates and patterns of morphological change observed in the fossil record. *Tempo and Mode in Evolution* (1944), revised in *Major Features of Evolution* (1953), gained instant recognition for its novelty and scope. *Horses* (1951) applied Simpson's approach to a well-known, specific case. These books became essential reading for generations of evolutionary biologists, though some criticized him for excessive speculation. Importantly, Simpson spoke both for and to paleontologists. For them, he rejected claims that evolution could be understood solely in terms of genetics. Instead, evolution required thinking about organisms within ecological space and paleontological time. To paleontologists, Simpson introduced some of the latest developments in genetics and statistics. This information radically recast how paleontologists should think about fossils and forced a rejection of several popular explanations for evolutionary change. Simpson worked sometimes in parallel, and sometimes in tandem, with other biologists seeking to modify biological theory in light of recent activities, including Theodosius Dobzhansky, Ernst Mayr and Julian Huxley. Together they oversaw a movement they dubbed the "modern synthesis" and, with others, they produced a sophisticated understanding of nature they dubbed the "synthetic theory of evolution." The Society for the Study of Evolution (founded 1946) and its journal, *Evolution* (launched 1947), were community-building projects for this movement. See also **Paleontology (The History)**.

Throughout his career, Simpson was a skilful self-publicist and eager to communicate his scientific work and world-view to lay audiences. Many articles appeared in small circulation magazines, especially the American Museum's *Natural History*. His general audience books included (1951) *Horses*, (1953) *Life in the Past*, (1980) *Splendid Isolation*, and (1983) *Fossils and the History of Life*. The posthumously published (1996) *Dechronization of Sam Magruder* demonstrates Simpson's lifelong love for fiction writing, mostly unpublished. He also produced several volumes of collected essays, including (1964) *This View of Life*, (1965) *The Geography of Evolution*, and (1969) *Biology and Man*. A successful textbook, launched as (1957) *Life: an Introduction to Biology*, went through several editions. Encouraged by his (1934) *Attending Marvels*, Simpson wrote several travelogues; though submitted, these were never published. Colleagues joked that Simpson so rarely spoke because he saved all his ideas for writing.

Widest read was (1949, rev. 1967) *The Meaning of Evolution*. Popularizing recent developments in evolutionary theory, this book also offered Simpson's views on evolutionary progress and considered the scientific basis for ethics. Grounded in his raw experience of war and its aftermath and influenced by his friendships with Teilhard De Chardin and Julian Huxley, it reflects a post-World War II biologist's search for meaning in life's events beyond the simplistic image of competitive struggle: what can be learned about life's meaning from its history? This book was widely translated and reprinted. See also **Huxley, Julian Sorrell (1887–1975)**.

SIMULATOR (Computer System). A device, data processing system, or computer program that represents a system or phenomenon, and that mirrors or maps the effects of various changes in the original, enabling the original to be studied, analyzed, and comprehended by means of the behavior of the model. The term also is used to designate a routine which is executed by one computer, but which imitates the operations of another computer.

SINGLE-ENDED AMPLIFIER. A device designed to amplify signals between a single input terminal and the ground or signal reference point. Generally, the output signal is generated between a single output terminal and the same signal reference point.

A disadvantage of the design stems from installation difficulties caused by the common connection between the input and output circuits. Unfortunately, any potential that exists between the amplifier signal reference point (ground) and the reference point for the input signal appears in series with the input signal. Thus, this additional potential is amplified with the signal and cannot be distinguished from the true signal voltage. Since, by definition, a potential between two signal reference points is a common-mode voltage, the common-mode rejection of the single-ended amplifier is zero. See also **Common-Mode Rejection Ratio**.

Where amplifiers of this kind are used in digital-data acquisition and instrumentation systems, careful attention must be given to the grounding circuits. Obviously, a major requirement is for the input signal reference point to be at precisely the same potential as the signal reference point for the amplifier input. Thus, a low-impedance connection between these two reference points at all frequencies of concern is needed. This is a difficult condition to achieve where the signal source and the amplifier are separated by a significant distance. Thus, amplifiers of this type seldom are used where such separation exists. For small subsystems where the ground structure is well controlled, single-ended amplifiers are used.

SINGULAR. A term for unusual or peculiar behavior of a mathematical entity. Thus, a singular matrix is one for which the determinant vanishes and a transformation involving that matrix is also singular. An integral equation with infinite limits of integration or an infinite kernel is singular. An algebraic or transcendental equation or function often becomes singular at one or more special values of the variables defining it. This is called a singular point or a singularity. If one studies these equations as the description of a curve, one is interested in points where tangents to the curve become indeterminate or infinite (see also **Singular Point of a Curve**). On the other hand, the function itself might become infinite or show some peculiarity at a point. This is of special concern in the study of a differential equation (see also **Singular Point of a Function**). The solution of a differential equation can also be singular. Such a solution cannot be obtained from the general solution by specifying the value of its parameters. See also **Clairaut Equation**.

SINGULAR POINT OF A CURVE. If the tangent to a curve becomes an indeterminate form at one or more points, either finite or infinite, that point is called a singular point. The methods of differential calculus can, however, be used to find the tangents at such points and to investigate the behavior of the curve there. Many possibilities exist but only a few of them can be treated here. Conic sections do not have singular points; hence, the results apply only to higher plane curves.

When a curve crosses itself, there will be two tangents at that point, which is called a *double point*. If the two tangents are different, it is a *node* (L. *nodus*, knot) or *crunode* (L. *crux*, cross). If the two tangents coincide, the point is a *cusp* (L. *cuspis, point*), a *parabolic point*, or a *spinode* (L. *spina*, thorn). A third possibility is that of imaginary tangents and the point is then a *conjugate* or *isolated point*, also sometimes called an *acnode* (L. *acus*, needle).

When k branches of a curve cross, the point is a multiple point of order k. When $k > 2$, several new kinds of behavior appear, the most common of which are: *point of osculation* (L. *osculare*, kiss) or *tacnode* (L. *tactus*, touch), the curve recedes from the point of tangency in opposite directions; *cusp of the second kind*, also called *rhamphoid* (Gr.$\pi\alpha\mu\phi o\varsigma$, beak), where the two branches of a curve lie on the same side of a common tangent. At a cusp of the first kind, also called *keratoid* (Gr. $\kappa\alpha\pi\alpha\varsigma$, horn), the two branches of the curve are on opposite sides of the tangent. This is the only kind of cusp which can occur at a double point.

The preceding cases apply generally to algebraic curves. There are further possibilities for transcendental curves: *end point, terminal point*, or *point d'arrêt*, the curve terminates abruptly; *salient point* or *point saillant*, two branches of the curve end without a continuous derivative, thus without a common tangent.

Typical examples of each of these types, where the singular point occurs at the origin, are: node, lemniscate of Bernoulli; point of osculation, $a^4y^2 = x^4(a^2 - x^2)$; cusp of first kind, semi-cubical parabola or cissoid; cusp of second kind, $(y^2 - x^2)^2 = x^5$; conjugate point, $y^2 = x^2(x - 1)$; end point, $y = x \ln x$; salient point, $x = \cot y/x$.

See also **Cusp (Mathematics)**; and **Maximum and Minimum (Mathematics)**.

SINGULAR POINT OF A FUNCTION. A value of the complex variable z, for which $f(z)$ is an analytic function, is called an ordinary point. Any point that is not an ordinary point is a singular point. According to a theorem of Liouville, if $f(z)$ has no singular point for z finite or infinite, it must be a constant. Another Liouville theorem, more familiar to chemists and physicists, occurs in statistical mechanics. See also **Liouville Equation**.

Singular points or singularities are classified as: (1) poles or unessential singularities; (2) essential singularities or poles of infinite order; (3) branch points caused by the fact that the function is not single-valued.

Let $w = u + iv$ be a single-valued function of $z = x + iy$, where u, v are real single-valued functions of x and y. Then $z = z_0$ is a pole of order k, provided that $(z - z_0)^k w(z)$ is analytic and not zero at $z = z_0$. The number k is an integer greater than unity and is the order of the pole. Singular points of this kind are nonessential because they are effectively removed if $w(z)$ is multiplied by $(z - z_0)^k$. They are called poles because a three-dimensional plot of w, x, y shows that w becomes infinite at the singular point and thus a pole of infinite height occurs there on the z-plane. Typical examples are $w = 1/z(z - a) \times (z - b)$, which has three simple poles at $z = 0, a, b$, respectively; $w = \csc z$, an infinite number of poles on the real axis.

A singularity that is not a pole or a branch point is called essential. It is actually a pole of infinite order. A simple example is $w(z) = \sin 1/z = 1/z - 1/3!z^3 + 1/5!z^5 - 1/7!z^7 \ldots$ and it is seen that no finite value of k in $z^k w(z)$ will remove the singular point of this function at $z = 0$.

The essential or nonessential character of a singularity can be investigated by expansion of the function in a Laurent series. In most cases, the result can be obtained more simply by inspection of the function. If the point $z = \infty$ is of interest, transfer to the new variable $z = \overline{1/\xi}$ and the function at $\xi = 0$.

When a function is multivalued its discontinuities are called branch points. Analytic continuation between two points will then give different values for $f(z)$ if the two paths include a branch point. Branch points always occur in pairs. The line joining them is a branch line and a contour crossing a branch line changes from one set of values of $f(z)$ to another. The two (or more) independent values of $f(z)$ are its branches. The values of the different branches of $f(z)$ are identical at a branch point. See also **Riemann Surface**.

Singular points are of considerable importance in the study of linear differential equations, especially when they are to be solved by expansions in series.

The point $z - z_0$ is a regular singular point of the second-order equation $(z - z_0)^2 y'' + P(z)(z - z_0)y' + Q(z)y = 0$, provided: (1) z_0 is not an ordinary point; (2) both $P(z)$ and $Q(z)$ are analytic functions at $z = z_0$. If these conditions are not met, the singularity is irregular. This classification of singular points may be extended to linear differential equations of any order.

At a regular singular point the difference between the two exponents of the indicial equation is arbitrary, except that it cannot be zero or integral. If this difference equals $\frac{1}{2}$, the singularity is elementary.

An irregular singular point arises from the confluence of two or more regular singular points. In the case of a second-order differential equation, the indicial equation at an irregular singular point is of first degree or less and there is only one series solution there or none.

See also **Complex Variable**.

SINKING. A mirage in which the image of distant objects is displaced downward. Because the displacement increases with distance, a horizontal surface, such as that of a body of water, desert, or road, appears to bend downward and one's perception is that of being on top of an inverted bowl or possibly on a planet with a very much smaller radius. Indeed, the downward bending surface results in an (optical) horizon that can be very much closer to the observer than in the absence of a mirage. Sinking is an example of an *inferior mirage*. The opposite of sinking is *looming*. Sinking occurs when the concave side of light rays from a distant object is up, and this in turn occurs when the refractive index of the atmosphere increases with height. This only happens near a surface when the heat flux is upward and so the temperature gradient decreases with height. This is common over a warm surface (such as might occur over sun-warmed ground or a lake at night). Sinking is often accompanied by a two-image inferior mirage. See also **Inferior Mirage**; **Looming**; **Mirage**; and **Stooping**.

SINKING SPEED (Aircraft). The vertical component of the velocity of an airplane gliding without acceleration in power-off condition is the sinking speed. It is analogous to "rate of climb" of climbing flight. Methods exist for estimating sinking speed using other data of the airplane, to wit, air speed, altitude, weight, parasite area, wing span, and airplane efficiency factor. Gliding at minimum sinking speed should not be confused with the flattest glide.

Referring to Fig. 1, the following equations of statics may be obtained, using the lift-drag axes as positive axes:

$$L_w + L_t = W \cos\theta \tag{1}$$

$$D_T - W \sin\theta = 0 \tag{2}$$

where L_w = lift of the wing, L_t = lift of the horizontal tail surfaces small relative to L_w, and may therefore be neglected, D_T = total drag of the glider, W = weight of the glider.

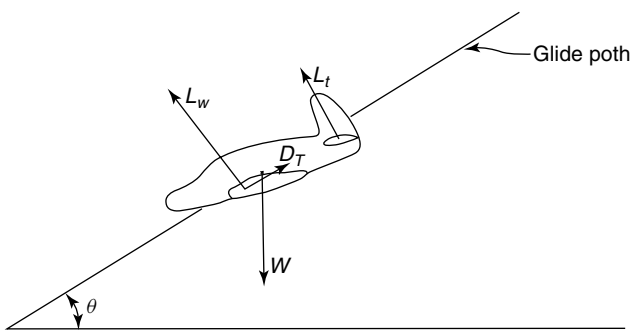

Fig. 1. Forces acting on a glider in a glide.

With the assumption that the lift on the tail surfaces is negligible, the following relationships are obtainable from equations (1) and (2) and from the usual lift and drag equations:

$$L = \frac{\rho v_g^2 C_L S}{2} \text{ and } D = \frac{\rho v_g^2 C_D S}{2}$$

where v is the glide path speed.

$$L_w = W \cos\theta$$

$$\cot\theta = \frac{L_w}{D_T} = \frac{C_L}{C_D}$$

Also, the sinking speed v_s, equals the gliding speed v_g multiplied by $\sin\theta$, and the horizontal component equals the gliding speed v_g multiplied by $\cos\theta$.

SINTERING. The heating of an aggregate of fine metal particles at a temperature below their melting point so as to cause them to weld together and agglomerate. See also **Agglomeration**.

SINUS. A pouch or cavity in any organ or tissue, or an abnormal cavity or passage formed by the destruction of tissue. The term is applied to a very large number of such structures in the human body, such as: a dilated portion of a vein containing venous blood; a chronically infected tract such as a fistula; the air cavities within the cranial bones, especially those located near the nose and connecting with it. See illustration that accompanies entry on **Skeletal System**. They are called accessory sinuses of the nose or paranasal sinuses. They extend from the nasal passages into bones of the skull, and are named according to the bones in which they lie as the frontal, ethmoidal, sphenoidal, and maxillary sinuses. The maxillary sinuses are also called antra. The maxillary sinuses are found on either side of the nose. They are large in size, and lie between the floor of the eye socket above and the upper teeth below. The frontal sinuses lie in the forehead above the roof of the eye socket, one on either side of the midline of the forehead. The ethmoidal sinuses are three groups with numerous air cells, situated between the eyes in either side of the midline or septum of the nose. The sphenoidal sinuses, two in number, are situated above and behind the nose proper. They are all lined with a delicate mucous membrane continuous with the nasal mucous membrane. When the sinuses become infected, sinusitis is said to be present.

SINUSITIS. Infection of the mucous membrane lining of the paranasal sinuses. This is a common condition, but sometimes overdiagnosed. The disease may be acute or chronic. Rhinitis (viral or allergic) sometimes predisposes sinusitis. Also, the disease may follow blockage of the nasal septum by nasal polyps. Other less frequent causes include sudden changes in altitude, foreign bodies or tumors in the intranasal system, and certain processes of a systemic nature, such as cystic fibrosis. Any process which interferes with the drainage or ventilation of the sinuses may induce sinusitis. Common causative microorganisms include pneumococci, Group A and other streptococci, and *Haemophilus influenzae*. Less frequent causes are staphylococcus, *Mycobacterium tuberculosis*, *Aspergillus* fungi, *Mucor* fungi, viruses, and *Mycoplasma pneumoniae*. Involvement may be confined to one sinus, or more commonly to both sinuses in adults. Children are more inclined to suffer from *ethmoiditis*.

Symptoms of sinusitis vary with the site. See also **Sinus**. Infection of the *frontal sinus* (*frontal sinusitis*) causes pain and tenderness over the lower forehead. There may be purulent (pus-like) drainage. In *maxillary sinusitis*, there is pain and tenderness over the cheeks. The pain may be referred to the teeth; the hard palate may become inflamed. *Ethmoid sinusitis (ethmoiditis)*, in the acute phase, is characterized by a dull headache, which may be moderate or intense. Ethmoid pertains to the bones at the front part of the base of the skull, forming part of the septum and walls of the nasal cavity. These are perforated bones through which the olfactory nerves pass. There may be swelling between the inner corner of the eye and nose. The nasal discharge may be profuse or entirely absent, depending upon whether the drainage passages are partially or fully blocked. In subacute ethmoiditis, headache may be bothersome, but pain is usually not severe. Chronic inflammation of the ethmoid sinuses is manifested by headache, cough, a general feeling of fatigue, and often a slight fever. Acute *sphenoid sinusitis*

occurs relatively frequently, with accompanying headache, which has been described as excruciating and may be only partially relieved by drugs. Sphenoid pertains to the wedge-shaped compound bone at the base of the skull. Symptoms of sleeplessness and a fear of choking are sometimes present, caused by the thick discharge from the sinus. In the chronic form of the disease, the patient may experience pressure pains spreading in diverse directions, accompanied by a thick, sticky postnasal drip.

Therapy for acute sinusitis includes analgesics, topical heat, and decongestants. Pseudoephedrine is often used. Antihistamines may be used to aid in decongestion. There is no strong body of evidence to date that indicates the usefulness of antibiotics in the treatment of acute sinusitis per se, although these drugs are frequently administered as a preventive measure. When used, ampicillin, penicillin, cloxacilin, or erythromycin are frequently the drugs of choice. Antibiotics are always indicated in toxic patients and when treatment with decongestants is insufficient. In chronic sinusitis, irrigation and surgical drainage may be required.

Although relatively uncommon, sinusitis can predispose a number of conditions, such as osteomyelitis of the frontal bones (particularly in children), orbital infections, such as orbital cellulitis, septic cavernous sinus thrombophlebitis, among others. These are serious, sometimes life-threatening conditions, but uncommonly seen because of antibiotic therapy.

SIPHON BAROMETER. A mercury barometer so constructed that the upper and lower mercury surfaces have the same diameter. It is not a standard meteorological instrument, but is sometimes utilized for special purposes.

SIPHON (Zoology). A passage between the mantle folds of bivalve mollusks through which water enters or leaves the mantle cavity. In some species these passages are developed into long muscular tubes and in others they are no more than poorly marked openings. They are two in number, a dorsal or excurrent siphon and a ventral or incurrent siphon. Water is taken in through the latter, passes through the gills to the chambers above them, and flows out through the dorsal siphon.

A part of the mantle border in some of the marine gasteropods also forms a tube through which water can be drawn into the mantle cavity. This tube is known as the siphon.

The term oral siphon is applied to the canal leading to the mouth of ascidians and the opening from the atrial cavity is sometimes known as the atrial siphon.

Unlike these organs, all of them associated with respiration, the siphon of sea urchins (*Echinoidea*) is a slender tube associated with the alimentary tract.

SIRENIA. See **Sea Cows**.

SIRIUS (α Canis Major). This is the brightest star in the sky and volumes have been written concerning its matchless brilliancy. Historically, it is undoubtedly the most interesting star in the heavens and references to it are found throughout all ancient literatures back to the earliest known writings. Aside from its surpassing brilliancy, the fact that it may be observed from every habitable portion of the earth has served to make it an object of veneration by all peoples. Sirius was worshiped in the valley of the Nile long before Rome was even heard of, and many ancient Egyptian temples were so arranged that the light from this star would penetrate to the inner altars.

Sirius has a true brightness value of 23 as compared with unity for the sun. Sirius is a white, spectral type A star and is relatively nearby ($\pi = 0.''375$), estimated distance from the earth 8.7 light years. The mass of Sirius is well known because it is a double star. The companion is a white dwarf. See also **Constellations**; and **Star**.

SIROCCO. See **Winds and Air Movement**.

SISKIN. See **Finch**.

SIZING COMPOUND. 1. A material such as starch, gelatin, casein, gums, oils, waxes, asphalt emulsions, silicones, rosin, and water-soluble polymers applied to yarns, fabrics, paper, leather, and other products to improve or increase their stillness, strength, smoothness, or weight.

2. A material used to modify the cooked starch solutions applied to warp ends prior to weaving.

SKARN. A petrological term describing the process of contact metamorphism by which certain mineral silicates such as amphibole, pyroxene and garnet replace limestone and dolomite.

SKATES AND RAYS *(Chondrichthyes).* Like sharks, the skates and rays are cartilage fishes. Of the order *Batoidei*, skates and rays may be subdivided into: (1) Electric rays (*Torpedinidae*); (2) guitarfishes (*Rhinobatidae*); (3) sawfishes (*Pristidae*); (4) skates (*Rajidae*); (5) stingrays, whiprays, butterfly rays, and round rays (*Dasyatidae*); (6) eagle rays, bat rays, and cow-nosed rays (*Myliobatidae*); and (7) devil rays (*Mobulidae*). Certain features characterize the skates and rays as compared with other elasmobranches (cartilaginous skeleton, plate-like scales, lack of air bladder). Some of the differences include: — instead of to the head, the pectoral fins fasten to the sides of the head; the pectoral fins are much enlarged; gills are located on the undersides of the fins; the method of respiration is altered, to accommodate for bottom dwelling in muddy environs; and there is no free upper eyelid, as found in sharks.

The electric ray carries a large electric organ under the wings and adjacent to the head. On the average, an electric ray can generate from 75 to 80 volts, but potentials as high as 200 volts have been recorded. Several days are needed by the ray to recharge the electric-producing apparatus. These fishes are of no food value and largely of interest because of their electrical characteristics. As with other fishes having electrical apparatus (see also *Catfishes*; and *Gymnotid Eels*); the electrical ability of the fish is used to stun potential or overactive food and for defense. However, it also has been postulated that if the fish can control the discharge to a low, possibly microvoltage level, the apparatus may be used for detection and navigation along the lines of sonar. This would be reasonable in the case of the rays, which live in muddy waters where visibility at best is poor. The electric ray holds a positive charge on its upper surface; negative on the undersurface. Approximately 40 species of electric rays are catalogued. The largest genus is *Torpedo*. The American Atlantic *Torpedo* attains a length of 5 feet (1.5 meters) or more and a weight of from 160 to 200 pounds (73 to 91 kilograms). The electric rays are ovoviviparous — eggs laid and hatched within the parent. Widely distributed in ocean waters of temperate or tropical regions, electric rays prefer small crustaceans for their diet and range from the surface down to depths of about 3,000 feet (900 meters).

In appearance, the guitarfish looks a bit like a shark and a bit like a ray, perhaps something like a flattened out shark. The guitarfishes are of nine genera with a total of over 150 species. The common Mediterranean guitarfish (*Rhinobatos rhinobatos*) frequents Mediterranean waters from Angola, Africa to Portugal; the *Rhinobatos horkelii* (Brazilian guitarfish) is found along the South American coast. The American Pacific guitarfish (*Rhinobatos productus*) is found in the waters of the Gulf of California and as far north as Monterey Bay. Guitarfishes are also ovoviviparous. They eat small crabs and fish. They survive quite well in captivity.

The sawfish looks like a guitarfish with a long, double-edged saw fastened to its nose. These fishes are classified as giant rays and six species are known. Records indicate that some species attain a length of up to 35 feet (10.5 meters) and a weight up to 5,000 pounds (2268 kilograms). Sawfishes prefer salt and brackish waters, but also migrate to fresh water. The landlocked Lake Nicaragua has a significant population of sawfishes. They also are found in the Indian River (Florida). The *Pristis pectinatus* is

the common western Atlantic sawfish and possesses from 25 to 32 pair of rostral teeth. The *Pristis pristis* (eastern Atlantic sawfish) has fewer pairs of such teeth. The sawfish uses the saw for clubbing its prey and also for digging. In preparing for a meal, the sawfish sweeps through the water flailing the saw, thus wounding its victims, which then are consumed in due course. Even in captivity, the sawfish retains its habit of swinging the saw back and forth during feeding time.

Also an elasmobranch, the skate (*Rajidae*) has a very flat body and a pair of pectoral wings. Cartilage projected forward of the body creates a very elongated nose. Skates prefer tropical and temperate waters and are widely found with exception of the areas of Micronesia, Polynesia, the Hawaiian Islands and the waters off the northeastern coast of South America. They prefer sandy, muddy bottoms of shallow water, preferably less than 600 feet (180 meters) deep. The number of species exceeds 100. The hedgehog skate (*Raja erinacea*) is common and can be found in the western Atlantic from Nova Scotia south to South Carolina. Adults measure about 20 inches (51 centimeters) in length and weigh about a pound. The *Zearaja nasuta* that frequents New Zealand waters attains a length of over 6 feet and may weigh up to 70 pounds. Possibly the largest of these fishes is the *Raja binoculata*, occurring in the American Pacific, which attains a length of about 8 feet (2.4 meters). Some species of skates have electric organs, but the voltages are considered to be quite small. It is possible that the skate may have electrogenic capabilities. Skates found along European coasts are sold commercially, but they are not a major item.

Stingrays are characterized by venom spines. See Fig. 1. The spines can be replaced if lost. Death can result if the venom gland is driven into a swimmer. It has been recorded that large stingrays can thrust the venom spine through the planking of a small boat. There are approximately 80 species of dasyatid stingrays, ranging from fishes of about $1\frac{1}{2}$ pounds (0.7 kilogram) and about 1 foot (0.3 meter) across the wings to a weight of 750 pounds (340 kilograms) and wingspan of 6 to 7 feet (1.8 to 2.1 meters), as found in the Australian stingray. Stingray young are born alive.

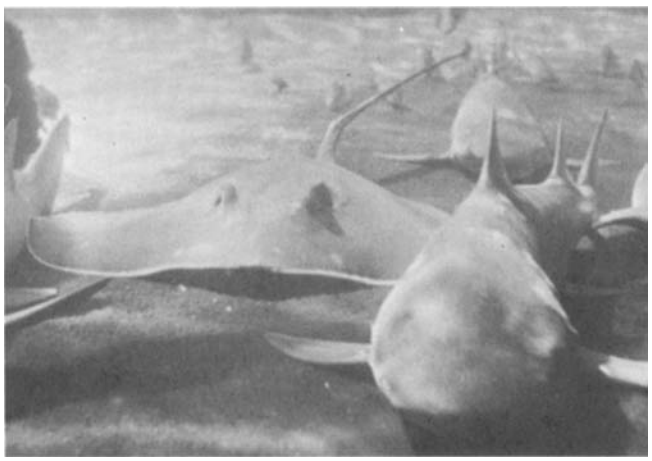

Fig. 1. Sting ray shown in the company of several lemon sharks. (*A.M. Winchester.*)

Although enjoying a very bad reputation, the devil rays (*Mobulidae*) under scientific investigation have proved to be quite docile. The *Mobula diabolis* (Australian devil ray) measures but 2 feet (0.6 meter) across the wingtips, whereas *Manta* may attain a wingspan of 22 feet and weigh up to 3,500 pounds (1588 kilograms). They usually travel singly or in pairs, seldom in schools. They are ovoviviparous.

SKELETAL SYSTEM. An aggregation of rigid or semirigid structures that provide mechanical support for the body and usually a lever system on which the muscles act.

The simplest type of skeletal system is found in the sponges (see also **Porifera**) and some of the coelenterates. Sponges have scattered spicules of calcareous or siliceous matter among their loosely integrated tissues or are held together by a meshwork of fibers composed of the material spongin, so familiar in the sponges of commerce. The commercial sponge is, in fact, the skeleton freed of organic matter. Spicules are variously formed bodies, some straight rods, some with radiating axes from three to six in number, and some expanded at the ends. Approximately similar scattered bodies are found also in alcyonarians, and in some of these animals they are united to form a continuous mass in which the polyps are imbedded or a solid core surrounded by softer material. Rock corals lay down a calcareous deposit beneath the base to which each polyp of the colony adds.

In many invertebrates the body wall is the sole support of the animal. Even though it is soft, the incorporation of muscular layers in it provides for movement without rigid skeletal structures.

The echinoderms differ in having calcareous plates (ossicles) throughout the integument. In the sea urchins they are closely joined to form a shell and in the sea cucumbers they are small and scattered. Other groups show an intermediate condition with closely associated but movable ossicles. These structures in the sea urchin also illustrate lever action in the use of the spines for locomotion and in the peculiar chewing organ known as Aristotle's lantern.

The arthropods and vertebrates differ in the presence of a complex skeletal system, which supports the body and forms the foundation of the jointed appendages. In no other phyla are lever-like appendages found.

The arthropods have an exoskeleton made up of hard plates (sclerites) of chitin and calcareous matter, formed in circumscribed areas of the cuticula. They are separated by flexible zones, which provide for freedom of movement, and are moved by muscles attached to their inner surfaces. The appendages are formed of rigid segments attached to each other and to the body by the flexible tissue of the joints. The skeleton forms a sheath enclosing the muscles in such appendages.

Among the half-million species of arthropods wide variation is inevitable. In general, the exoskeleton of the head forms a compact capsule. The skeleton of the thorax also tends to become compact, although its segments are distinctly recognizable in many species. This portion of the exoskeleton also forms a shield-like carapace in many species. The abdomen retains greater mobility, although its segments may be reduced in number and the exoskeleton of each may be consolidated to a ring surrounding the body. A moderately complex segment of the exoskeleton contains a dorsal, a ventral, and two lateral sclerites known respectively as the tergum or tergite, the sternum or sternite, and the pleura or pleurites. In many cases this plan is simplified by fusion or made more complex by subdivision of the sclerites.

An endoskeleton of limited extent in the arthropods is made up of internal projections from the exoskeleton known as apodemes. They serve as places of attachment for muscles.

One important result of exoskeletal support is the provision of wings in the insects as thin-walled sacs of the body wall. By the apposition of the upper and lower walls of these sacs they become thin membranous planes sufficiently strong and rigid to support the body in flight. Thus, the jointed appendages are freed from participation in adaptation for flight.

Exoskeletal structures also appear in the vertebrates but here they are merely hard parts without the usual supporting functions of the skeleton. They are derived from either or both layers of the skin. The category includes teeth and beaks, horns, claws, hoofs and nails, scales, feathers, and hair. Bony plates associated with scales, as in the alligator and armadillo, are also exoskeletal.

The supporting skeleton of the vertebrates (Fig. 1) is an endoskeleton composed of bones and cartilage. It is made up of two chief divisions, an axial skeleton consisting of a vertebral column, ribs, and skull, and an appendicular skeleton including pectoral and pelvic girdles, each bearing a pair of appendages. The pharyngeal wall of fishes is supported by the visceral skeleton, which persists to a limited extent in the more advanced classes. In the elasmobranch fishes now living, the skeleton is composed entirely of cartilage. In most vertebrates, it is made up very largely of bone.

The skull in the elasmobranch fishes consists of a mass of cartilage below, behind, and partially enclosing the brain. This structure is called

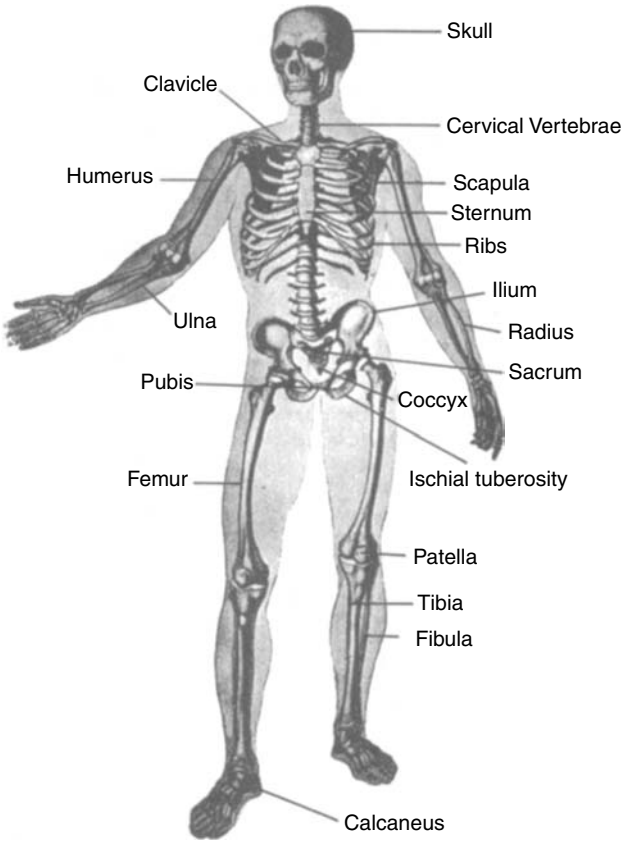

Fig. 1. Skeletal system of human.

the chondrocranium. In the bony fishes it is replaced by bones in the same position and is supplemented by superficial bony plates enclosing the remainder of the brain. The jaws of the elasmobranch are also supported by cartilages and in the bony fishes these cartilages are supplemented by bones. Above the fishes, a chondrocranium appears in the embryo and is replaced during development by the ethmoid bone and parts of the sphenoid, temporal, and occipital bones, taken in order from front to back. The remaining bones are not preformed in cartilage. They are more numerous in the lower form than in humans. In the human skull (Fig. 2), they are the pair of nasal bones in the bridge of the nose, the pair of lachrymals in the orbits, the vomer in the nasal septum, the large frontal bone of the forehead, the parietals in the top and sides of the skull, the upper part of the occipital forming the lower back wall of the skull, and the temporals above the ears. The upper jaw is based on the maxillary bone from which the palatine extends into the hard palate. A slender rod, Meckel's cartilage, supports the lower jaw of the human fetus but the permanent lower jaw is the mandible, a dermal bone formed independently.

The vertebrae that make up the spinal column consist typically of a centrum bearing a neural arch above and a haemal arch below. The neural arch surrounds the spinal cord and is surmounted by a neural spine. In the fishes the haemal arch encloses the dorsal aorta and in the region of the body cavity open haemal arches form ribs known as fish ribs. In other classes, and in a few fishes, these ribs are replaced by similar slender bones known as true ribs. They develop between the segments of the body lateral to the fish ribs and above them, and articulate with processes of the vertebrae. These ribs join a median ventral structure, the sternum or breast bone, composed of bones and cartilages.

The vertebrae differ in various regions of the body. The first, with which the skull articulates, is the atlas. The second, the axis, is noteworthy for its odontoid process, a solid anterior extension of the centrum. This process is the centrum of the atlas. These two and the remainder of the series in the neck are called cervical vertebrae. The following series with which the ribs articulate are the thoracic vertebrae. The lumbar vertebrae extend to the articulation of the pelvic girdle, where one vertebra or a fused series constitute the sacrum. The following caudal vertebrae lie in the tail or, in the apes and man, are fused to form a mass called the os coccyx.

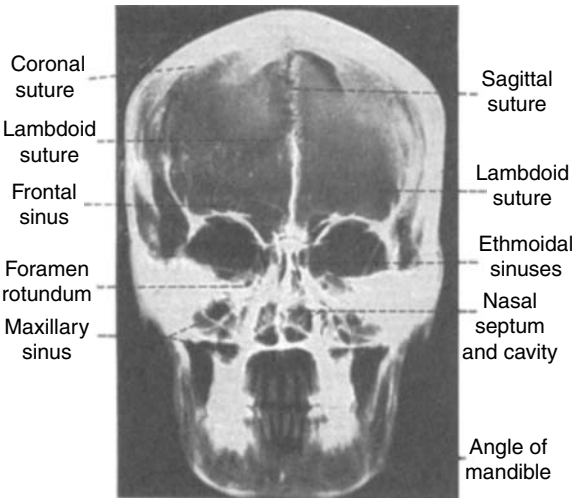

Fig. 2. Antero-posterior radiography of a skull. (*Cunningham.*)

The pectoral and pelvic girdles are composed of three pairs of bones, two passing downward and toward the median line of the body from the articulations of the appendages and one upward. Of the more constant bones in the pectoral girdle, also called the shoulder girdle, the upper bone is the scapula (shoulder blade), the anterior of the lower bones is the clavicle (collar bone), and the posterior is the coracoid. The two pairs attach to the sternum. They are supplemented in amphibia and reptiles by other bones. The bones of each half of the pelvic girdle are the dorsal ilium, the anterior pubis, and the posterior ischium. This girdle in many forms is firmly attached to the sacrum.

The girdles are modified in various ways. The principal tendency of the pectoral girdle is toward simplification by the loss of bones, so that in many species only the scapula and clavicle remain, as in man, the coracoid being reduced to a process on the scapula. In the hoofed mammals only the scapula persists. In the moles, however, the girdle is large and strong. The pelvic girdle, in correlation with the stresses that it bears in locomotion, becomes compact. The bones of each side tend to fuse and the pubic symphysis, at the ventral union of the two halves, is very firm. The name pelvis or pelvic bone is often applied to this composite structure.

The primitive appendages are the paired fins on the fishes. These structures are precursors of the pentadactyl appendage of terrestrial vertebrates. From this basic plan the structure of appendages in various groups has come by modification of the proportions and relations of the bones, by loss of digits, and to a limited extent by the fusion of separate bones. Both loss and fusion have occurred in the wings of birds, and maximum loss is found in the legs of the horse and allied species, where a single functional digit remains.

The appendages also contain sesamoid bones, small rounded bones developed in the tendons spanning movable joints. The most constant of these bones is the patella or knee cap.

The visceral skeleton in its primitive condition consists of a series of small bones and cartilages supporting the branchial arches between the gill slits. In the existing vertebrates the embryonic primordia of the hinged jaws are derived from these arches but the visceral skeleton is otherwise greatly reduced except in the fishes. It persists in part as the small bones (ossicles) of the middle ear, the hyoid bones supporting the tongue, and the cartilages of the larynx and upper part of the trachea.

SKEWNESS (Mathematics). That property of a frequency distribution involving its symmetry or asymmetry. Skewness is usually measured by the departure from zero of the third *moment* about the mean, standardized by division by σ^3 where σ is the standard deviation.

SKIMMER. See **Waders, Shorebirds, and Gulls**.

SKIN. The covering of the body of vertebrates. It consists of two parts, an outer epidermis and an inner dermis or corium. The former develops in

the embryo from the outer germ layer, the ectoderm, and the latter from the middle germ layer, the mesoderm.

The epidermis is composed of many layers of cells in two principal strata, the stratum corneum and the stratum germinativum. The flattened cells next the surface are hardened by deposits of pareleidin, a substance related to keratin, and are said to be keratinized. They make up the stratum corneum. Below them are several layers of thicker cells whose active proliferation gives rise to the cells of the stratum corneum. These layers constitute the stratum germinativum. In the outer cells of this stratum granules of keratohyalin appear as forerunners of the pareleidin of the stratum corneum, forming the thin stratum granulosum. A thin clear zone just outside of the granular layer, known as the stratum lucidum, is regarded as the basal layer of the stratum corneum. In its cells, the granules of keratohyalin become a diffuse intermediate substance, eleidin.

The corium is a dense connective tissue layer extending from the fatty subcutaneous tissue. It is obscurely divided into an inner stratum reticulare and an outer stratum papillare, which rises in papillae beneath the epidermis. Epidermal derivatives including hair follicles, sweat glands, and sebaceous glands extend into the corium, and it contains nerve endings, tactile corpuscles, and blood vessels. Smooth muscle fibers attached to the hair follicles lie in it, and in some parts of the skin it contains other muscle fibers. The voluntary muscles of the face by which expression is controlled end in it.

Aging of the Skin. The deep, felt-like layer (dermis) gives the skin its suppleness and substance. The connective tissue fibers of the dermis form a woven pattern that, in infants, gives the skin a soft, velvety texture. As the skin ages, this woven pattern becomes tighter and less resilient, tougher, and wrinkled. These essentially undesirable changes are hastened by certain deleterious factors, including overexposure to ultraviolet (UV) rays of the sun, exceptionally large doses of vitamin C (ascorbic acid), exposure to heat, wind, drying agents (such as alcohol), and frigid temperatures. These changes are noted as "wrinkling" and often include the formation of "crow's feet" at the outer corner of the eyes, as well as some withering at the joining of the lips.

To date, these aging processes are not subject to reversal. Moisturizing agents (wool fat and lanolin) as well as extra doses of vitamins A and E and retinoic acid (Retin-A) have been tried, but documentation to date has been less than convincing. At best, these substances may slightly slow the natural skin aging processes.

Diseases of the skin are numerous and are described in the article on **Dermatitis and Dermatosis**. In the following article on **Skin Cancer**, the principle life-threatening skin diseases are described. The principal trauma to the skin includes burns, either from fire and heat or from chemical substances. See also **Burn**.

Progress has been made in using "artificial" skin, particularly in the treatment of burn cases. As reported by Erickson, some success has occurred in the development of so-called skin "stand-ins," or dermal substitutes, which may partially replace the need for testing skin medications and cosmetics on laboratory animals. These substitutes are comprised of complex cultures of cells, look like real skin, and are available in sheets. The possible use of such new dermal substitutes (*TestSkin*) ultimately may revolutionize skin-product testing and research and obsolete most needs for laboratory animals. The concept also is being investigated for possible use in burn therapy. (See *Sci. Amer.*, 168, September 1990).

SKIN CANCER. Probably because the skin is the largest organ of the body and because it is so continuously exposed to the hazards of sunlight, ionizing radiation, abrasion, chemical attack, and other hostile conditions, it is more frequently the seat of cancer than any other site on the body. Although not responsible for all carcinomas of the skin, chronic exposure to sunlight, where the individual is not protected by intense melanin pigmentation, is the most important etiologic factor in the development of skin cancer. This itself may be further mediated genetically.

In the late 1990s, the number of newly diagnosed skin cancers per year ranged between 600,000 and 800,000 cases per year in the United States. These statistics are paralleled in other countries located in similar climate zones and with comparable life-styles. Part of the increase in the skin cancer treatment load may be attributed to the growing awareness of the general populace to public and institutional educational programs that have stressed the dangers of exposure to sunlight as well as a growing awareness of individuals to seek professional help more frequently when confronted with changes in their skin and the appearance of doubtful lesions. However, the bulk of the increase is due to new cancers brought about by failure to heed the warnings.

The death rate from skin cancer varies widely with the type of cancer and the timing of diagnosis and therapy. Deaths due to nonmelanoma cancers, especially basal-cell carcinomas, are comparatively low. In 1992, Weinstock et al. reported on a population-based study of mortality from nonmelanoma skin cancers that indicated that 59% of deaths were due to squamous-cell carcinoma and 20% were due to basal-cell carcinomas. Increased risk was associated with cancers on the ears and eyelids.

There were 32,000 deaths in the U.S. in 1991 attributed to cutaneous melanoma. This incidence has nearly tripled since the 1950s. Most increases were in young adult whites (ages 25 to 29 years). The annual incidence is higher than that of any other cancer. Sunlight is considered the most important environmental factor favoring the pathogenesis of melanoma. There appears to be some familial connection, with a risk factor of 2 to 8 times for individuals whose parents had melanoma. It was learned that dysplastic nevi are potential precursor lesions from which melanoma may develop.

The prognosis of malignant melanoma worsens with increasing thickness of the tumor. It also is related to site, age, and sex. Early diagnosis and removal of the lesion usually has been successful in warding off the usual incurable metastatic phase of the disease. In patients with tumors less than 0.75 mm thick, the 5-year survival rate is 96% dropping to 47% in cases where the tumor exceeds 4 mm. The 5-year survival rate falls to 36% in those persons with distant metastes.

In an excellent article by Phillips et al. (reference listed), the authors describe the latest surgical margins in the management of Stage I melanoma (i.e., those limited to the skin).

A number of benign skin lesions may develop into malignancies if left untreated. The most common of these is *actinic keratosis* (senile or *solar keratosis*) which will occur in areas frequently exposed to sunlight — the face, lower arms, neck, scalp (where not shielded by hair) and the dorsal surfaces of the hands. Varying in size up to one centimeter (diameter), the lesions may be pink to tan, smooth or scaly, and of almost any shape. *Leukoplakia* is much like actinic keratosis except that it will appear on mucous membranes (lips, oral mucosa, vulva, etc.) the lesions being somewhat elevated, irregularly shaped and sharply bordered white patches. Squamous cell carcinoma in situ (*Bowen's disease*) presents as single or multiple sharply defined plaques that are slightly thickened and brownish-red with varying amounts of scale. The lesions resemble eczema or psoriasis, but fail to respond to local therapy.

Although only about 5% of these lesions become invasive and less than 2% metastatize, more important is the recognition that the patient is at significant risk of developing carcinoma of the respiratory, gastrointestinal, and genitourinary systems. Intraepidermal metastases (*Paget's disease*) is an uncommon carcinoma presenting as a sharply defined, red, weeping, crusted or scaly lesion resembling atopic eczema which does not respond to topical corticosteroids. It may develop within the epithelium of the mammary ducts and extend upward into the epidermis or appear on the pubis, perineum, genitals and other sites related to underlying apocrine or eccrine sweat glands.

Basal Cell Carcinoma. This accounts for more than 75% of all skin cancers and these are among the most strongly antigenic of all human cancers. They arise from the epidermis, cytologically resemble the normal basal cells, and show little tendency to undergo the usual differentiation into squamous cells that produce keratin. Although these tumors rarely

metastasize, they are locally invasive and may go deeply into nerves, bone, and brain. Like most cancers, they are remarkably painless in their course and this lack of symptoms leads to prolonged neglect of a lesion. The typical basal-cell carcinoma is an uninflamed smooth, waxy nodule which appears to be translucent and may show varying amounts of melanin pigment in the form of small dots. Such nodules often ulcerate and may re-epithelialize leading the patient to believe that the nodule is resolving. A patient with one basal-cell carcinoma is likely to have others at the same time or shortly thereafter. Because the tumors are malignant, they should be excised or otherwise destroyed after diagnosis has been confirmed. A border of normal tissue, adjacent to the tumor, must be removed to prevent recurrence from invasive strands of tumor cells.

Squamous Cell Carcinoma. This also arises from the epidermis, but shows significant squamous differentiation and usually keratin production. The lesions have a variable tendency to metastasize depending upon their size, extent of invasions, and their mode of origin. The typical squamous-cell carcinoma is a painless, firm, red nodule or plaque with visible scales on the surface. Ulceration may occur, in contrast with the basal-cell variety and, when this is so, they have the lowest frequency of metastasis. On the other hand, where they arise from mucous membranes, burn scars, sinus tracts, or from apparently normal skin, they have a much higher tendency to metastasize.

Primary Malignant Melanoma of the Skin. This is the most serious disease in dermatology. Pigmented moles are among the most common growths on the skin of humans, yet cancer involving pigment cells is relatively uncommon, constituting about 1.5% of all cancers. The diseases is, however, virtually incurable by chemotherapy or X-rays and so far has only responded to deep excision.

Even in its early stages, primary malignant melanoma is relatively easy to detect. The variegation of color and irregularities in surface pattern and configuration are characteristic even when the tumor has red, white, or blue surface color. Any of the several types of melanoma may exist for several years in the pre-invasive stage.

These tumors are usually seen in the fourth and sixth decades of life. White people with light complexions are more prone to melanomas than persons with dark pigmented skin and there is a significant relationship between incidence and exposure to sun. Three forms are recognized: (1) *Lentigo malignant melanoma* with a median onset of 70 years. The lesions are various shades of brown and black and the margin is flat. The lesions are usually found on the head and neck, being less common on hands and legs. They usually commence as freckles with irregular outlines and may grow very slowly over 5 to 15 years. (2) *Superficial spreading melanoma* is the most common form, with a median onset of 55 to 60 years. The lesions may have several different colors from brown to gray and rose-pink. The margins are distinctly palpable and the lesions are found on all body surfaces, beginning as small irregular, brown pigmented areas with various shades of color. Growth into papules or nodules may require from 1 to 5 years. (3) *Nodular melanoma* has a median age of onset of about 50 years. The lesions are uniformly bluish-black with a depigmented halo and the margins are palpable. Usually commencing as a papule or nodule with a smooth, scaly, eroded surface, the lesions grow rapidly.

Survival rates are highest for the lentigo type and may be as high as 95%. In nodular melanoma where distant metastases frequently form, the prognosis is much poorer. Immunotherapy or chemotherapy when combined with surgery may improve the situation.

Sarcomas of the Skin. These may be primary or metastatic and single or multiple. They involve connective tissue, the vascular system, adipose tissue, muscle and/or the lympho-reticular system. Kaposi's idiopathic hemorrhagic sarcoma is manifested by firm, reddish-brown or bluish plaques or nodules on the hands and feet.

Mycosis Fungoides. This is the most common primary lymphoma (tumor of lymphoid tissue) of the skin and technically is a relatively indolent cutaneous T-cell lymphoma characterized by a neoplastic proliferation of mature helper T cells. Each year, about a thousand new cases are presented in the United States. However, the incidence is increasing. The lesion may present as a nonspecific erythematous, scaly, eczematous eruption that may go on for years before a diagnosis is made. It gradually develops thicker, scaly, annular plaques reminiscent of psoriasis. In the accelerated phase the disease is characterized by skin tumors, lymph-node involvement, and a spreading to the viscera. These conditions are associated with a survival of 2.5 years. Patients who present only superficial skin involvement have a better prognosis (some 12-plus years). Sézary syndrome, where there are plaques, tumors, erythrodermic, and lymph-node or blood involvement, but no visceral involvement, has a median survival of 5 years.

Protection from the Sun

Life-styles have changed a lot during the last few decades, and, unfortunately, the incidence of skin cancer has increased markedly. Cases of skin cancer in earlier years were almost always associated with outdoor manual laborers, and thus a tanned skin was shunned by many of the elite. In recent years, particularly with the younger generation, a tanned skin has become a status symbol by people who regard a nicely tanned body as a symbol of health and strength. Young males and females alike have taken to sun bathing, to using tanning parlors, and taking tanning pills. This is despite increasingly frequent warnings, by numerous public and private institutions, against excessive exposure to solar rays, and their relationship with skin cancer.

While tanning pills generally have been considered hepatotoxic (adverse effects on the liver), a large number of satisfactory and safe UV blocking and screening lotions has become available. The labels on these products should be read carefully to make certain that sufficient protection will be provided over what periods of exposure time. But, even with such safeguards, sunbathers must always act in moderation.

Professional dermatologists suggest:

1. Always wear sunglasses that absorb from 90 to 100% of UV light. Glasses with gray lenses are preferred to avoid undue alterations in color perception. Glasses that wrap around the side provide protection against reflected-light trauma. Sunglasses protect against *solar keratitis*, which is a sun-induced inflammation of the cornea of the eye. The glasses also provide long-term protection against later cataract development.
2. Apply lip balm to lips, zinc oxide paste to the nose, and wear a broad-brimmed hat. A weekly lanolin facial treatment is excellent for maintaining a good skin condition.
3. Use a sun block (screen) over all areas of the body that will be exposed to the UV light. Light-skinned people require a highly protective blocking agent (rated 12 to 20). Dark-skinned people can use a lighter blocking agent.
4. Under no circumstances should babies or older family members be permitted to bask in the sun. Exposure for just a few minutes can be damaging.
5. Do not relax precautions on cloudy days. Such days are a special hazard because clouds are radiolucent, offering no barrier to UV rays.
6. The foregoing also apply when in the water. A water film provides no protection and, in fact, may partially remove the blocking agent (usually PABA [para -amino benzoic acid]).

SKIN DISEASES. See **Dermatitis and Dermatosis**.

SKIN EFFECT. The alternating current flowing in a conductor is not uniformly distributed over the cross section of the conductor but becomes denser the farther the cross section being considered is from the center of the conductor. This effect, known as skin effect, is caused by the varying inductance of the different parts of the conductor. If a circular conductor is considered to be specific, and imagined to be composed of many elemental filaments in parallel it can be seen readily why the current flow is more dense as the distance from the center becomes greater. The current in each filament sets up a flux around it which links both it and any other filaments which may be within the lines of flux. It will be realized at once that the filaments in the center can be linked by many more lines than those on the outside, since the outer ones are beyond much of the flux of the inner ones. Thus the inductance of the inner filaments is greater than that of the outer ones and so the reactance of the inner ones is greater. This greater impedance of the inside causes more of the current to flow in the outer-layers and gives rise to the skin effect. As the effective cross-section of the conductor is decreased by this, the resistance to A.C. is greater than the resistance to D.C. In certain cases, such as the induction motor, where the conductor is largely surrounded by iron, the skin effect is very much greater than in a conductor in free space. In this motor the effect is utilized to obtain high starting torque without serious impairment of the running characteristics. In the layout of A.C. buses, various arrangements such as hollow squares, channels, etc., are used to save material since the inner part would be of very little use. At radio frequencies the effect is very pronounced so only a thin outer layer of the conductor is effective, thus greatly increasing the resistance. It is convenient to speak of a "skin depth" which is defined as the depth below the surface of a conductor at which the current density has been reduced to $1/e$ times its value at the surface of the conductor. The skin depth δ is given by the expression

$$\delta = \sqrt{\pi f \mu T}$$

where δ is depth in meters, f is frequency in cycles/second (Hz), μ is the permeability in henries/meter and T is the conductivity in mhos/meter.

SKIN FRICTION. The drag force on a body arises from tangential stresses at its surface, usually viscous, from the normal pressure distribution over it, and, for supersonic flow, from wave-drag. The component calculated from the tangential viscous stress is the skin friction and, for a bluff body, is the component most sensitive to change of Reynolds number. Roughly, the skin friction coefficient, the stress per unit area divided by the dynamic head of the free stream is proportional to the one-fifth-power of the Reynolds number.

SKINKS. Of the class *Reptilia*, subclass *Lepidosauria*, order *Squamata* (scaly reptiles), suborder *Sauria* (lizards), infraorder *Scincomorphs* (skinks and allies), these animals are found in three subfamilies: *Tiliquinae*, which includes the Giant, Cape Verde, Stumped-tail, Blue-tongued, and Spiny-tailed skinks; Scincinae, which includes the common skink and the Eastern, Hemprich's, Arabian, Sand, and Algerian skinks, among many others; and Lygosominae, which has many genera, including the East Indian Brown-sided, Emerald, Spotted, Casque-headed, Dart, and Blind skinks, among others. Closely related and part of *Scincomorpha* are two additional families, the tailed lizards and night lizards, which are described under **Lizards**.

Skinks are distinguished by the head, which is covered on top with large, symmetrically arranged, ossified plates, and by the round scales on the back and belly that overlap like roof shingles. The tongue is free and moderately long. It is slightly notched at the end and bears imbricating scale-like papillae. The body is usually cylindrical, and the head ends in a sharp snout. The feet in most species bear five toes; the tail is pointed at the tip. The skinks demonstrate a gradual transition from lizards that have four strong legs to the legless "snake-type" lizard. In this transition, it is hypothesized that, initially, the trunk became longer, the limbs became smaller and more delicate, and the number of fingers and toes was reduced until finally becoming stumpy vestiges, with the forelegs disappearing entirely and, lastly, the hindlegs vanishing as well. Thus, the manner of locomotion changed from walking to snakelike slithering. These changes reflected a move from the original mode of life above ground to the specialized life of the subterranean burrower. These changes are reflected in varying degree among the numerous genera of skinks. The form of the tail also was involved in the slowly evolving transition. Some genera of skinks, such as the Australian stumped-tailed skink (*Tiliqua rugosa*), has only a stump tail, whereas others have a spine-like tail. Ear openings also changed, wherein the external ear opening is found reduced and has become covered with scales. This may have occurred as the result of the animal's transition to a subterranean form of life — to protect or even close the openings of sense organs. In many skinks, according to I.E. Fuhn, the lower eyelid, customarily movable and scaly in lizards, evolved into a transparent window that allows the animal to see through when it is closed. If the lids fuse, a rigid, transparent "spectacle" is formed, much as in snakes. Where skinks colonized rocky regions or trees, it became advantageous to develop adhesive mechanisms on the fingers and toes. There are exceptions, as in the case of the giant skink, which evolved a prehensile tail.

Skinks are *thermophilous* (heat-loving) and are found mainly in the tropical and subtropical regions of the earth, such as southern Asia, Africa, and regions of Australia and Polynesia. Some, however, are found in the Americas and Europe. Because of their highly terrestrial preference, skinks are not usually found near bodies of water.

Formal classification of the skinks is based largely upon the structure of the skull, thus accounting for the three families previously mentioned.

Fuhn suggests that the *Tiliquinae* are relicts of the Tertiary Period. The giant skink (*Corucia zebrata*) is, on the average, about 65 centimeters long. It is presently found in the tropical forests on San Cristobal in the Solomon Islands. The largest of all modern skinks, this animal lives in trees, a characteristic that is rare among skinks. Especially adapted to arboreal life, its characteristics of long prehensile tail, strong limbs armed with claws, large ear and eye openings, broad head, and short, blunt nose are distinguishing features. The upper body is greenish-white, marked with irregular brown bands; the head is sometimes a reddish-brown. This animal has not been studied extensively in its habitat.

Also of *Tiliquinae* is the Cape Verde skink, which at one time was a favorite animal for terrariums. It is relatively easy to sustain in captivity, but, because of extensive hunting for its flesh by fishermen in its natural habitat, the species is threatened. A close relative of this creature became extinct as early as 1708.

Among the *Tiliqua*, the blue-tongued skink (*Tiliqua scincoides*) is well known and named because of its cobalt-blue tongue. Also studied is the stump-tailed skink (*T. rugosa*), which achieves a length of about 36 centimeters. The latter is found in Western Australia, South Australia, and New South Wales. Notably, this skink is quite short and wide, has a flat tail that is widened at the end and, because of its round end, that appears to have been chopped short (sometimes referred to as "bob-tail"). The threat display of the animal has been described by Robert Mertens: "It rolls itself into an arc and, hissing, opens its mouth to show the wide, long, cobalt-blue tongue in sharp contrast to the red mouth. Though its mouth, armed with strong teeth, is wide open, the animal does not bite, but rather tries to scare its enemy away simply by its threat display." The "bobtail" often lives on sandy dunes and can burrow into upper layers of sand. It

moves slowly, but in an emergency can run quite fast. The animal's diet consists of vegetation, fruit, and small animals. The blue-tongued skink is ovoviviparous, the female bearing two or three young at a time. The animal has been featured in terrariums.

Of the subfamily *Scincinae*, the common skink is the best representative of this group. See Fig. 1. The species (*Scincus scincus*) generally is adapted to live in the desert or other sandy regions. The characteristic ability of these lizards to move about rapidly in the sand was noted in early Biblical times. At one period, in the late 1700s, it was believed that the lizard had aphrodisiac and medicinal properties. All members of this species have sturdy, cylindrical bodies. The tip of the snout has an elongated wedge-like shape, and the tail, conically shaped, is short. The legs each bear five toes with serrated fingers. The coat of scales is remarkably smooth and firm.

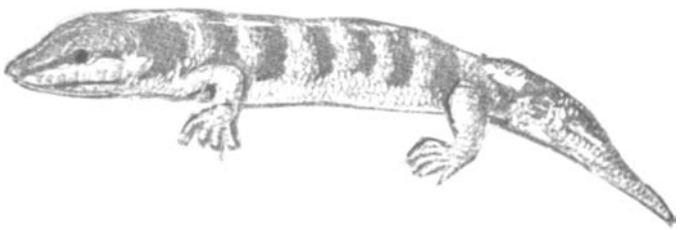

Fig. 1. Common skink (*Scincus scincus*).

Scincinae also includes the genus *Chalcides*, with its well-known cylindrical skinks, which are distributed in the Mediterranean, from eastern Africa and Arabia into Iran, Pakistan, and India. The species *Chalcides chalcides* is a snake-like animal, with three toes on the limbs. This animal may reach a length of about 42 centimeters. During rapid locomotion, the legs are pressed against the body and not used. The upper side is olive to bronze in coloration, with up to 11 dark, longitudinal stripes. The tail is moderately long, and the head is not set off from the trunk. The limbs are short, with five toes. The smooth and shiny scales are brown. These animals are ovoviviparous, bearing about three young at a time. A popular terrarium specimen is *C. ocellatus*. Its natural habitat is Morocco and environs. It prefers valleys in which date palms grow or else groves of tamarisk on clay soil, where it uses the tracks formed during dry periods as hiding places. This skink is active all day until sunset, during which time it feeds on crickets. Because the animal has a snakelike appearance, there are numerous superstitions about it. For terrariums, Franz Werner observes: "It loves the sun and needs a warm, sunny container with a sandy floor and stones under which it can withdraw at twilight. One can feed it with small mealworms and flies. The skink can become quite tame and will come out to take food handed to it."

SKIP DISTANCE. As the frequency of a radio wave is increased, the minimum angle of incidence at which the wave will be reflected from the ionosphere rather than pass on through becomes greater. This means that the higher the frequency the farther from the transmitter the reflected sky wave strikes the earth. This distance between the transmitter and the point closest to it at which the sky wave can be received is the skip distance. The ground wave is attenuated more rapidly the higher the frequency so that at high frequencies there may be a region in which the ground wave has become too weak for use and in which the sky wave cannot be received because of its skip. Above about 4 MHz this effect becomes very noticeable, the dead region for higher frequencies running to a distance of a few hundred miles from the transmitter.

SKIPJACK TUNA. See **Tunas**.

SKIPPER *(Insecta, Lepidoptera)*. An insect much like the butterflies but in many ways intermediate between the butterflies and moths. Most species are distinguished by their knobbed and hooked antennae. The few that lack the hook are less easily distinguished from the butterflies except by the veins of the wings or by other details of structure. Most of the skippers of the temperate zones are of moderate size and modest colors but many tropical species are brilliant. They constitute the superfamily *Hesperioidea*.

The name skipper refers to the vigorous and often erratic flight of these insects. Their small wings and powerful muscles accompany rapid flight. Many species perch readily and make short darting flights from place to place.

SKUNK. See **Mustelines**.

SKUTTERUDITE. This mineral includes an isomorphous series with *smaltite-chloanthite*, essentially cobalt/nickel arsenides, (Co, Ni) As_{2-3}, crystallizing in the isometric system. The usual habit is cubic, octahedral, or cubo-octahedral. The mineral also occurs in massive and granular forms. Skutterudite has a metallic luster; hardness of 5.5 to 6.0, a specific gravity of 6.5. The mineral is opaque with tin-white to silver-gray color. The nickel-rich material alters surficially to annabergite (green color); the cobalt-rich material to erythyrite (rose color). The streak is black. The mineral is an essential ore of cobalt and nickel.

Skutterudite is found in moderate-temperature veins, commonly associated with other cobalt/nickel minerals, e.g., cobaltite and nickeline. The mineral was named for its occurrence at Skutterud, Norway. Important ore sources are Norway, Bohemia, Saxony, Spain, France, and New South Wales, Australia. Notable occurrences are in Ontario, Canada, mainly Sudbury, South Lorrain, and Gowganda.

SKY COVER. In surface weather observations, *sky cover* is a term used to denote one or more of the following: (a) the amount of sky covered but not necessarily concealed by clouds or by obscuring phenomena, i.e., any atmospheric phenomenon that obscures a portion of the sky from the point of observation; (b) the amount of sky concealed by obscuring phenomena that reach the ground; or (c) the amount of sky covered or concealed by a combination of (a) and (b).

"Opaque" sky cover is the amount of sky cover that completely hides everything above it; *transparent sky cover* is that portion of sky cover through which higher clouds, blue sky, etc., may be observed; and *total sky cover* is the two taken together. Sky cover, for any level aloft, is described as "thin" if the ratio of transparent to total sky cover at and below that level is one-half or more.

Sky cover is reported in *eighths* under international observing and reporting practice. The "0" indicates $\frac{0}{8}$, or clear; and "8" indicates $\frac{8}{8}$, or total cover.

Sky cover is also reported in *tenths*, so that 0.0 indicates a clear sky; 1.0 ($\frac{10}{10}$) indicates a completely covered sky. According to the *summation principle* used in weather observing practice, the sky cover at any level is equal to the summation of the sky cover of the lowest layer plus the additional sky cover provided at all successively higher layers up to and including the layer in question. Thus, no layer can be assigned a sky cover that is less than a lower layer, and no sky cover can be greater than 1.0. If, at any level, the ratio of transparent sky cover to total sky cover is one-half or more (excluding transparent portions of surface-based obscuring phenomena), the layer at that level is classified as thin.

The term *ceiling*, in aviation weather observing practice, refers to the ascribed height of the lowest layer of clouds or obscuring phenomena when that layer is reported as "broken," "overcast," or "obscuration," and not classified "thin" or "partial." When none of these conditions is satisfied, the ceiling is termed "unlimited." Whenever the height of a cirriform cloud layer is unknown, a slant "/" is reported in lieu of a height value; at all other items, the ceiling is expressed in feet above the surface.

The following classifications of sky cover are used in aviation weather observations:

a. Clear: sky cover less than 0.1 (no ceiling).
b. Scattered: sky cover 0.1 to 0.5 (clouds or obscuring phenomena aloft only; no ceiling).
c. Broken: sky cover 0.6 to 0.9 (minimum requirement for a ceiling; must be some clouds or obscuring phenomena aloft).
d. Overcast: sky cover 1.0 (must be some clouds or obscuring phenomena aloft).
e. Partial obscuration: sky cover 0.1 to 0.9 (surface-based obscuring phenomena only).
f. Obscuration: total sky cover (surface-based obscuring phenomena only).

See also **Clouds and Cloud Formation**; and **Weather Technology**.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

SKYHOOK BALLOON. (Originally a code name for a U.S. Navy Project.) A large free balloon having a plastic envelope, used especially for constant-level meteorological observations at very high altitudes.

SKYLARK. See **Lark**.

SLACK. 1. Descriptive of a soft paraffin was resulting from the incomplete pressing of the settlings from the petroleum distillate. Though it has some applications in this form, it is actually an intermediate product between the liquid distillate and the scale wax made by expressing more of the oil.

2. Specifically, to react calcium oxide (lime) with water to form calcium hydroxide (slaked or hydrated lime), the reaction is $CaO + H_2O \rightarrow Ca(OH)_2 + \text{heat}$. The alternate spelling "slake" has the same meaning.

SLAG. Slag is a fused product occurring in connection with metallurgical and combustion processes. It is composed of the oxidized impurities in a metal, and of a fluxing substance, and of ash. In the steel industry, slag is the neutralized product of anhydrous compounds entering into the process. Slag is of great importance to the operator of a steel furnace or a cupola, in that, through the slag, impurities are separated and removed from the metal. By floating as a molten covering on the pool of metal, slag protects it from oxidation and serves to keep it clean. By controlling the character of slag, and continuous observation, the metallurgist insures that the metal is of the quality desired.

Molten ash is one of the products of combustion of coal in certain high-capacity boiler furnaces. It is also called slag. In some plants, the ash is removed from the furnace in this fluid form. Such furnaces are known as slag tap furnaces. Slag has some commercial value as ballast, coarse aggregate for concrete, road metal, etc.

SLATE. A fine-grained homogeneous sedimentary rock composed of clay or volcanic ash which has been metamorphosed (foliated) so as to develop a high degree of fissility or slaty cleavage which is usually at a high angle to the planes of stratification. This high degree of fissility makes the better grades of slates an extremely useful roofing material which, however, has been somewhat replaced in recent years by synthetic and manufactured substitutes. Fine slate can also be used as a whetstone to hone knives. Because of its thermal stability and chemical inertness, slate has been used for laboratory bench tops and for billiard table tops. In 18th and 19th century schools, slate was extensively used for blackboards and individual writing slates for which slate pencils were used.

Slate-producing regions include Cornwall (famously the town of Delabole) and Wales in the United Kingdom, Portugal, the east coast of Newfoundland, and the Slate Valley of Vermont and New York.

Slate is also found in the Arctic and was used by the Inuit to make the blades for ulus.

SLAVE ANTENNA. A directional antenna that is positioned in azimuth and elevation by a servo system. The information controlling the servosystem is supplied by a tracking or positioning system.

SLEEP. Recurrent physiological loss of consciousness at regular intervals, predominantly in humans once in 24 hours and lasting for a more or less constant time of an average of about 8 hours for adults. The newborn infant sleeps 18 to 20 hours a day. The periods of sleep last from 2 to 3 hours, and usually are interrupted by hunger. As the baby's stomach grows and more food is consumed, the periods of hunger are farther apart and the periods of sleep are longer. When the child is 6 months old, it sleeps less — 16 to 18 hours a day. At the age of about one year, the child sleeps about 12 hours at night, with usually a morning and an afternoon nap. Although it may be more difficult for older people to get the necessary sleep, there is little if any truth that older people do not require as much sleep as younger persons. Some of the problems of the aged can be derived because of a lack of sustained sleep. The amount of sleep for any person varies with each individual. The prime requisite is that the individual should sleep long enough to awaken rested and refreshed.

The human body cannot work around the clock. It must have a regular opportunity to catch up on its repair activities and to dispose of wastes that have accumulated during the day faster than they can be discarded. During sleep, the entire body slows down. The liver stores starches needed for the next day. The kidneys clean the blood. The rate of metabolism is at its lowest, being just sufficient to keep the vital parts of the body in operation. The blood pressure drops; the pulse rate is slower; and breathing is irregular and slowed down. The body is less sensitive to stimulation by pain, light, or sound. Even the temperature may drop by as much as a degree. Since the brain does not have muscles, it does not tire in the same way the body does. But there is evidence that the brain requires sleep for other reasons, particularly as sleep is related to memory.

The autonomic nervous system and the involuntary muscles, such as those of the heart and the respiratory mechanism, continue to work in sleep, at a slightly reduced rate, so that the whole body does not share equally in the recuperative process. A number of bodily changes are constantly observed in sleep; these include deep muscular relaxation, loss of some reflex activity, slowing of the heart rate and reduction in volume of many glandular secretions. Deep sleep brings no dreams; those which accompany light sleep are generally the result of external stimuli received at the time, and which, in the absence of the critical faculty of the cerebral cortex, are greatly misinterpreted.

Although research continues, there is no fully satisfactory explanation of the phenomenon of sleep. In particular, the biochemical aspects of sleep have received comparatively little detailed attention. There are many ancillary problems which have been investigated, but the central one — what is accomplished biochemically each day by long hours of sleep — has been attacked only a relatively few times and with no marked success. The symptomatic treatment of insomnia by the use of sleep-inducing drugs is largely on an empirical basis. Knowledge of the fundamental reasons behind a person's vital need to sleep can be obtained only by further biochemical investigation.

The amount of sleep enters into an assessment of the efficiency of the human body. Just how much work is actually obtained for the fuel that has been fed the body? When gasoline is burned in an engine, only about one-eighth of the energy released can be captured to drive the motor, and the remainder is lost in the form of the heat that is given off. Such an engine is said to have an efficiency of 12.5% because it wastes 87.5% of the fuel through heat loss. Some diesel engines have a 32% efficiency. If one were to calculate the work produced by a person performing strenuous work, it would be found that the efficiency of the human body is about 20%. Much of the fuel burned by the body is converted to heat to maintain the body temperature and is lost by the body to the surroundings without doing any real work. Since the human body cannot work regularly the full 24 hours of a day, its efficiency is in reality considerably lower — perhaps about 10 to 12%. Nevertheless, the human body is built to last a great many years as contrasted with most other energy-consuming mechanisms. Some of the basic accomplishments of the human body during a 24-hour period include:

— Kidneys filter over 150 quarts (142 liters) of fluids.
— Heart beats over 100,000 times.
— 1,500 gallons (5678 liters) of blood are pumped through the body.
— Over 10 million red cells are destroyed every second, all of which must be replaced at an equally rapid pace.
— Nerves carry millions of messages.
— Eyelids blink thousands of times to cleanse and lubricate the eyes.

Electroencephalography (EEG) reveals a pattern of large slow waves which appear when a subject falls asleep. As shown in Fig. 1, this pattern can be made to appear experimentally in cats by partially cutting through the midbrain at a certain level. It is thought possible that such an incision cuts off the vital centers in the midbrain from certain postulated driving centers elsewhere in the brain, and that with the stream of awakening impulses removed, sleep occurs. But the means by which this process occurs almost unfailingly every 24 hours in the human being remains obscure. EEG and eye-movement studies, however, are shedding some light on the process.

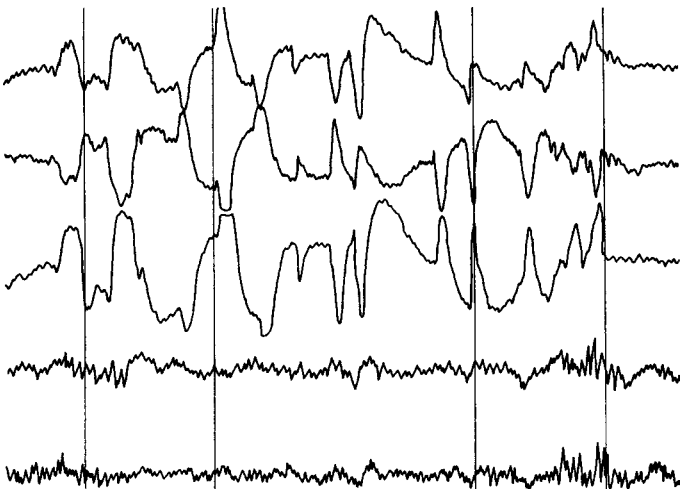

Fig. 1. Alpha. The subject drowses, on the edges of sleep. Top three EEG channels show rolling movements of right eye, left eye, and both. Two bottom channels trace brain's electrical changes. The even pattern of alpha rhythm indicates relaxation.

The alpha waves grow smaller as the subject passes through the gates of the unconscious. The eyes are very slowly rolling. For a moment, the subject may wake up during the early part of this descent, alerted by a sudden spasm that causes the body to jerk. This, like the brain waves, is a sign of neural changes within. It is known as the *myoclonic jerk*, resulting from a tiny burst of activity in the brain, somewhat related to that of an epileptic seizure. The myoclonic jerk, however, is normal in all human sleep. It is gone in a fraction of a second and descent continues. The subject does not note the peculiar transformation as true sleep is approached. The lower chart records of Fig. 1 indicate Stage 1 of sleep. The pattern of the sleeper's brain waves is small and pinched, low, irregular and rapidly changing. Occasionally the regular waves of the alpha rhythm break through. The sleeper may be enjoying a floating sensation or drifting with idle thoughts and dreams. The muscles are relaxing, the heart rate is slowing. The subject could be awakened easily and might insist that actually sleep had not occurred. But, after a few minutes at this port of entry, if not disturbed, the subject descends again to another level, another step removed from the real world.

As the sleeper passes into Stage II, the brain waves change again. Now they trace out quick bursts — a rapid crescendo and decrescendo, resembling a wire spindle, and unmistakable on the EEG chart. The eyes roll slowly from side to side, but if the experimenter gently opens a lid the sleeper will not see. If awakened, which can be accomplished easily with a modest sound, the subject may still think that actual sleep has not occurred. At this point, however, the subject has been soundly asleep for perhaps 10 minutes. Whatever happens now in the subject's imagination will be totally beyond conscious grasp.

Still the sleeper descends to Stage III. This is characterized by large slow waves that occur about one a second. Sometimes they are about five times the amplitude of the waking alpha rhythm. It will take a louder noise to awaken the subject, perhaps some repetition of the person's name. The muscles are very relaxed and the breathing is even. The heart rate has become slower; body temperature declines; blood pressure drops.

Some 20 to 30 minutes after the subject fell asleep, the sleeper reaches Stage IV, the deepest level. This is marked by large, slow brain waves, called delta waves (Fig. 2) that trace a pattern resembling jagged buttes. Stage IV is a relatively dreamless oblivion. The breathing is even, heart rate, blood pressure, and body temperature slowly falling. But, the sleeper does not remain in Stage IV. After 20 minutes or so in this depth, the subject begins to drift back up through the lighter levels toward the surface. By the time the subject has been asleep for about 90 minutes, brain waves of the lightest sleep, even resembling those of waking, will be indicated. Still the sleeper is not easy to awaken, lying limply, the eyes moving jerkily under closed lids as if watching something. This is a special variety of Stage I, known as REM (for rapid eye movement) sleep. See Fig. 3. If awakened during this period, the subject would almost certainly remember dreaming and most often in vivid detail. After perhaps 10 minutes in the REM state, the sleeper will probably turn over in bed and begin shifting down the levels of sleep again to the depths, only to return in another hour or so for a longer REM dream. Each night, the entire cycle may be repeated 4 to 5 times.

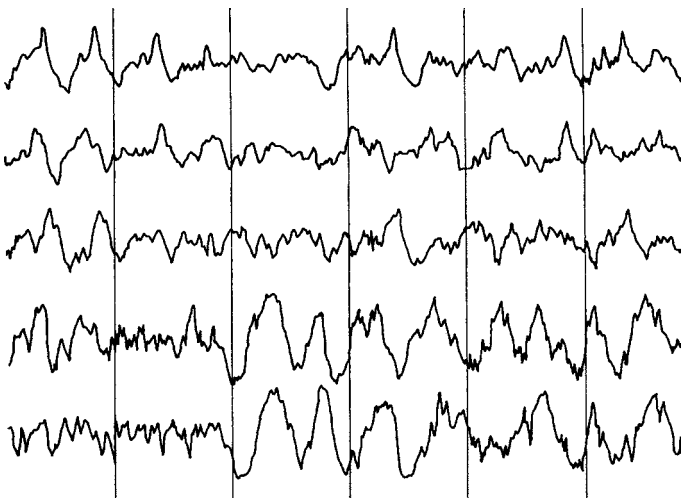

Fig. 2. Delta. Marked by large, slow brain waves (bottom channels). This is the deepest stage of sleep, the first to be made up for after total deprivation.

In an excellent paper on sleep and memory (see references), Fowler, Sullivan, and Ekstrand describe experiments conducted to determine the relationship of sleep with ability to remember. The interference theory of forgetting essentially states that forgetting is due to interference from learning taking place during the retention interval. It then would possibly follow that by putting subjects to sleep, recall could be facilitated. The experiments described in the reference paper demonstrated that memory over an interval with relatively high amounts of rapid eye movement (REM) sleep was inferior to memory over an interval with relatively high amounts of Stage IV sleep. The findings to date suggest that, at least for humans, REM sleep does not facilitate memory consolidation and that Stage IV sleep may be beneficial to memory.

In studying patients complaining of insomnia, Guilleminault, Eldridge, and Dement uncovered a new clinical syndrome, sleep apnea (partial suspension of breathing) sometimes associated with insomnia. These findings came out of combining respiratory studies with sleep research. Quoting briefly from the aforementioned reference. "Sleep apneas have been reported in the cardiopulmonary syndrome of obesity (Pickwickian) and in other syndromes involving hypersomnia, such as narcolepsy. The apneas in hypersomniacs seem to be temporarily associated with sleep. Several

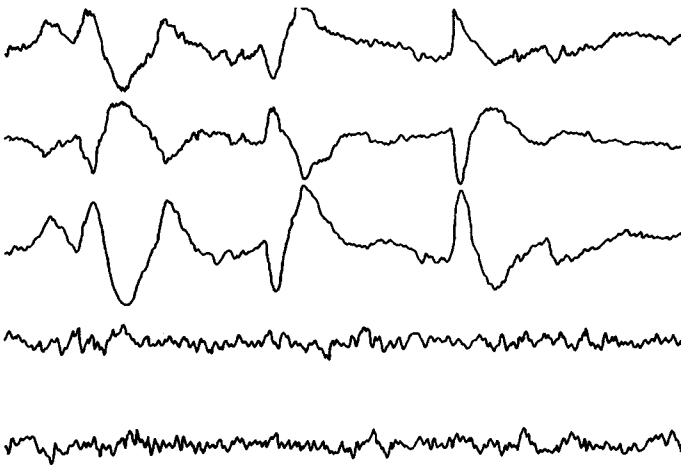

Fig. 3. REM. Rapid eye movements, spaced in the top three channels, indicate dreaming. This is the most dramatic of the night's phases. Although brain waves are low, a psychological storm is raging in breathing, pulse, brain temperature, and hormone circulation.

distinct types of sleep apnea have been defined in these conditions. They include a "central" type, characterized first by cessation of breathing and then, after the apnea, by a simultaneous resumption of diaphragmatic movements and oral airflow; an "obstructive" or "peripheral" type characterized by the interruption of airflow secondary to upper airway obstruction, but with continuance of diaphragmatic and thoracic muscle contraction; and a "mixed" type, characterized by an initial central apnea followed by temporary upper airway obstruction at the subsequent resumption of diaphragmatic movements." It is concluded from these early studies that some unknown percentage of patients complaining of chronic insomnia may have profound disorders of respiratory control mechanisms, with resulting disruptive sleep. The investigators conclude with the suggestion that respiratory function during sleep should be evaluated in patients who complain of chronic insomnia characterized by several conscious arousals throughout the night and early morning, and who also have a short latency before onset of sleep and a history of heavy snoring.

Somnambulism (sleepwalking) and talking while asleep are symptoms most commonly observed in persons with conflicts. Some investigators ascribe the sleepwalking (and other actions performed by a person who is apparently otherwise asleep) to underlying unconscious distress. The phenomenon indicates that certain brain areas, more than others, are inhibited during sleep.

SLEEP DISORDERS. The two principal sleep states, synchronized sleep and rapid-eye-movement (REM) sleep, are now known to be correlated with differences in the activity of certain specific populations of neurons, mainly localized to the cerebral cortex, thalamus and brainstem. At a neuronal level there are many similarities between wakefulness and REM sleep. In this article, the synchronized state of sleep will be referred to as non-rapid-eye-movement (nonREM) sleep, a term that will include both the lighter stages of sleep and the deeper stages that are characterized by the presence of more δ frequency (0.5–4 Hz) activity. The term slow-wave sleep will be used here exclusively to describe the more synchronized, deeper stages, which are also frequently referred to elsewhere as stage 3 and 4 sleep. See also **Sleep**.

Although the origins of sleep medicine can be traced back at least 100 years, and a book describing sleep abnormalities and disorders was written by a French physician, Roger, in 1932, it was not until the 1960s and 1970s that the importance of sleep medicine began to be recognized, first in Europe and then in North America. If a single event was responsible for this growth of interest, it was probably the discovery of sleep apnoea in 1975 at the Stanford University Sleep Medicine Center. Apnoea during sleep is a pause in breathing that lasts for more than 10 s and that usually interrupts sleep. It may be caused by collapse of the upper airways, referred to as obstructive apnoea, or there may be a failure of breathing commands from the brain, described as central apnoea.

The discovery of sleep apnoea was made possible by the incorporation of respiratory (breathing) and cardiac (heart) measures into the sleep recording process, known as polysomnography (literally meaning many (poly) records (graph) of sleep (somnos). A polysomnographic study (Fig. 1) now routinely includes such measurements combined with recording of cerebral electrical activity with the electroencephalogram (EEG), of eye movements with the electrooculogram (EOG) and of muscle tone with the electromyogram (EMG). Recent developments in electronics have enabled small portable polysomnographic recorders to be made. These devices, called ambulatory recorders, can be carried by the patient to enable sleep states and wakefulness to be evaluated continuously outside the sleep laboratory environment.

Fig. 1. A polysomnographic technician prepares to record sleep data from a patient at a sleep clinic. The electroencephalography electrodes are positioned at standard locations over the scalp. Digital polysomnographic systems, like the one from Grass Instruments being used here, allow data to be recorded directly to the computer, so avoiding the use of paper records. The reader interested in summary descriptions of the many sleep disorders now recognized should refer to The International Classification of Sleep Disorders (ICSD), http://www.absm.org/PDF/ICSD.pdf, first published by the American Sleep Disorders Association (ASDA) in 1979. Sleep medicine includes study and treatment not only of primary disorders related to pathology of the mechanisms of sleep and arousal, but also the secondary disorders caused by other medical conditions affecting sleep. For example, breathing abnormalities can disturb sleep, and sleep apnoea remains by far the most important presenting complaint at sleep disorder centers. Other important examples of secondary sleep disorders are the insomnias associated with mood or generalized anxiety disorders, or caused as a side effect of medication. Most importantly, sleep medicine clinics are now located in most towns in the USA and anyone suspecting the presence of a primary or secondary sleep disorder should consult a physician for referral to a nearby sleep clinic.

Sleep Disorders

The current classification of sleep disorders as recognized by the American Academy of Sleep Medicine (AASM, previously ASDA) has three major categories: dyssomnias, parasomnias, and medical/psychiatric sleep disorders. The first category, dyssomnias, includes disorders that cause either a difficulty in getting to sleep or staying asleep, or excessive sleepiness during the daytime. When we think of a sleep problem, we usually think of dyssomnias first because these are the disorders associated with disturbed sleep at night or impaired wakefulness during the day. The second category, parasomnias, has been defined to include all those disorders that are manifested as undesirable intrusions of behavior, or abnormal autonomic nervous system function, occurring primarily during sleep. The reader will not therefore immediately recognize many parasomnias as sleep disorders. It is notable that when the ICSD classification was last revised in 1990, parasomnias were not considered abnormalities of the mechanisms responsible for the states of sleep and wakefulness *per se*. Our understanding of brain anatomy and physiology, however, has improved in the past decade. Thus, although it is true that parasomnias do not seem to be related to executive control of vigilance states, many of the behaviors listed under parasomnias can now be considered as being caused by dysfunctional brain mechanisms effective during sleep. For example, abnormal transitions between vigilance states are responsible for a group of sleep disorders, known collectively as arousal disorders, which are reviewed in detail in this article. Another important example is the presence of muscle tone during REM sleep, which is manifested as REM sleep behavior disorder, in which a patient will "act out" their dreams because of this muscle activity during REM sleep. Conversely, it should be noted that the ICSD classification of dyssomnias currently includes such sleep disorders as sleep apnoea syndrome, which causes repeated awakening during the night because of a breathing disorder. This is therefore classified here as a medical condition that affects sleep, or as a secondary sleep disorder. And finally, our use of the term secondary sleep disorders will also include the third category of sleep disorders recognized by AASM, namely medical and psychiatric sleep disorders, as caused, for example, by a neurological deficit or generalized anxiety disorder.

The tables provide a summary of the dyssomnias (Table 1) and parasomnias (Table 2) as currently categorized by the ICSD, to provide an indication of the scope of sleep medicine. The interested reader should refer to the ICSD for a description of each disorder and relevant references in the scientific and medical literature.

TABLE 1. CLASSIFICATION OF THE DYSSOMNIAS ACCORDING TO THE INTERNATIONAL CLASSIFICATION OF SLEEP DISORDERS (1990)[a]

6. Non-24-h sleep–wake disorder
A. Intrinsic sleep disorders
1. Psychophysiological insomnia
2. Sleep state misperception
3. Idiopathic insomnia
4. Narcolepsy
5. Recurrent hypersomnia
6. Idiopathic hypersomnia
7. Posttraumatic hypersomnia
8. Obstructive sleep apnoea syndrome
9. Central sleep apnoea syndrome
10. Central alveolar hypoventilation syndrome
11. Periodic limb movement disorder
12. Restless legs syndrome
B. Extrinsic sleep disorders
1. Inadequate sleep hygiene
2. Environmental sleep disorder
3. Altitude insomnia
4. Adjustment sleep disorder
5. Insufficient sleep syndrome
6. Limit-setting sleep disorder
7. Sleep-onset association disorder
8. Food allergy insomnia
9. Nocturnal eating (drinking) syndrome
10. Hypnotic-dependent sleep disorder
11. Stimulant-dependent sleep disorder
12. Alcohol-dependent sleep disorder
13. Toxin-induced sleep disorder
C. Circadian rhythm sleep disorders
1. Time zone change (jet lag) syndrome
2. Shiftwork sleep disorder
3. Irregular sleep–wake pattern
4. Delayed sleep phase syndrome
5. Advanced sleep phase syndrome

Genetics of Sleep Disorder. An understanding of the possible mechanisms involved in sleep induction and maintenance may lead to the comprehension, treatment and eventual prevention of some sleep disorders. Since this review is a brief introductory summary of sleep disorders, only a few primary disorders related directly to dysfunctional brain mechanisms of sleep are considered, and the scope is limited further by including only those sleep disorders for which the evidence of genetic linkage is unequivocal. These selected examples, narcolepsy and the behavioral disturbances known collectively as arousal disorders, are also those for which an understanding based on knowledge of central nervous system physiology may lead to new treatments in the foreseeable future.

Narcolepsy. The Discovery of Narcolepsy and its Characterization. One of the first descriptions of narcolepsy was made in 1877 by Westphal, a German physician, based on his observation of a patient presenting with sudden sleep attacks associated with symptoms of motor incapacity and aphasia. He considered it a form of epilepsy. Westphal also noted the genetic character of the disorder by observing that the mother of his patient had been affected by the same symptoms as her son. Three years later, the French physician Gélineau described the disorder for the first time as a distinct clinical entity rather than as a symptom of another condition, and proposed the term narcolepsy, which means "sleep seizure." Gélineau's description in his 1880 paper is of a patient who, from the age of 36 years, began to fall asleep suddenly in the middle of the day and presented with sudden falls or "astasia" (cataplexy in current terminology), which occurred whenever he became emotional.

Narcolepsy is a primary sleep disorder characterized by two principal symptoms, excessive daytime sleepiness and cataplexy, and three supplementary symptoms, hypnagogic or hypnopompic hallucinations, sleep paralysis, and nocturnal sleep constantly disturbed by awakenings. The significance and meaning of each of these characteristics are reviewed:

- Excessive daytime sleepiness is an irresistible need for sleep during the day, associated with a chronically low level of alertness and lapses of memory. Sudden sleep attacks, lasting from several minutes to more than an hour, might occur while the narcoleptic patient is actively engaged in another task, although typically the patient wakes up refreshed and remains alert for some time after such attacks.
- Cataplexy is an abrupt and reversible decrease or loss in muscle tone without alteration in the level of consciousness. This is a defining symptom of narcolepsy.
- About 25–30% of narcoleptic patients report hypnagogic or hypnopompic hallucinations, which can be auditory, visual or occasionally somataesthetic. These perceptual experiences occur at sleep onset (hypnagogic) or at the moment of awakening (hypnopompic), and are vivid hallucinations, appearing as if surroundings are being integrated into a dream. Narcoleptic patients report that these hallucinations usually appear when they try to avoid sleep and are often accompanied by feelings of fear or anxiety. It should be noted that normal people also report these hallucinations after being deprived of sleep.
- Sleep paralysis is a terrifying experience for the narcoleptic patient at sleep onset or on awakening from sleep or a nap. Patients find that a total loss of muscle tone, which can last for more than a minute, prevents movement, speech or even being able to breathe normally.
- Nocturnal sleep fragmentation and occasional complaints of insomnia are paradoxical symptoms of narcolepsy. Although the narcoleptic patient sleeps easily, their sleep is fragmented and continuously interrupted by awakenings during the night.

TABLE 2. CLASSIFICATION OF THE PARASOMNIAS ACCORDING TO THE INTERNATIONAL CLASSIFICATION OF SLEEP DISORDERS (1990)[a]

10. Benign neonatal sleep myoclonus
A. Arousal disorders
1. Confusional arousals
2. Sleepwalking
3. Sleep terrors
B. Sleep–wake transition disorders
1. Rhythmic movement disorder
2. Sleep starts
3. Sleep talking
4. Nocturnal leg cramps
C. Parasomnias usually associated with REM sleep
1. Nightmares
2. Sleep paralysis
3. Impaired sleep-related penile erections
4. Sleep-related painful erections
5. REM sleep-related sinus arrest
6. REM sleep behavior disorder
D. Other parasomnias
1. Sleep bruxism
2. Sleep enuresis
3. Sleep-related abnormal swallowing syndrome
4. Nocturnal paroxysmal dystonia
5. Sudden unexplained nocturnal death syndrome
6. Primary snoring
7. Infant sleep apnoea
8. Congenital central hypoventilation syndrome
9. Sudden infant death syndrome

Prevalence and Genetic Basis. Narcolepsy usually begins before the age of 25 years, but age of onset is very variable and it can occur at any time between the ages of 5 and 55 years. Males and females are equally affected. Prevalence of the disorder is estimated to be between 0.02% and 0.18%, but the risk to first-degree relatives is higher, probably about 1–2%, indicating genetic transmissibility, although concordance rates in monozygotic twins are only about 30%. Furthermore, in about half the patients the onset of narcolepsy is associated with an exogenous factor, such as head injury or severe stress, indicating that the disorder probably requires both genetic predisposition and a triggering environmental event. In fact, since most cases of narcolepsy occur sporadically, the disorder had always been considered multigenetic and environmentally influenced.

A genetic linkage for the disorder was found in early studies which showed that narcolepsy was associated with two major histocompatibility complex human leucocyte antigen (HLA) class II antigens, called DR2 and DQw1. Since these initial observations, the nomenclature for HLA typing has been extended and refined, and data from diverse populations included, but this initial finding still remains true: narcolepsy is frequently associated with particular histocompatibility genes, now defined as DQ6 (DQB1*0602) and DR15 (DRB1*1501) subtypes as the most likely haplotypes. Although exceptions to these associations are rare, the existence of such exceptions, combined with the fact that exactly the same alleles are found in the general population, means that factors other than HLA alleles must be involved in narcolepsy. One such factor was discovered recently and is described below. Despite these limitations, HLA typing remains of practical use in the evaluation of patients with excessive daytime sleepiness if the presence of these histocompatibility antigens cannot be verified, as narcolepsy can then usually be eliminated as a diagnosis.

Interestingly, at present there appears to be no known direct link between these genetic markings of narcolepsy and the recent discovery, in narcoleptic dogs, that this sleep disorder may be related to a dysfunction of genes controlling a specific brain neuropeptide. This neuropeptide, named orexin, was linked in two unrelated publications to narcolepsy [Siegel, 1999]. In one of these studies, narcoleptic dogs were found to have a dysfunctional orexin receptor. In the second study, a strain of mice was created with the gene for the production of orexin missing, and these mice demonstrated many of the characteristics of narcolepsy. These were unexpected findings that will be the focus of intense research as the mechanisms involved in the action of orexin are elucidated. At present it is known that orexin is contained in cell bodies that are situated uniquely in the lateral hypothalamus; although these orexin-containing neurons project widely to all levels of the brain, there is a particularly significant orexin innervation of some major nuclei that have been implicated in sleep regulation. These include the anterior hypothalamic sleep-promoting cell group, as well as basal forebrain cholinergic neurons and other components of the diffuse generalized activating system situated in the brainstem. The latter include the noradrenergic neurons of the locus ceruleus, serotonergic neurons of the dorsal raphe and cholinergic neurons located in two groupings at the midbrain–pontine junction. It will be the subject of future research to see how our view of narcolepsy is eventually changed by this discovery.

Monitoring and Treatment. To evaluate the severity of narcolepsy, continuous ambulatory or laboratory polysomnography provides a measure of total sleep time together with information about the timing of sleep attacks, their duration and the sleep stage in which they occur. An analysis of nocturnal sleep of the narcoleptic patient typically reveals that sleep begins quickly after lights-off, within about 10 min, but that sleep is then interrupted by multiple awakenings throughout the night. The cardinal characteristic of narcolepsy, however, is sleep-onset REM during the day, or at the beginning of the night. Sleep-onset REM is defined as sleep with a REM episode occurring within the first 15 min of the patient being placed in quiet and darkened surroundings that make it easy to sleep.

Narcolepsy is currently treated with medications directed at each of the symptoms. Thus daytime sleepiness and sleep attacks have been treated with amphetamine-type drugs and their derivatives. These include methylphenidate and amphetamine, although treatment with these compounds is complicated by the risk of abuse and development of tolerance. They also induce irritability, anxiety disorders, convulsions and dependence as side effects. A recently introduced alternative, modafinil, is a central nervous system stimulant with a high efficacy against sleep attacks. In chronic use it appears to be well tolerated and is associated with little dependency.

Cataplexy is treated with tricyclic antidepressants, including clomipramine and imipramine. These compounds are effective, but side effects related to their anticholinergic activity, such as dryness of the mouth, tachycardia, constipation, impotence and reduced libido, are not unusual. Furthermore, if treatment is withdrawn for any reason after several months, reappearance of cataplexy is likely. In such a situation, selective serotonin-uptake inhibitors, including fluoxetine and fluvoxamine, are an alternative treatment. Sleep paralysis and hallucinations are usually ameliorated by treatment of excessive daytime somnolence and cataplexy. Generally available hypnotics are effective against insomnia and improve nocturnal sleep fragmented by multiple awakenings.

Perspectives. Narcolepsy is an exceptionally disabling, chronic disorder. Although symptoms decrease in intensity with age, the disorder shows little tendency to remit spontaneously. Patients can fail scholastically, be involved in accidents, perform poorly at work and be socially isolated. Overlapping cataplectic attacks, which confine the patient to bed for periods as long as several weeks, can be observed after withdrawal from treatment.

From this review of the disorder, it is apparent that narcolepsy is an intrusion into wakefulness of the signs of REM sleep, particularly muscular atonia, combined with excessive daytime sleepiness. On the basis of current knowledge about the anatomical distribution of orexin-containing neurons, it is likely that orexin is implicated in coordinating the activation or inhibition of groups of neurons that have brain-arousing properties. One of the important differences between the states of REM sleep and wakefulness at a neuronal level is the cessation of firing of the monoaminergic cells (noradrenaline (norepinephrine), serotonin and histamine) during REM sleep. One possibility, therefore, is that orexin plays a role in the progressive and orderly shutdown of monoaminergic cell firing as vigilance normally changes from non REM sleep to REM sleep. Another avenue for future research will be to consider the influence that orexin neuronal projections may have on the sleep-promoting inhibitory neurons of the anterior hypothalamus that project to the activating histaminergic area of

the posterior hypothalamus. A dysfunction at this level may explain the excessive sleepiness of the narcoleptic patient.

In summary, the genetic character of narcolepsy may well be linked to abnormal orexin functionality, possibly through specific brain receptors for orexin. And while research is now needed to understand how orexin dysfunction can lead to narcolepsy, the currently available anatomical evidence points to a role for orexin in the control of vigilance state transition, particularly the transition from wakefulness into REM sleep but also from wakefulness into non REM sleep, and this function is presumably abnormal or lacking in the narcoleptic.

Arousal Disorders: Sleepwalking, Confusional Arousals and Night Terrors Similarities among the Arousal Disorders. This cluster of sleep disorders is also genetically linked and, as will be noted, can also be considered as a group of disorders of vigilance state transition, but in this case it is the transition between non REM and REM sleep that is affected.

Sleepwalking, confusional arousals and night terrors form a symptomatic cluster because they show several similarities, including age of onset and typical spontaneous resolution during adolescence. Furthermore, in adults, they also commonly occur together in the same individual. They happen at about the same time of the night during deep slow-wave sleep and their episodes are similar in length. They are considered disorders of arousal in that they all reflect impaired mechanisms of arousal from sleep. Importantly, there is evidence that sleepwalking, confusional arousals and night terrors also show similar familial patterns of incidence, typically in families of deep sleepers, and this implies genetic linkage. For example, one case in the literature describes a family of sleepwalkers awakening to find themselves all sitting around the dining table without any memory of how they got there. The arousal disorders were first described clinically as a related cluster by a Canadian physician, Broughton [1968], although this early description was incomplete in the case of confusional arousals. Here, they are considered as different symptomatic manifestations of the same, or closely related, underlying disorder(s).

Sleepwalking. Sleepwalking or somnambulism is typified by automatic, involuntary ambulation that occurs during non REM sleep. Onset is typically between 3 and 6 years of age and spontaneous remission usually occurs with puberty. Its prevalence has been estimated at about 15% in children up to the age of 15 years, and in adults the prevalence is about 2.5%. In all age groups, the incidence in males is slightly higher than that in females. In addition to ontogenetic changes which clearly play a role in the appearance of sleepwalking, several studies have demonstrated the importance of innate factors, as the incidence increases from about 20% when neither parent is affected to about 60% when both parents walked in their sleep and/or had night terrors at some time during their lives. Concordance is also higher in monozygotic twins. The somnambulist shows no evidence of epilepsy or any form of seizure activity. Sleepwalking occurs typically during slow-wave sleep, about 1–3 h after sleep onset and at a time when the first period of REM sleep would be expected. During an episode of sleepwalking, the EEG is often dominated by slow, 1–4-Hz, δ waves, although their amplitude is less than that during the preceding slow-wave sleep. At the onset of an episode, the child will get up in the middle of sleep and begin undirected walking while staring vacantly ahead with open eyes, usually for between 3 and 5 min. More than one incident in the same night is rare, and the child will not remember the episode by the following day. Fever or stressful life events can also trigger sleepwalking. In adults, automatic aggressive behavior might occur during an episode of somnambulism and it is this fact, as well as the way in which sleepwalkers can injure themselves, that makes this a significant sleep disorder requiring treatment.

Confusional Arousals. Confusional arousals occur while awakening from deep slow-wave sleep, usually during the first part of the night. This sleep disorder occurs particularly in the younger child, aged less than 5 years, and is characterized by confusion, disorientation and amnesia of varying degree. Considered a mild form of night terror, confusional arousal may also be accompanied by moaning, muttering and thrashing movements. An episode can last as long as 40 min, although 5–15 min is more typical. The manifestation of confusional arousal suggests that sleep is being maintained in the presence of brain activation. Isolated instances are probably due to a child being overtired, or when the drive for sleep is excessive because of fever or illness. Confusional arousals are infrequent in older children or adolescents, in whom they may also be caused by psychological factors. Recurrent confusional arousals and night terrors, especially in the adult, show a significant familial pattern, implying genetic linkage.

Night Terrors. Night terrors, also called *pavor nocturnus*, first appear at about 4 years of age, and usually remit spontaneously by puberty, although they can occur in adults. The prevalence of night terrors has been estimated as about 6% during preschool years, but less than 1% in adults. A typical episode, lasting for between 1 and 15 min, begins between 1 and 3 h after sleep onset during slow-wave sleep at about the time that the first REM period would be expected. Night terrors only rarely occur more than once per night. The child typically sits up, cries with terror, screams and presents with intense anxiety accompanied by autonomic arousal, including polypnoea, tachycardia, sweating, mydriasis and muscular hypertonia. By the following day, the child will have completely forgotten the episode.

Treatment. When the intensity and/or frequency of an arousal disorder necessitate treatment in the adult, medications that suppress slow-wave sleep such as benzodiazepines, including diazepam, or tricyclic antidepressants are usually effective when administered in the evening before bedtime. Children showing arousal disorders are medicated only if behaviors are so severe that they are likely to cause injury.

Perspectives. Arousal disorders can be summarized as a dysfunction of the normal transition from slow-wave sleep to REM sleep. In two of the disorders (confusional arousal and night terror), disturbed awakening occurs at this time and in the third (sleepwalking), the subject remains in non REM sleep while manifesting a dissociated state of behavioral arousal. These disorders occur mostly in childhood, when they probably reflect immaturity of vigilance state control mechanisms. But the incidence in adults, especially when viewed in the light of a genetic linkage, points to the possibility of a disorder in the mechanism of brain activation that normally occurs at the onset of REM sleep.

SLEW. To change the position of an antenna or range gear assembly by injecting a synthetic error signal into the positioning servo amplifier.

SLICE METHOD. A method of evaluating the static stability over a limited area at any reference level in the atmosphere.

Unlike the parcel method, the slice method takes into account continuity of mass by considering both upward and downward motion but not mixing. The temperature excess of the rising air will be 1) negative (stable conditions), 2) zero (neutral or indifferent conditions), or 3) positive (unstable conditions) according to whether the expression

$$\frac{A_d}{A}(\gamma_d - \gamma') - (\gamma_d - \gamma)$$

is 1) less than zero, 2) equal to zero, or 3) greater than zero, respectively, where A is the total area of the region under consideration, A_d the area covered by the descending current, γ the environmental lapse rate of temperature, and γ' and γ_d the adiabatic process lapse rates followed, respectively, by the ascending and descending currents. Since the ratio A_d/A can be evaluated only after convection has set in, the slice method is used mainly as a diagnostic, rather than a prognostic, tool.

See also **Convection**; and **Parcel Method**.

AMS

SLICKHEAD FISHES *(Osteichthyes).* Of the order *Isospondyli*, family *Alepocephalidae*, these are very deep sea fishes, rarely seen in collections. They have slender bodies and are of a dark color and considered quite a small fish. The *Dolichopteryx* is equipped with "telescopic eyes."

SLIDER *(Reptilia, Chelonia).* Turtles related to the painted turtles and land tortoises. The several species are brownish or greenish, marked with yellow and in some cases also with red. They constitute the genus *Pseudemys*. Most of the species are confined to the southern states but one, known as the red-bellied terrapin, is found near coastal rivers from Florida to Cape Cod and another lives in the Mississippi valley as far north as Iowa. Both of these species are edible. Also called cooters.

SLIDE RULE. A hand-held, manually operated analog computer for multiplying, dividing, extracting roots, and obtaining powers of numbers mechanically by logarithmic means. In construction, the simple slide rule consists of two adjacent logarithmic scales, which may be so set that a reading on one is added to a reading on another. This represents the addition of logarithms when multiplying numbers. The slide rule for general use is found in several different forms, and there are many special slide rules such as stadia rules, electrical rules, hydraulic computing rules, etc.

Figure 1 illustrates the principle of multiplication by the slide rule. Two logarithmic scales, A and B, are arranged on a slide rule so that they may be mechanically added. In the illustration given, the process of multiplying three by two is shown. The end of the B scale is aligned over the 3 on the A scale, so that to 3 on the A scale may be added 2 on the B scale. Now if these scales were uniformly divided, the result, of course, would be five units on the A scale, but since they are logarithmically divided, the result on the A scale is the product rather than the sum. Thus, under the 2 on the B scale, one reads the product of $3 \times 2 = 6$ on the A scale. A glass runner is provided so that the alignment of the numbers of the two scales may be facilitated. By halving the divisions, two complete scales could be placed on the rule. Using a full scale, such as A of the figure, and a double scale, one can extract square roots. A triple scale can be used for cube roots. Other scales contained on the ordinary slide rule are a uniform division scale for logarithms, and scales for reading the value of two trigonometric functions of an angle, the sine and tangent.

With the advent of fast, low-cost, solid-state electronic pocket and portable calculators, the conventional engineer's slide rule has largely been replaced. But the slide rule is still in use, because the availability of plastic materials and manufacturing techniques has greatly lowered the cost. Customized slide rules directed to the solution of specific problems remain quite popular, particularly among manufacturers of equipment who frequently provide slide rules to users of their products as an aid to application, maintenance, and procurement decisions. The principal features of a simple slide rule are shown in Fig. 1.

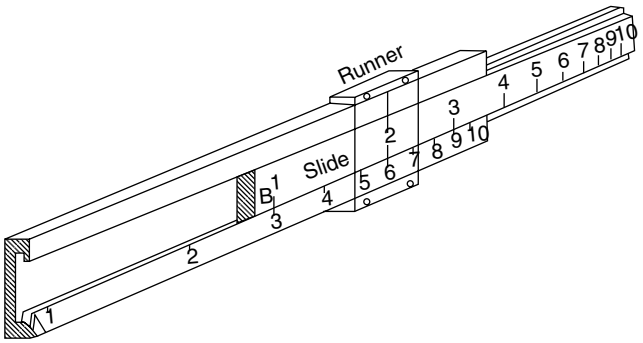

Fig. 1. Simple slide rule.

SLIP RINGS. These are conducting rings attached to a rotating part of an electrical machine to make connection through brushes with the stationary part of the circuit. They are used where it is not necessary to commutate the current being conducted.

SLIT. The long narrow opening by which radiation enters or leaves certain diffraction instruments. Slits are often used as line sources of radiation or of particles, and combination of two or more slits are employed as a collimator.

SLIT LAMP. The slit lamp, or biomicroscope, is a tabletop microscope that uses an adjustable beam of light to provide concentrated illumination and magnification of various parts of the eye. The light beam may be adjusted both as to width of the slit of light and the height of the slit, thus the term, *slit lamp*. This microscope magnifies the structure of the eye some 6 to 40 times, and the eye doctor uses it to detect and evaluate any abnormalities in the structures of the eye.

Comprehensive eye examinations comprise an evaluation of the physiologic function and anatomic status of the eye, visual system and its related structures, and always include a slit lamp examination. Before a slit lamp examination, the eyes are sometimes dilated with special eye drops to enlarge the pupil size. This provides the doctor with a larger "window" to examine the inside structures of the eye.

Vision Rx, Inc., Elmsford, NY

SLOPE. In rectangular coordinates, the ratio of the change of the ordinate to the corresponding change of the abscissa of a point moving along a line. If a straight line is determined by the points (x_1, y_1) and (x_2, y_2) its slope $m = (y_2 - y_1)/(x_2 - x_1)$. If the line is not straight its slope is given by

$$\lim_{x_2 \to x_1} m = (\mathrm{d}y/\mathrm{d}x)_{x = x_1}$$

which is the tangent or derivative at the point.

See also **Coordinate System**.

SLOTH-BEAR. See **Bears**.

SLOTHS. See **Edentata**.

SLUDGE. When fresh sewage is admitted to settling tanks a certain amount of the solid matter in suspension will settle out, 50% more or less for sedimentation periods of an hour and a half or so. This collection

of solids is known as fresh sludge. Such sludge will become actively putrescent in a short time and in modern treatment plants must be passed on from the sedimentation tank before this stage is reached. This may be done in two common ways. The fresh sludge may be passed through the slot in an Imhoff tank to the lower story or digestion chamber. Here, decomposition by anaerobic bacteria takes place with considerable liquefaction and reduction in volume. After the decomposition process has run its course (in 6–9 months) the resulting sludge is called "digested" sludge and is relatively inoffensive in character. It may be disposed of by drying on sludge drying beds and spreading on the land. It has little, if any, fertilizing value, being in the nature of humus. The sludge digestion chamber is operated on a periodic schedule of sludge withdrawals.

Alternatively, plain sedimentation basins with mechanical equipment for continuous collection of the fresh sludge may be used. The fresh sludge, so collected, is discharged into separate sludge digestion tanks which operate on the principle of the lower story of the Imhoff tank except that by means of higher and better temperature control the digestion cycle is much more rapid and efficient than for the Imhoff tank.

SLUG *(Mollusca, Gasteropoda)*. Not an insect, but a mollusk, this pest is damaging to certain food crops and is a serious pest in glasshouse operations, notably on certain ornamental plants, such as coleus, geranium, marigold, and snapdragon. The slug is also a severe pest on lawns, particularly on dichondra. The pest eats very large holes, often entire leaves, always at night. The creatures are fleshy, worm-like, gray-to-brown, slimy. They are without body segmentation and are apodal. Slugs range up to 3 inches (7.5 centimeters) in length. See Fig. 1. During the day, the pests hide under leaves, debris, etc., but in a heavy infestation, they emerge at night in the scores. Some of the species include: the *spotted garden slug* (*Limax maximum*, Linne); the *gray garden slug* (*Deroceras reticulatum*, Müller); the *gray field slug* (*D. laeve*, Muller); and the *greenhouse slug* (*Milax gagates*, Linne).

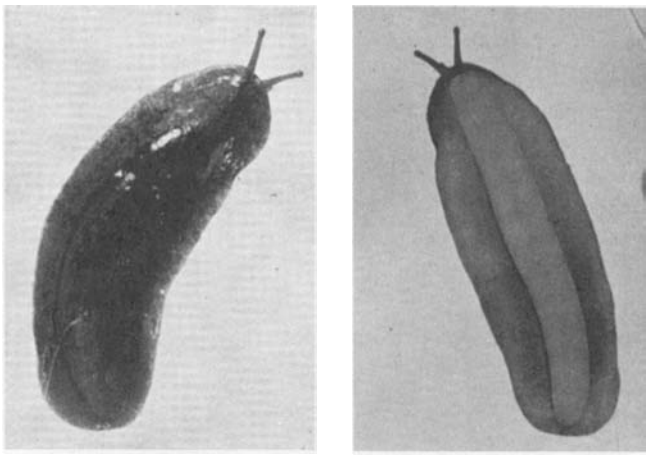

Fig. 1. Slugs. (*A.M. Winchester*.)

The control measure most frequently used is poisoned bait, placed in suspected locales at night. The quantity required varies with the strength of the mixture used. Ingredients frequently used include bran as the base, plus calcium arsenate, metaldehyde, blackstrap molasses, and water. The molasses is used as an attractant.

The *pear slug*, which damages cherry, pear, and plum trees, is not a true slug, but rather the larva of a species of sawfly. See also **Sawfly**.

SLUG TUNING. A means for varying the frequency of a resonant circuit by introducing a slug of material into either the electric or magnetic fields or both.

SLUICE. A channel through which water flows is, in some cases, called a sluice. A sluice may be a pressure conduit, or it may be an open flume. For instance, the word may be applied to an artificial channel to lead water from one point to another, especially a temporary wooden channel. Sluices are often incorporated in dam structures. A sluice through a dam is a conduit cast in the concrete and equipped with controls called sluice gates. The purpose of the sluice is to empty the reservoir if necessary, to control the water level, and to aid in passing floods.

SLURRY EXPLOSIVES. See **Explosive**.

SLUSH. Snow or ice on the ground that has been reduced to a soft watery mixture by rain, warm temperature, and/or chemical treatment.

SMALLEY, RICHARD E. (1943–2005). Smalley was a Professor of Chemistry, Physics and Astronomy at Rice University, in Houston, Texas. He was awarded the Nobel Prize in chemistry along with Robert. F. Curl, Jr. also a professor of chemistry at Rice, and Sir Harold W. Kroto, a professor at the University of Sussex in 1996, the 100th anniversary of Alfred Nobel's death. The trio won for the discovery of the C_{60} compound called buckminsterfullerene ("buckyballs").

Smalley attended Hope College before transferring to the University of Michigan where he received his B.S. in 1965. Between his studies, he worked in industry, where he developed his unique managerial style. He received his Ph.D. from Princeton University in 1973. He completed postdoctoral work at the University of Chicago, with Lennard Wharton and Donald Levy, where he was a pioneer in the development of supersonic beam laser spectroscopy. See also **Buckminsterfullerene (Buckyballs)**.

SMALLPOX. This disease caused by a large, enveloped poxvirus featuring a complex helical nucleocapsid structure containing double-stranded DNA and several enzymes, was once described as the most devastating pestilence in human history. Worldwide eradication culminating in the last reported case in late 1977 (patient in Merka, Somalia recovered) indeed marked a major hallmark in the professions of public health and preventive medicine. In 1967, when the World Health Organization (WHO) instituted a campaign to eradicate smallpox from the last reservoirs on earth, the disease was still endemic in 33 countries and 11 other countries reported cases. The eradication process started many years ago, of course, with mandatory vaccination policies in a number of countries and with particularly tight control over travelers who could carry the disease from one country to the next. The thrust of the last decade by WHO concentrated on mass vaccinations of the populace of countries where the disease still persisted, as in Brazil, Indonesia, Bangladesh, India, Afghanistan, and Africa south of the Sahara. In the last few years of the WHO program, the emphasis also included strict isolation of smallpox patients. At a time when it appeared that the disease had finally been overcome, an outbreak occurred in 1977 among nomads in eastern Africa and in Mogadishu (capital of Somalia) during which time nearly 1400 cases were reported. One of the final steps was a last major mass vaccination program in Somalia.

Smallpox (also called variola), an acute contagious disease characterized by high fever, chills, headache, generalized pain, and vomiting and with an accompanying skin eruption that resulted in severe scarring, has been known since antiquity. Lesions have been seen on the skin of an Egyptian mummy of the twentieth dynasty. The classical scarring which labeled a person for life as a victim of smallpox was often accompanied by development of blindness. The disease originally spread from India and Central Asia to Europe and became especially prevalent at the time of the Crusades in the eleventh century. It was first introduced in America by a Negro slave of Cortex in 1520, producing an epidemic that killed several million people. One century later it appeared in New England. It was first called smallpox in Europe, to differentiate it from grand-pox (syphilis of the skin). The discovery of vaccination by Jenner in 1798 is one of the landmarks in the development of medical science.

Black or hemorrhagic smallpox, a virulent fulminating form of the disease, commonly caused death within two to six days. Fatalities from smallpox often arose from complications, including abscesses, pneumonia, septicemia, nephritis, and ulcers on the cornea of the eye. In recent decades, these complications were treated with chemotherapy. However, no specific

drug to assure the cure of smallpox had been found by the time of its eradication.

SMART MATERIALS. The primary characteristic of a "smart material" is that it has the ability to respond to external stimuli in a *technically useful* and *technically controlled* way. The words "technically useful" and "technically controlled" are emphasized since all materials respond to external stimuli of some sort or other (as a simple example, all materials respond to temperature by changing their volume), however, to be considered a "smart material" the response must be one that is useful in an engineering application. Thus, any discussion of smart materials must include a consideration of the application of these materials. (Animals and plants could be considered as consisting of a large number of smart materials, however, the scope of this article will be restricted to inorganic and organic materials that are used in a more traditional engineering sense.)

The term smart material often also has a historical context, only being applied to relatively new materials. For example, consider the simple bimetallic strip. Bimetallic strips have been around for centuries and consist of two metals joined so that the difference in the coefficient of thermal expansion causes the strip to bend in response to a change in temperature. This can be used, e.g., to open or close a mechanical valve or electrical circuit. The stimuli may either be provided by the natural environment or engineered into a structure that the material is part of. However, bimetallic strips are often not thought of as smart materials because they have been around and used for a long time.

Smart materials are also often characterized by the fact that they transform energy from one mode to another, e.g., from electrical energy to mechanical energy. Smart materials are also often incorporated in so-called *Smart Structures*, which are structures that, as well as being the structural support of a building or vehicle, also have a further function. For example, a load-bearing structure that also measures the load that it is carrying is an example of a smart structure.

Classification Schemes

How a material is considered or classified depends to some extent on the scientific or technical discipline that is considering the material. For example, a material scientist is interested in the internal structure and how this may change under the influence of an external stimulus, whereas an application engineer may be more concerned with the function of the material and what it can be used for.

Classification According to Function. Smart materials can be classified according to the intended primary function, eg, as a sensor, actuator, or energy generator. Piezoelectric material is an example of a class of smart materials that can be used in all three of these functions. When subjected to stress these materials generate an electrical voltage that can be used as a response signal and also to generate power. Alternatively, when subjected to a voltage these materials generate a mechanical stress. The interchangeable nature of stimulus and response is a common, but not universal, characteristic of smart materials. Materials that exhibit this interchangeable nature are often good candidates for smart structures with minimal external support requirements: one smart material both sensing and generating power and also capable of providing a mechanical or other response.

Active Sensing Materials. The primary action of these materials is to transform one form of energy to another form of energy for, in most cases, a further device or material used to then generate a response. Active sensing materials may often be used to generate energy. For example, the voltage developed by electric polarization of a material can be used to accumulate charge, and the solar cell both detects the presence of incident light and generates a significant voltage and current.

Passive Sensing Materials. These materials have a passive response to external stimuli, i.e., do not transform an energy source to another energy. Thus these devices need an external source of power to operate. They are not really "smart", but are included here for completeness since they do appear as sensors in larger smart systems. An example of a passive response is a change in electrical conductivity due to, e.g., a change in pH of a solution.

Actuating Materials. The primary function is to transform one form of energy to another form as a response to some external stimuli and to perform an action.

Classification According to Smartness. Another possible classification is according to the degree of independence of operation that the smart material needs to operate in a smart structure. In this case, materials that require the least external support (e.g., external power or processing capability) being considered smarter. A common example of a totally independent smart material is that used in photochromic sunglasses. In this case, the energy required to drive the response, darkening of the sunglasses is provided directly by the stimulus, the incident light.

Classification According to Material Properties. A further way to look at smart materials is to consider the primary physical–chemical property of the material that is used in smart applications. This is particularly useful in studying and understanding the operation of smart materials.

Crystal Structure Modification. A number of classes of smart materials have crystal structural properties that can be used directly for smart actuating or sensing applications. These include materials that undergo a crystallographic phase change (e.g., shape memory alloys), materials that have an electrical polarization natural to the crystal structure that responds to external stress (e.g., piezoelectric materials) and materials that undergo realignment of internal domains, such as electro- and magnetostrictive materials.

Energy Absorption-Emission. This includes materials that absorb incident energy by an internal excitation process (e.g., promotion of electrons, on absorption of a photon, to a higher energy band). These often have a de-excitation process that involves the emission of energy. Examples include semiconductor devices as light sensors and energy harvesting devices.

Macroscopic Ordering. Includes (generally) mixtures of materials where the large scale ordering of the particles in the mixture induces a change in properties of the mixture. Examples include electro- and magnetorheological fluids, where an applied field induces particles in the fluid to align resulting in a change in viscosity. The liquid crystal display can also be considered in this category.

Chemical Interaction. Includes materials with sensitized surfaces that interact with target chemical or biological species. Examples include conducting polymers with functional groups that bind to chemical species and change the resistance of the polymer, and antigen coatings on microbalance mass detectors. Indicator chemicals that change color with, eg, pH, are another form of chemical sensor.

Overview

Table 1 is a summary of a number of materials that can be used in smart applications, i.e., classified as to function. The table is not an exhaustive

TABLE 1. NONEXHAUSTIVE SUMMARY OF A NUMBER OF TYPES OF SMART MATERIALS WITH THE STIMULUS REQUIRED TO ELICIT THE RESPONSE[a]

Materials Type	Stimulus	Response	Examples
Piezoelectric and ferroelectric	Mechanical electric	Electric mechanical	Lead zirconate titanate poly(vinylidene fluoride)
Pyroelectric	Temperature	Electric	Barium strontium titanate
Electrostrictor	Mechanical electric	Electric Mechanical	Lead magnesium Niobate-lead titanate
Magnetostrictor	Mechanical magnetic	Magnetic Mechanical	Terfenol-D
Electroactive polymer	Mechanical electric chemical species	Electric Mechanical Mechanical	Polyacrylonitrile, Polypyrrole, sol–gel
Liquid-crystal elastomer	Temperature change	Mechanical	
Electroluminescent	Electric field	Light emission	Gallium arsenide (GaAs), poly(alkylfluorines)
Photoluminescent	Incident light	Light emission	Copolymers with poly(*p*-phenylene benzobisthiazole), zinc oxide (ZnO)
Electrochromic	Electric	Color change	Tungsten oxide (WO_3)
Other chromic	Light	Color	Vanadium oxide (VO_2)
Photochromic, Thermochromic, Piezochromic, Solvatochromic, Carsolchromic	Temperature Strain	Change	
Photostrictive	Light	Mechanical	Lead lanthanum Zirconium titanate (PLZT)
Semiconductor	Temperature Incident light Mechanical	Charge resistance Resistance	Doped silicon, Germanium, Semiconducting polymers
Piezoresistive	Mechanical, Temperature	Resistance	Doped semiconductor
Metal oxide Semiconductor	Chemical species (chemisorption)	Resistance	Oxides of Tin (SnO_2), Zinc (ZnO), titanium (TiO_2), tungsten W(O_3), silicon carbide (SiC)
Conducting polymer	Chemical species, Temperature	Resistance/impedance	Polypyrrole, polyaniline
Optical fiber	Strain, temperature, Electric/magnetic fields	Light intensity, phase, frequency, polarization	
Shape memory alloy	Temperature change	Mechanical	Nitinol
Shape memory polymer	Temperature change	Mechanical Mechanical	Thermoplastic poly(urethane)
Electrorheological fluid	Electric field	Viscosity change	Cornstarch in silicone oil
Magnetorheological fluid	Magnetic field	Viscosity change	Magnetic particles suspended in fluid
Nanoparticles, carbon nanotubes	Chemical Light	Color, resistance Reactivity, resistance	Coated gold nanoparticles

[a] A number of these, as indicated, are two-way systems, i.e., the stimulus and response can be interchanged.

list of smart materials, but serves as examples of the more common smart materials.

Many of the materials in Table 1 can be described as "responsive" rather than truly smart, ie, these materials can form one part of a smart system, either the sensor or actuator, but require another responsive material for the actuator or sensor, respectively, to make up a complete smart system. Only a few materials, e.g., the photochromic sunglasses mentioned in the section classification schemes, are both sensor and actuator. Even materials that can be used as an actuator and sensor often cannot be engineered to perform both functions effectively at the same time. Thus, most smart materials are used in combinations to form smart systems. An example of a possible system is an antivibration device that uses a piezoelectric sensor to detect the vibration and a magnetorheological fluid as the damper.

Nanotechnology

The field of nanotechnology has seen a dramatic increase in attention over the last few years. While not a material *per* se, nanotechnology is an enabling technology. Nano-engineered materials have unique properties compared to bulk materials due to their extremely high surface area/volume ratio, high surface energy and the ability for elements to be located together, or compounded, in ways that would not occur under "normal" chemical or physical processing routes. Nano-engineered and nano-fabricated materials promise to produce materials with unique properties to enhance smart materials, imbue a material with smart characteristics, or be a smart material in its own right. See also **Nanotechnology**.

Fullerenes and Carbon Nanotubes (CNT). Fullerenes are spherical caged molecules with carbon atoms at the corner of a polyhedral structure consisting of pentagons and hexagons. Buckminsterfullerene, which is known as the "buckyball", is the best known of this family. Fullerenes have been under commercial development for several years. One interesting application of fullerene as a smart material has been in the area of embedding fullerenes into sol–gel matrices for the purpose of enhancing optical limiting properties. A semiconducting material with a magnetic ordering at 16.1 K was produced from the reaction of buckyball with tetra(dimethylamino)ethylene. The CNTs, as described above, consists of a roll of graphite structure capped with carbon cages at each end. CNTs are

produced as either single walled (SWNT), which consists of a single carbon roll layer, or multiwalled (MWNT), which consists of many concentric rolls of graphitic-like carbon. The way in which the graphitic roll connects to itself and the size of the roll affects the electrical properties of the CNT producing insulator, conductor, and semiconductor materials. See also **Carbon**.

Nanoparticles and Nanowires. These can be fabricated from a number of materials using different techniques. High surface area nanowires of Pt can be used as catalytic gas detectors: A nano Pt wire is heated and a catalytic reaction occurs in the presence of, e.g., oxygen and a hydrocarbon. The heat of this reaction is then detected by the wire itself. The color of nanoparticle aggregates is very dependent on the spacing of the particles. Nanoparticles coated with suitable molecules can be used to detect chemical species. The molecule changes shape in the presence of the target chemical, and thus the spacing of the nanoparticles changes resulting in a change in color. The electrical conductivity of conductive nanoparticles is also very dependent on the spacing of the particles and thus an electrical response can also be obtained.

Nano-Microstructured Surfaces. Nano–microstructures surfaces are not a material, but a modification to a material. However, "simply" altering the surface of a material can result in interesting properties since many material interactions with the external world are through the surface of the material. Examples include low friction surfaces, self-cleaning (which has seen application in self-cleaning windows), and properties associated with exceptionally high surface area.

Other Materials

Smart catalysts behave in such a way as to reduce the chance of exothermic chemical runaways. One class of smart catalysts is based on homogeneous rhodium-based poly(alkene oxide)s, in particular those with a poly(ethylene oxide) backbone. Traditionally, catalyzed chemical reactions proceed in a manner in which the catalysts becomes more soluble and active as the temperature is raised. This can lead to exothermal runaways that pose both safety and yield problems. On the other hand, as the temperature increases smart catalysts become less soluble, precipitate out of solution and become inactive. As the reaction mixture cools down the smart catalysts redissolves and becomes active again. Other smart catalysts are being developed that dissociate at high temperatures (less active) and recombine at low temperatures (more active).

Water is one of the few materials with the property that it expands as the liquid approaches the freezing point. This behavior is responsible for the freeze–thaw–freeze erosion of cracked rocks and has been used in indicator system where the expansion of the water cracks a container indicating that the temperature has dropped below the freezing point of water.

SMECTIC LIQUID CRYSTALS. See **Liquid Crystals**.

SMELTING. The process of heating ores to a high temperature in the presence of a reducing agent, such as carbon (coke), and of a fluxing agent to remove the accompanying rock gangue is termed smelting. Iron ore is the most abundantly smelted ore. It contains about 20% gangue (clay and sand). The ore is heated in an air blast furnace with coke and limestone (fluxing agent) at a temperature above the melting point of iron and slag (fusion mixture of impurities and flux). The molten iron (the more dense material) and molten slag (the less dense material) are removed separately from the furnace. See also **Arsenic**; **Cadmium**; **Cobalt**; **Copper**; **Indium**; **Iron Metals, Alloys, and Steels**; **Lead**; **Silver**; and **Tin**.

SMELTS *(Osteichthyes)*. Of the order *Isospondyli*, family *Osmeridae*, smelts (more properly termed true smelts) seldom exceed 14 inches in length, and thus classified as a small fish. They prefer the cold or temperate in-shore waters of the northern hemisphere. The osmerid smelts are frequently confused with the atherinid smelt (silverside family). See also **Silversides (Osteichthyes)**. The true smelts have a small adipose fin on the dorsal fin, which is absent in the silversides.

Most true smelts, numbering some 13 species, are found in the Pacific, with no occurrence in the Indian Ocean or the southern hemisphere. They can be extremely abundant. From time to time, for example, the *Spirinchus thaleichthys* (Sacramento smelt) has occurred in extremely large numbers in San Francisco Bay. Smelts are, of course, logical prey for larger fishes. Fisheries for adult smelts have long prospered.

The *Thaleichthys pacificus* (eulachon) is found in the waters off the American Pacific Northwest. Nicknamed "candlefish," the fish, when dried and because of its excessive oil content, can be burned as a candle or torch, a practice sometimes used by Indians. The *Hypomesus olidus*, which attains a length up to 12 inches (30 centimeters), is found in the Sacramento River delta (fresh water), whereas its Japanese counterpart is a marine form, frequenting fresh waters only for spawning. The *Osmerus mordax* (American Atlantic smelt) occurs from Virginia northward to the Gulf of St. Lawrence. In the early 1900s, this fish was introduced to the Great Lakes where it has done very well. On the Pacific coast, ranging from southern California northward to Alaska, *Hypomesus pretiosus* (surf smelt) prefers the surf. It is a popular bait. The *Osmerus eperlanus* (European smelt) is well regarded commercially and occurs in numerous European rivers, including the Seine.

SMITH DIAGRAM (or Smith Chart). A diagram with polar coordinates, developed to aid in the solution of transmission line and waveguide problems. It is composed of the following sets of lines: (1) constant resistance circles; (2) constant reactance circles; (3) circles of constant standing-wave-ratio; (4) radius lines representing constant line-angle loci. The chart employs normalized quantities for maximum flexibility. See Fig. 1.

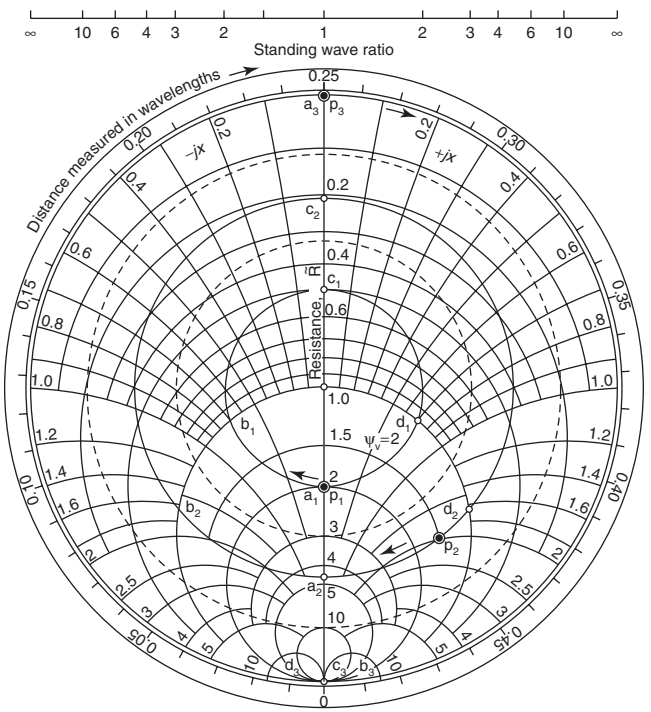

Fig. 1. Smith diagram showing circles of constant standing wave ratio, each corresponding to a particular terminal impedance as follows: (**a**) The terminal impedance (p_1) is $\tilde{Z}(1) = 2 + j0$. (**b**) The terminal impedance (p_2) is $\tilde{Z}(1) = 1.5 + j2$. (**c**) The terminal impedance (p_3) is $\tilde{Z}(1) = 0 + j0$.

SMITHSONITE. Smithsonite is zinc carbonate [CAS: 3486-35-9], $ZnCO_3$, a hexagonal mineral with a rhombohedral cleavage. It is a brittle mineral; hardness, 4–4.5; specific gravity, 4.3–4.5; luster, vitreous to dull; color, usually white, but may be colored yellowish or brownish or perhaps blue or green due to impurities. It is translucent to opaque. Historically, smithsonite was identified with hemimorphite before it was realised that they were two distinct minerals. Smithsonite is a secondary mineral after sphalerite or may replace limestone or dolomite. It is sometimes called calamine (but true calamine is a zinc silicate) and often associated with it. Smithsonite occurs in Siberia, Greece, Rumania, Austria, Sardinia, Cumberland and Derbyshire, England; New South Wales, Australia; South West Africa, and Mexico. In the United States, it is found in Pennsylvania, Wisconsin, Missouri, Arkansas, and Utah. This mineral was named in honor of James Smithson, whose legacy founded the Smithsonian Institution at Washington, DC.

SMITH, THEOBALD (1859–1934). Theobald Smith was an American bacteriologist, known particularly for his contributions towards the study of tuberculosis and the tick transmission of Texas fever in cattle.

Born in Albany, New York, the only son of recent immigrants from Germany, Smith on graduation from a local school won a state scholarship to Cornell University, where he showed increasing interest and ability in studies of biology and mathematics. This led him back to medical school in Albany, where during the two-year course he was able to spend one semester in the biological laboratories at Johns Hopkins. It was an eye-opener for the young Smith: he decided on a life in research rather than medical practice. He returned to Cornell for graduate work in biology; but very soon, at the age of 25, he was offered the chance to become Director of the Pathology Laboratory of the Bureau of Animal Industry, working under D. E. Salmon. He spent eleven very productive years there, cementing his interest in comparative studies with work on human and bovine tuberculosis. Like John McFadyean in London, he challenged Robert Koch's authoritative views, and continued to explore differences in mammalian tubercle bacilli, and consequent problems associated with vaccination procedures, to the end of his life. See also **Koch, Heinrich Hermann Robert (1843–1910)**; **Tuberculosis**; and **Vaccination**.

Smith's earliest notable results were obtained when, on arrival at the US Bureau of Animal Industry (USBAI), he was presented with the problem of "hog cholera" — a problem that neither he, nor Koch, Louis Pasteur or Elie Metchnikoff succeeded in solving before E. A. de Schweinitz and Marion Dorset in 1903 showed the disease to be transmitted by bacteria-free filtrates — i.e. a virus disease — and the "hog cholera bacillus" so carefully studied by Smith and others to be merely a secondary invader. See also **Pasteur, Louis (1822–1895)**; and **Metchnikoff, Elie (Ilya) (1845–1916)**.

Propelled so suddenly into the study of animal diseases, and fully occupied in the pathology laboratory, Smith never had the opportunity — or the funds — to spend time in European universities as was almost obligatory for his American contemporaries at the time. But with his solid European family background he read French and German fluently, and so could glean the information he needed from European language journals; and he himself published a number of papers in German journals.

Smith's crowning achievement during his time at the USBAI in the 1880s was the seminal study with which his name will always be linked: the demonstration that Texas cattle fever is caused by a protozoan parasite which he named *Piroplasma bigeminum*, now known as *Babesia bigemina*, transmitted by ticks — unlike the filaria of elephantiasis, earlier shown by Patrick Manson to be transmitted by *Culex* mosquitoes. Smith, working with cattle, could carry out crucial transmission experiments which had been unthinkable for Manson working with a human disease. See also and **Manson, Patrick (1844–1922)**; and **Protozoa**.

In 1895 Smith was called to Harvard, appointed the first George Fabyan Professor of Comparative Pathology, and also Director of the antitoxin laboratory of the Massachusetts State Board of Health. He stayed at Harvard until 1914, when he was invited to head a newly established department of animal pathology at Princeton, New Jersey, of the Rockefeller Institute, where he stayed until retirement in 1929.

LISE WILKINSON, Wellcome Institute for the History of Medicine, London, UK

SMOG. A coined word denoting a persistent combination of smoke and fog occurring under appropriate meteorological conditions in large metropolitan or heavy industrial areas. The discomfort and danger of smog is increased by the action of sunlight on the combustion products in the air, especially sulfur dioxide, nitric oxide, and exhaust gases (photochemical smog). Strongly irritant and even toxic substances may be present e.g., peroxybenzoyl nitrate. Fatalities have resulted from exposure from exposure to particularly severe photochemical smogs.

Photochemical smog is a complex mixture of constituents that are emitted directly to the atmosphere (primary pollutants) and constituents that are formed by chemical and physical transformations that occur in the atmosphere (secondary pollutants). Ozone (O_3), is generally the most abundant species formed in photochemical smog. Ozone is a secondary pollutant formed by the reactions of hydrocarbons and NO_x. Extensive studies have shown that O_3 is both a lung irritant and a phytotoxin. It is responsible for crop damage and is suspected of being a contributor to forest decline in Europe and in parts of the United States. There are, however, a multitude of other photochemical smog species that also have significant environmental consequences. The most important of these pollutants are particles, hydrogen peroxide (H_2O_2), [CAS: 7722-84-1], peroxyacetyl nitrate (PAN) ($C_2H_3NO_5$), [CAS: 2278-22-0], aldehydes, and nitric acid (HNO_3), [CAS: 7697-37-2]. All of these pollutants are secondary, produced in the atmosphere by the reactions of precursor species (although some types of particles, such as diesel soot, are emitted directly). See also **Pollution (Air)**.

Smog can form in almost any climate where industries or cities release large amounts of air pollution. However, it is worse during periods of warmer, sunnier weather when the upper air is warm enough to inhibit vertical circulation. It is especially prevalent in geologic basins encircled by hills or mountains. It often stays for an extended period of time over densely populated cities, such as London, Los Angeles, Mexico City, Houston, Toronto, Athens, Beijing, Hong Kong or the Ruhr Area and can build up to dangerous levels.

Smog is a problem in a number of cities and continues to harm human health. Ground-level ozone is especially harmful for seniors, children, and people with heart and lung conditions such as emphysema, bronchitis, and asthma. It can inflame breathing passages, decreasing the lung's working capacity, and causing shortness of breath, pain when inhaling deeply,

wheezing, and coughing. It can cause eye and nose irritation and it dries out the protective membranes of the nose and throat and interferes with the body's ability to fight infection, increasing susceptibility to illness. Hospital admissions and respiratory deaths often increase during periods when ozone levels are high.

The U.S. EPA has developed an Air Quality index to help explain air pollution levels to the general public. 8 hour average ozone concentrations of 85 to 104 ppbv are described as "Unhealthy for Sensitive Groups", 105 ppbv to 124 ppbv as "unhealthy" and 125 ppb to 404 ppb as "very unhealthy". The "very unhealthy" range for some other pollutants are: 355 $\mu g\,m^{-3}$ −424 $\mu g\,m^{-3}$ for PM10; 15.5 ppbv −30.4ppb for CO and 0.65 ppbv −1.24. See also http://www.epa.gov/ttn/oarpg/t1/memoranda/rg701.pdf.

SMOKE. A colloidal or microscopic dispersion of a solid in gas, and aerosol.

1. **Coal Smoke** A suspension of carbon particles in hydrocarbon gases or in air, generated by combustion. The larger particles can be removed by electrostatic precipitation in the stack (Cottrell). Dark color, nauseating odor.
   See also **Cottrell, Frank, C.**; **Pollution (Air)**; and **Smog**.
2. **Wood Smoke** Light-colored particles of cellulose ash, pleasant aromatic odor. Smoke from special kinds of wood (e.g., hickory, maple) is used to cure ham, fish, etc., also to preserve crude rubber.
3. **Chemical Smoke** Generated by chemical means for military purposes (concealment, signaling, etc.).
4. **Metallic Smoke (Fume)** An emanation from heated metals or metallic ores, the particles being of specific geometric shapes. Such smoke is particularly damaging to vegetation in the neighborhood of zinc and tin smelters.
5. **Cigarette Smoke** There is conclusive evidence that the tars occurring in cigarette smoke can lead to lung cancer; chief factors are age of individual at initiation of smoking, extent of inhalation, an amount smoked per day. Polonium, a radioactive element, is known to occur in cigarette smoke; more than 100 compounds have been identified including nicotine, cresol, carbon monoxide, pyridene, and benzopyrene, the latter a carcinogen.

Chemical Composition

The composition of smoke depends on the nature of the burning fuel and the conditions of combustion.

Fires with high availability of oxygen burn in high temperature and with small amount of smoke produced; the particles are mostly composed of ash, or in large temperature differences, of condensed aerosol of water. High temperature also leads to production of nitrogen oxides. Sulfur [CAS: 7440-34-9] content yields sulfur dioxide [CAS: 7446-09-5]. Carbon [CAS: 7440-44-0] and hydrogen [CAS: 1333-74-0] get completely oxidized to carbon dioxide [CAS: 124-38-9] and water [CAS: 7732-18-5].

Fires burning with lack of oxygen produce significantly wider palette of compounds, many of them toxic. Partial oxidation of carbon produces carbon monoxide [CAS: 630-08-0], nitrogen-containing materials can yield hydrogen cyanide [CAS: 74-90-8], ammonia [CAS: 7664-41-7], and nitrogen oxides. Content of chlorine [CAS: 7782-50-5] (eg. in polyvinyl chloride) [CAS: 9002-86-2] or other halogens may lead to production of eg. hydrogen chloride [CAS: 7647-01-0], phosgene [CAS: 75-44-5], dioxin [CAS: 1746-01-6], and chloromethane [CAS: 74-87-3], bromomethane [CAS: 74-83-9] and other halocarbons. Pyrolysis of the burning material also results in production of large amount of hydrocarbons, both aliphatic (methane [CAS: 74-82-8], ethane [CAS: 74-84-0], ethylene [CAS: 74-85-1], acetylene [CAS: 74-86-2]) and aromatic (benzene and its derivates, polycyclic aromatic hydrocarbons; eg, benzo[a]pyrene, studied as a cancerogen, or retene), terpenes. Heterocyclic compounds may be also present. Heavier hydrocarbons may condense as tar. Presence of sulfur can lead to formation of eg. hydrogen sulfide [CAS: 7783-06-4], carbonyl sulfide [CAS: 463-58-1], sulfur dioxide [CAS: 7446-09-5], carbon disulfide [CAS: 75-15-0], and thiols; especially thiols tend to get adsorbed on surfaces and produce lingering odor even long after the fire. Partial oxidation of the released hydrocarbons yields in a wide palette of other compounds: aldehydes (eg. formaldehyde [CAS: 50-00-0], acrolein [CAS: 107-02-8], and furfural [CAS: 98-01-1]), ketones, alcohols (often aromatic, eg. phenol [CAS: 108-95-2], guaiacol [CAS: 90-05-1], syringol [CAS: 91-10-1], catechol [CAS: 120-80-9], and cresols [CAS: 1319-77-3]), carboxylic acids (formic acid [CAS: 64-18-6], acetic acid [CAS: 64-19-7], etc.).

The visible particles in such smokes are most commonly composed of carbon (soot). Other particulates may be composed of drops of condensed tar, or solid particles of ash. Content of metals yields particles of metal oxides. Particles of inorganic salts may also be formed, eg. ammonium sulfate [CAS: 7783-20-2], ammonium nitrate [CAS: 6484-52-2]. Many organic compounds, typically the aromatic hydrocarbons, may be also adsorbed on the surface of the solid particles.

Smoke emissions may contain characteristic trace elements. Vanadium [CAS: 7440-82-2] is present in emissions from oil fired power plants and refineries; oil plants also emit some nickel [CAS: 7440-02-0]. Coal combustion produces emissions containing selenium [CAS: 7782-49-2], arsenic [CAS: 7440-38-2], chromium [CAS: 7440-47-3], cobalt [CAS: 7440-48-4], copper [CAS: 7440-50-8], and aluminium [CAS: 7429-90-5].

Some components of smoke are characteristic for the combustion source. Guaiacol and its derivates are products of pyrolysis of lignin and are characteristic for wood smoke; other markers are syringol and derivates, and other methoxy phenols. Retene, a product of pyrolysis of conifer trees, is an indicator of forest fires. Levoglucosan is a pyrolysis product of cellulose. Hardwood vs softwood smokes differ in the ratio of guaiacols/syringols. Markers for vehicle exhaust include polycyclic aromatic hydrocarbons, hopanes, steranes, and specific nitroarenes (eg. 1-nitropyrene). The ratio of hopanes and steranes to elemental carbon can be used to distinguish between emissions of gasoline and diesel engines.

Health and Safety

Smoke from oxygen-deprived fires contains a significant amount of compounds that are flammable. A cloud of smoke, in contact with atmospheric oxygen, therefore has the potential of being ignited — either by another open flame in the area, or by its own temperature. This leads to effects like eg. backdraft and flashover.

Many compounds of smoke from fires are highly toxic and/or irritant. The most dangerous is the carbon monoxide, leading to carbon monoxide poisoning, sometimes with supporting effect of hydrogen cyanide and phosgene. Smoke inhalation can therefore quickly lead to incapacitation and loss of consciousness.

SMOKELESS POWDER. Smokeless powder is the name given to a number of gunpowder-like propellants used in firearms which produce negligible smoke when fired, unlike the older black powder which it replaced.

Types of smokeless powder include cordite, ballistite and, historically, Poudre B. They are classified as single-base, double-base or triple-base powders.

Smokeless powder consist of nitrocellulose containing about 13.1% nitrogen [CAS: 7727-37-9], produced by blending material of somewhat lower (12.6%) and slightly higher (13.2%) nitrogen content, converting to a dough with alcohol-ether mixture, extruding, cutting, and drying to a hard, horny product. Small amounts of stabilizers (amines) and plasticizers are usually present, as well as various modifying agents (nitrotoluene [CAS: 1321-12-6], nitroglycerin salts [CAS: 55-63-0]).

The reason that they are smokeless is that the combustion products are mainly gaseous, compared to around 60% solid products for black powder (potassium carbonate, potassium sulfate etc).

Smokeless powder burns only on the surfaces of the granules, flakes or cylinders - described as *granules* for short. Larger granules burn more slowly, and the burn rate is further controlled by flame-deterrent coatings which retard burning slightly. The intent is to regulate the burn rate so that a more or less constant pressure is exerted on the propelled projectile as long as it is in the barrel so as to obtain the highest velocity. Cannon powder has the largest granules, up to thumb-sized cylinders with seven perforations (one central and the other six in a circle halfway to the outside of the cylinder's end faces). The perforations stabilize the burn rate because as the outside burns inward (thus shrinking the burning surface area) the inside is burning outward (thus increasing the burning surface area, but

faster, so as to fill up the increasing volume of barrel presented by the departing projectile). Fast-burning pistol powders are made by extruding shapes with more area such as flakes or by flattening the spherical granules. Drying is usually performed under a vacuum. The solvents are condensed and recycled. The granules are also coated with graphite to prevent static electricity sparks from causing undesired ignitions.

SMOKE POLLUTION. See **Pollution (Air)**.

SMOKE TREE. See **Cashew and Sumac Trees**.

SMOOTHING (Of a Curve). The replacement of a curve, or of a sequence of points by another that is in some sense more regular, and yet whose ordinates, for any abscissa, are changed as little as possible. The irregularities in a sequence of points may be due to errors in measurement. If theory requires the theoretically correct points to lie on a given curve, one may apply some method of curve fitting, possibly least squares. If not, one may select arbitrarily a simple function, possibly a polynomial, and fit it by least squares. If the purpose is merely to obtain a smooth graph, this may be drawn visually. A somewhat more sophisticated method is to take, say, 5 consecutive points, fit a parabola, and replace the middle point by the one on the parabola. The next parabola requires four of these points and one new one.

See also **Neighborhood of a Point**.

SMUT FUNGI. See **Fungus**.

SNAIL DARTER. See **Perches and Darters**.

SNAIL *(Mollusca, Gasteropoda)*. A name properly applied to most members of this class, but usually given only to the small fresh-water and terrestrial species with coiled shells. The term does not correspond with the scientific classification of mollusks beyond this general application.

Snails are regarded as a food delicacy in many countries of the world. Closely related to the slug, the snail is a garden pest with tastes and habits much the same as those of the slug. See also **Mollusks**; and **Slug**.

SNAKE FLY *(Insecta, Neuroptera)*. A peculiar insect found only in the western United States. It has four membranous wings and the body is prolonged at the anterior end. These insects are insect eaters and are found commonly on the bark and foliage of trees.

SNAKES. According to one view, primitive snakes were specialized burrowers, whereas according to another view, they were surface-dwelling or aquatic boa-like snakes from which specialized burrowers evolved in one line and fast-moving terrestrial and arboreal types in another. Snakes are in the class *Reptilia* (reptiles), the order *Squamata* (scaly reptiles), and the suborder *Serpentes* (snakes). Although there are variations to this classification, this is the classification followed by Grzimek (1971).

About 3000 species and subspecies of snakes range from southern Canada, northern Sweden and the Kamchatka Peninsula southward throughout Africa and most of the Americas, Australia, and temperate and tropical islands except Polynesia (only one tiny species, for example, occurs in Hawaii). There are no snakes in Ireland or New Zealand. Islands have been populated by snakes from adjacent mainland or by subsequent chance. Ireland lacks them because it was separated from continental contact before the last glacier departed, and no introduction has since occurred.

As shown in Table 1, there are 3 infra-orders, 12 families, and nearly 20 subfamilies, but this number has been variously estimated in accordance with the degree of significance attached to specializations of diverse groups. Even with these complications, a few generalizations can be made.

The most primitive families of snakes possess internal vestiges of the skeletal girdle of the hind limbs. In some families, a vestige of the thigh (femur) remains, often visible externally as a small spur on either side of the anal opening. Snakes do not possess movable eyelids. The skin over the eye is in the form of a large scale flush with the rest of the cranial surface in the most primitive snakes. In more advanced forms, the scale fits the eye perfectly and is designated a *brille* or tertiary spectacle. Snakes sleep, but little outwardly visible evidence reveals when they are asleep.

The ears cannot directly receive airborne sounds, since the external ear and middle ear cavity are missing. The middle ear ossicle or columella is present, but is embedded in muscle except where it fits into the *fenestra ovalis* of the capsule of the inner ear. Snakes can detect some ground-borne vibrations, since the inner ear is largely intact. They are deaf to music of snake charmers and to their own noises. The tongue in all snakes is long, slender and forked at the tip. It functions primarily in picking up airborne particles that go into solution on its moist surface. By placing the tips of the tongue into the paired vomeronasal organs at the anterior tip of the roof of the mouth, the snake can detect odors.

Snakes periodically molt the outer epidermal layers of the entire skin, including eye covering and tips of tongue. Frequency varies with species and health, but is not known to be less than once per year. Molting commonly occurs three times per year, but more frequently if the snake has been injured. The molt usually proceeds toward the posterior, starting at the snout and lower jaw where the skin is rubbed backward over the head, turning it wrongside out and leaving it usually in one piece. In preparation for the molt, the basal layer of epidermis rapidly proliferates, producing a completely new outer epidermis, with cuboidal and squamous cells. Breakdown of the basal cuboidal cells of the older layer forms a milky fluid, giving a dull cast to the snake as a whole and a milky appearance to the eye. At this time snakes can see but dimly, if at all, and tend to remain inactive and hidden from view. They are more likely during this period to be defensive if disturbed. The fluid disappears by evaporation or absorption after about three days, and about two days thereafter the slough is shed.

Many snakes lay eggs. Others bear their young live. Parental care is generally absent. The eggs may be abandoned after deposition in damp sand, soil, sawdust, ground litter, or rotting logs. Eggs hatch in about three days to three months. Some viviparous types possess a placenta. As pointed out later, some species, such as cobras, pay more attention to their eggs than other species.

Like other reptiles, snakes are ectothermic, their body temperatures being controlled largely by behavior and to only a slight degree by intrinsic mechanisms.

Males court by repeatedly rubbing chin and body along length of the female's body. In rare circumstances the two animals intertwine the bodies and rise straight upward until only tail and rear part of the body remain on the ground. Ordinarily the latter behavior is a "combat dance" between males. Snakes, like lizards, possess two copulatory organs (hemipenes). Copulation occurs with either and with both structures, but not with both at once, and persists for long periods, from one-half to several hours.

Snakes have numerous well-developed salivary glands, the secretions of which have been shown, experimentally, to be powerfully toxic in almost all species. Yet the bites of most snakes produce no signs or symptoms of poisoning because of the absence of venom-conducting fangs. So-called nonpoisonous snakes have only "solid" teeth, lacking a groove down one side. All "poisonous" species possess one to four pairs of fangs. Fangs are teeth specialized for injection of venom, having either a tube-like structure acting as a needle, or a groove down one side which conducts venom like a capillary tube when it is imbedded in a victim's flesh.

Snakes have teeth, usually all conical, slender, curved, of about the same size and shape. They are found on five paired jaw bones: the maxilla, palatine, pterygoid, dentary, and rarely the premaxilla. They vary in total number from about 20 to 200. Three sorts of fang modification have evolved. Snakes possess venoms containing numerous protein enzymes capable of promoting various types of tissue degeneration. Snakes feed upon animals, never plant material. They often scavenge. Snakes usually swallow the food head first. The trachea can be extended forward below the food far enough to enable the snake to breathe while swallowing.

Four modes of locomotion are concertina, sidewinding, rectilinear, and horizontal undulation.

Blind Snakes, Primitive Snakes, and Wart Snakes

The infraorder of blind snakes (*Scolecophidia*) contains two snake families whose members burrow in the ground: (1) Blind snakes (*Typhlopidae*),

and (2) slender blind snakes (*Leptotyphlopidae*). These two families bear such a remarkable resemblance that it may appear as if they are very closely related and belong to the same family. However, differences in skull structure and skeletal elements cause them to be divided into distinct families. These are very primitive snakes. They have small, poorly differentiated scales that remain small on the belly and do not form the large scutes or ridges seen on more advanced snake species. And, they have vestiges of upper hind leg bones and the pelvic girdle. Some zoologists

TABLE 1. CLASSIFICATION OF SNAKES

CLASS EPTILIA (Reptiles)
ORDER QUAMATA (Scaly Reptiles)
SUBORDER ERPENTES (Snakes)

INFRAORDER: BLIND SNAKES (*Scolecophidia*)
- FAMILY: Blind Snakes (*Typhlopidae*)
  - *Examples:* Peter's blind snake (*Typhlops dinga*); Common blind snake (*T. braminus*)
- FAMILY: Slender Blind Snakes (*Leptoryphlopidae*)
  - *Examples:* Texas blind snake (*L. dulcis*); Western blind snake (*L. humilis*)

INFRAORDER: PRIMITIVE SNAKES (*Henophidia*)
- FAMILY: PIPE SNAKES (*Aniliidae*)
  - *Examples:* False coral snake (*Anilus scytale*); Pipe snake (*Cylindrophis rufus*)
- FAMILY: SHIELD-TAILED SNAKES (*Uropeltidae*)
- FAMILY: SUNBEAM SNAKES (*Xenopeltidae*)
  - *Example:* Sunbeam snake (*Xenopeltis unicolor*)
- FAMILY: ACROCHORDIDS (*Acrochordidae*)
  - *Examples:* Javan wart snakes (*Acrochordus javanicus*); Indian wart snake (*Chersydrus granulatus*)
- FAMILY: PYTHONS AND BOAS (*Boidae*)
  - SUBFAMILY: *Loxoceminae*
    - *Example:* Mexican python (*Loxocemus bicolor*)
  - SUBFAMILY: *Pythoninae*
    - *Examples:* Reticulate python (*Python reticulatus*); Indian python (*P. molurus*); Rock python (*P. sebae*); Blood python (*P. curtus*); Timor python (*P. timorensis*); Ball or royal python (*P. regius*); Angola python (*P. anchietae*); Carpet python (*Morelia argus*); Brown python (*Liasis fuscus*); Boa (*Bothrochilus boa*); Black-headed python (*Aspidites* and *Chondropython*); Burrowing python (*Calabaria reinhardtii*)
  - SUBFAMILY: Boas (*Boinae*)
    - *Examples:* Wood snakes (*Tropidophis*); Cuban boa (*Epicrates angulifer*); Rainbow boa (*Epicrates cenchris*); Rubber boa (*Charina bottae*); California boa (*Lichanura roseofusca*); Madagascar boa constrictor (*Acrantophis madagascariensis*); Sand boas (*Eryx*); Brown sand boa (*Sanzinia johnii*); Emerald tree boa (*Corallus caninus*); Boa constrictor (*Boa constrictor*); Anaconda (*Bunectes murinus*); Yellow Anaconda (*Eunectes notaeus*)
  - SUBFAMILY: *Bolyeriinae* (Round Island Boas)

INFRAORDER: ADVANCED SNAKES (*Xenophidia* or *Caenophidia*)
- FAMILY: COLUBRID SNAKES (*Colubridae*)
  - SUBFAMILY: *Xenoderminae* (Xenodermin Snakes)
  - SUBFAMILY: *Sibynophinae*
  - SUBFAMILY: *Xenodontinae*
    - *Examples:* Eastern hognosed snake (*Heterodon platyrhinos*); Western hognosed snake (*H. nasicus*)
  - SUBFAMILY: *Natricinae*
    - *Examples:* Ringed snake (*Natrix natrix*); Diced snake (*N. tessellata*); Common water snake (*N. sipedon*); Diamond-back water snake (*N. rhombifera*); Brown water snake (*N. taxispilota*); Glossy water snake (*Regina rigida*); Queen snake (*R. septemvittata*); Kirtland's water snake (*Clonophis kirtlandii*); Common garter snake (*Thamnophis sirtalis*); Mexican garter snake (*T. eques*)
  - SUBFAMILY: *Colubrinae*
    - *Examples:* King snakes (*Lampropeltis* spp.); Milk snake (*L. triangulum*); Common king snake (*L. getulus*); Green snakes (*Opheodrys* spp.); Racer snakes (*Coluber* spp.); Eastern coast coachwhip (*Masticophis flagellum*); Speckled racers (*Drymobius*, spp.); Patch-nosed snakes (*Salvadora* spp.); Leaf-nosed snakes (*Phyllorhynchus*, spp.); Rat snakes (*Elaphe* spp.); Rat snake (*E. obsoleta*); Fox snake (*E. vulpina*); False water cobra (*Hydrodynastes gigas*); Indian rat snake (*Ptyas korros*); Keeled rat snake (*P. carinatus*)
  - SUBFAMILY: *Calamarinae* (Dwarf Snakes)
    - *Example:* Linne's dwarf snake (*Calamaria linnaei*)
  - SUBFAMILY: *Lycodontinae* (Lycodontine Snakes)
    - *Examples:* Indian wolf snake (*Lycodon aulicus*); African wolf snake (*L. capense*); Cape file snake (*Mehelya capensis*); Brown house snake (*Boaedon fuliginosus*); Rainbow snake (*Farancia erythrogrammus*); Mud snake (*F. abacura*)
  - SUBFAMILY: *Dipsadinae*
  - SUBFAMILY: *Pareinae*
  - SUBFAMILY: *Dasypeltinae* (Egg-eating Snakes)
    - *Examples:* African egg-eating snake (*Dasypeltis scabra*); Indian egg-eating snake (*Elachistodon westermanni*)
  - SUBFAMILY: *Homalopsinae* (Homalopsine Colubrid Snakes)
    - *Examples:* White-bellied water snake (*Fordonia leucobalia*); Tentacled snake (*Erpeton tentaculatum*)
  - SUBFAMILY: *Boiginae* (Boigine Snakes or Boigine Vipers)
    - *Examples:* Tree snakes (*Boiga*, spp.); Mangrove snake (*B. dendrophila*); Twig snake (*Thelotornis kirtlandii*); Green vine snake (*Oxybelis fulgidus*); Flying snakes (*Chrysopelea* spp.)
- FAMILY: COBRAS (*Elapidae*)
  - *Examples:* King cobra (*Ophiophagus hannah*); True cobras (*Naja* spp.); Asian or Indian cobra (*N. naja*); Egyptian cobra (*N. haje*); Spitting cobra (*N. nigricollis*); Black-lipped cobra (*N. melanoleuca*); Cape cobra (*N. nivea*); Gold's tree cobra (*Pseudohaje goldii*); Desert black snakes (*Walterinnesia* spp.); Shield-nose snakes (*Aspidelaps* spp.); Water cobras or water snakes (*Boulengerina* spp.); Black mamba (*Dendroaspis polylepis*); Mamba (*D. angusticeps*); Kraits (*Bungarus* spp.); Oriental coral snakes (*Calliophis* spp.); Long-glanded coral snakes (*Maticora* spp.); American coral snakes (*Micurus* spp.); Southern coral snake (*M. frontalis*); Eastern coral snake or Harlequin snake (*M. fulvius*); Western coral snake (*Micruroides* spp.); Arizona coral snake (*M. euryxanthus*); Death adder (*Acanthophis antarcticus*); Australian tiger snakes (*Notechis* spp.); Australian copperhead (*Denisonia* spp.)
- FAMILY: SEA SNAKES (*Hydrophiidae*)
  - SUBFAMILY: *Laticaudinae*
    - *Examples:* Black-banded sea krait (*Laticauda laticauda*); Olive-brown sea snake (*Aipysurus laevis*)
  - SUBFAMILY: *Hydrophiinae*
    - *Examples:* Yellow sea snake (*Hydrophis spiralis*); Beaked sea snake (*Enhydrina schistosa*)

(*continued*)

TABLE 1. (*Continued*)

FAMILY: VIPERS (*Viperidae*)
Examples: True vipers (*Viptera* spp.): Adder or common European viper (*V. berus*); Asp viper or European asp (*V. aspis*); Sand viper (*V. ammodytes*); Mountain viper (*V. sznthia*); Saw-scaled viper (*Echis carinatus*); Horned viper (*Cerastes cerastes*); Puff adders (*Bitis* spp.); Rhinoceros viper (*B. nasicornis*); Dwarf puff adder (*B. peringueyi*); Bush vipers or tree vipers (*Atractaspis* spp.); Common burrowing viper (*A. irregularis*); Night adders (*Causus* spp.); Common night adder (*C. rhombeatus*)
FAMILY: PIT VIPERS (*Crotalidae*)
Examples: Rattlesnakes (*Crotalus* spp.); Santa Catalina rattlesnake (*C. catalinensis*); Eastern diamond-back rattlesnake (*C. adamanteus*); Western diamond-back rattlesnake (*C. atrox*); Prairie rattlesnake (*C. viridis*); Timber rattlesnake (*C. horridus*); Green rattlesnake (*C. lepidus*); Sidewinder (*C. cerates*); Tropical rattlesnake (*C. durissus*); Pygmy rattlesnakes (*Sistrurus* spp.); Lance-head snakes (*Bothrops* spp.); Asian lance-head snakes (*Trimeresurus* spp.); Bushmaster (*Lachesis mutus*); Haly's viper (*Agkistrodon halys*); Himalayan viper (*A. himalayanus*); Chinese copperhead (*A. acutus*); Malaysian moccasin (*A. rhodostoma*); Cottonmouth or water moccasin (*A. piscivorus*); Copperhead (*A. contortrix*); Tropical moccasin (*A. bilineatus*)

Note: Some of the better known as well as other species selected at random are included in the various examples given. The examples represent only some of the species of snakes.

believe that blind snakes are actually closer to some lizards than to other snakes.

Both blind snake families are characterized by a subterranean mode of life. These snakes have a smooth, round body that makes them look like big worms, and a blunt head that merges smoothly with the rest of the body. The tail is short and often has a spiny structure whose function has not been clarified. Perhaps the spine helps anchor the snake in the ground so the body can move more easily. Some species use the spine as a weapon. The eyes are tiny and are covered by large head scales, but they gleam through these scales. The eyes are probably used to distinguish light and dark. The skull is used a great deal as blind snakes burrow beneath the ground, and it is shortened and forms a hard capsule.

The *common blind snake* (*Typhlops braminus*) has a habit of finding its way into flower pots that are left in the open for long periods of time. This species crawls about among the roots and feeds on the insect larvae and other creatures that may be dwelling there. This snake occurs in Madagascar, India, Sri Lanka, Southeast Asia, and the Indo-Australian islands, but is also found in southern Mexico. Other blind snake genera occur only in tropical South America.

The *Texas blind snake* (*Leptotyphlops dulcis*) and the western blind snake (*L. humilis*) occur as far north as the sandy, dry prairies of the southern United States, where they burrow in the ground, beneath rocks, or inside fallen trees. They often crawl about on the ground in the early evening hours, but they disappear again after dark. Their diet consists of insect larvae, ants, and termites. They usually lay a few elongated eggs.

The primitive snakes (*Henophidia*) comprise five primitive, nonpoisonous families, three of which have just a few species. Pipe snakes (*Aniliidae*) are three genera from South America and southern and southeastern Asia. They have vestiges of the pelvic girdle and the hind limbs. The hind limb remnants look like small claws on each side of the anal opening. In contrast to blind snakes, the head scales on pipe snakes have not fused much. The eyes are small, but do not lie beneath scales. The scales on the belly are clearly larger than those on the back, although they are not the size of those found in advanced snakes.

The *false coral snake* (*Anilius scytale*) has a length of some 75–85 centimeters (25–34 inches) and lives in South America. It is brilliant red and has black rings on its back, giving it an appearance not unlike poisonous coral snakes. It lacks the yellow bands. This snake bears live young. Diet consists of lizards and snakes.

Shield-tailed snakes (*Uropeltidae*) are called that because of the greatly enlarged, modified scale found near the tip of the tail. The function of this structure has not been clarified, but it possibly serves to anchor the animal to the ground. Shield-tailed snakes are thought by some to burrow by pushing the tail tip forward and turning it from side to side. They lack externally visible hind limb vestiges. Shield-tailed snakes give birth to 3 to 8 live young at a time. The diet consists of earthworms and insect larvae. Most species do not exceed 30 centimeters (12 inches) in length, but the *Rhinophis oxyrhynchus* achieve a length of about 60 centimeters (24 inches).

Sunbeam snakes (*Xenopeltidae*) are distributed across India and southeastern Asia. The toothed premaxillary bone, rudimentary pelvic girdle, and hind limb vestiges are all primitive characteristics. The sunbeam snake (*Xenopeltis unicolor*) achieves a length of about 1 meter (3.2 feet). The snake has a round body, and its dorsal scales shimmer with a rainbow effect. When a sunbeam snake is excited, it twitches its tail vigorously, with much the same action as in rattlesnakes. Sunbeam snakes lack rattles. Their prey consists of small snakes, frogs, small rodents, and birds.

Wart snakes (*Arochordidae*) are distributed from the coastal regions of India and Sri Lanka across the Indo-Australian islands as far as the Solomons. Unlike most other snakes, the scales of wart snakes do not overlap, but are set adjacent to each other (an arrangement often found in lizards) and bear a sharp ridge. The scale characteristics give the skin a rough, warty appearance. Wart snakes live in the brackish zone of rivers, but sometimes swim short distances in the sea. They are sluggish, slow-swimming snakes that can often stay underwater on the bottom for long periods without breathing. The nasal openings are on the upper side of the snout, enabling them to breathe by simply protruding this part out of the water. Wart snakes only rarely come onto land, where they crawl about clumsily.

Boids (*Boidea*)

These snakes arose toward the end of the Cretaceous period as species closely related to monitor-like lizards. Boids comprise not only the largest snakes alive today, but also small and medium-size species. The top of the head has small scales or large, symmetrical plates, and the back has small scales. The belly is covered with larger plates. The pupils are vertical. There are paired lungs. All three parts of the pelvic vestiges are present, and the skull bones are joined by flexible linkages. Prey is killed by constriction.

There are only four species in the entire boid family that pose a danger for people — the rock python, the Indian python, the reticulate python, and the anaconda. See Fig. 1. Boids are the only *large* animals on earth that are mute. At most, they can utter a hiss. They are also deaf and cannot perceive

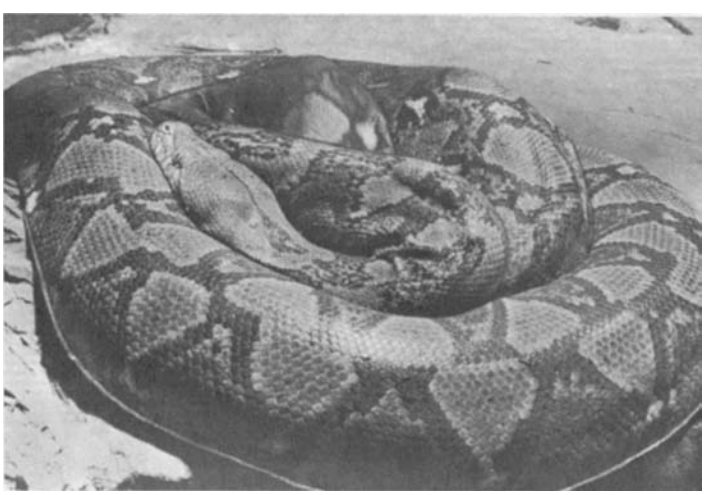

Fig. 1. Regal python. (*A.M. Winchester.*)

air vibrations. They can sharply perceive movements in the ground or on the substrate upon which they rest. In recent years, it has been shown that some snakes can perceive loud noises with the sensitive tips of the tongue.

As in all snakes, the eyes of boids lack lids and are covered by the epidermis. The skin is shed along with the rest at molting time, and a new

epidermal covering develops. The membrane protects the eye. The eyes of snakes are less mobile and less elastic than avian and mammalian eyes, and therefore their accommodation capability is less. Boids have fairly keen vision, however. They can distinguish outlines well at short distances and can recognize immobile objects in the vicinity and climb about on them. Prey and conspecifics are distinguished primarily by the way they move and from their odor.

During the day, the boid pupils constrict and form vertical slits, while at dusk and at night they widen and look like the eyes of a cat. The firm covering offers effective protection for the eyes when the snake crawls through thickets and holes, and underwater, where they enable the snake to see. The protective membrane gives the impression that the snake is constantly staring. The eyes are only useful for perceiving prey at close range and for the perception of movement; boids have another organ that helps them detect prey nonvisually. Small rectangular openings in the scales on the lower and upper lips (the openings being analogous to the pit organ of pit vipers) enable the snake to perceive even faint warmth radiations. They can detect a human hand at a few dozen centimeters with this heat organ. The organ enables boids to find warm-blooded prey hiding in concealed sites. The finest of all senses, however, is olfaction (smelling), which arises from the Jacobson's organ in the roof of the mouth. The tongue leads small particles in the air to this organ. The heat organ and Jacobson's organ make snakes independent of light conditions, for regardless of bright or dark, they can pursue their prey and often overtake it.

Boids move not only by means of swinging movements in the horizontal plane, but also by stretching the front of the body forward and pulling the rest behind (earthworm movement). A boid on a smooth surface can leave a straight track rather than a winding one. Boids move even better in the water than on land. They swim with surprising agility, diving and surfacing. When swimming, they make use of their ability to pump air inside the body, preventing it from sinking. If the snake wants to dive it releases some of the air. Some boids (not just the purely aquatic South American anaconda) cover considerable distances in water, even undertaking extensive trips into the open sea, sometimes floating along with drifting tree stumps.

One boa constrictor is reported to have covered the distance from the South American mainland to Saint Vincent Island, a distance of 320 kilometers. When the volcano Krakatoa erupted in 1888, all life was destroyed on that Indonesian island. Biologists then recorded the return to the island of various plants and animals in the following decades. Reticulate pythons were one of the first reptiles to reappear there, arriving in 1908.

A great deal has been fancifully written about the strike of a python (for example, Kipling's descriptions in the *Jungle Book*). Snake breeders know that pythons never intentionally strike an object with their head. Nevertheless, they are very strong animals. The entire body, from head to tip of tail, is a single muscle package, which enables boids to gain a powerful hold on their prey. A strong man can probably defend himself against a 4-meter (13-foot) long python or anaconda, but he could not deal alone with one of these weighing 50 kilograms (110 pounds) or more. The boid seizes its prey or an enemy by darting quickly toward the animal and seizing it with its long, sharp teeth. Then the snake wraps around the prey two or more times, at the same time constricting its muscles. Boids do not inflict killing wounds with the teeth. They strangle their prey or kill it by causing vital blood vessels to burst.

Boids must first gain a hold with their teeth if they are to deal effectively with prey, so their teeth are of utmost importance. A reticulate python has about 100 very sharp teeth that point backward. If the snake grabs even a finger, the finger can not be pulled out. One would have to force open the snake's jaw and push the finger further in before it could be released from the teeth. Boids kept in zoos become fairly tame quickly. Even pythons caught in the wild defend themselves by biting and almost never by attempting to wrap themselves around the persons capturing them. In handling newly arrived boids at zoos, one man must be assigned for each meter (3.2 feet) of length of the snake. Each man must be able to grab the snake firmly and not let go.

Although boids become tame in a short time, snake charmers often literally cool their animal down before doing a performance. The dulled snake lets the charmer do about anything when it is cool and it does not regain its normal activity level until after the display.

It was formerly believed that boids cover their prey with saliva prior to swallowing them, but it is now known that this does not occur until the prey is in the jaws and inside the snake's body. A snake can regurgitate its prey if the snake is startled, but this is uncommon. However, a goat or antelope that is swallowed can cause so much discomfort with its horns that the snake may rid itself of the animal.

Although large snakes can swallow huge amounts at a single time, they actually eat modest amounts and require just a little more than their own weight in food per year. After swallowing large prey, a boid may not eat at all for many weeks and may fast for several months without losing any significant body weight.

Gases forming in the snake's stomach cause the body to become even more inflated several days after eating prey, and the gases sometimes cause the snake considerable discomfort. The swallowing capacity of boids has its limits, and reports about them swallowing horses, cows, and other large animals are considered fantasy.

Large boids reach sexual maturity in three years (in captivity). Males recognize females by the anal secretions of the female. Copulation may last for several hours. While all pythons lay eggs, all boa species are live-bearers. Boa ovoviviparity is to some extent believed to be the result of a more advanced stage of adaptation. Female pythons, which coil around their eggs and may incubate them two or more months, are in greater potential danger than female boas, which can move away right after they give birth. The young boas, which are able to crawl into all sorts of recesses immediately after birth, are also less vulnerable than eggs. The eggs that female boas develop within their bodies, are covered by a membrane instead of a shell.

Tree Boas (Corallus). The *emerald tree boa* (*C. caninus*), which attains a length up to 2 meters (6.4 feet) is from northern South America and Brazil and is one of the most beautiful boas of all. Its brilliant green coloration with whitish or yellowish bands offers superb camouflage when it crawls about in trees or shrubs as it hunts birds or lizards, or when simply resting in a tree. The body is compressed laterally, enabling the snake to press close to the tree branches. On the ground it is not a particularly agile snake. In the resting position, the prehensile tail often grasps a branch as the body is wound around the tail, with the coils of the body equally divided on both sides of the point where the tail is grasping. The long, powerful teeth enable tree boas to catch birds, which they snap at and then hold onto with these teeth.

The *garden tree boa* (*Corallus enhydris*) attains a length of up to 2.5 meters (8.2 feet) and is distributed in the Central and South American tropics, as well as the Antilles. The basic coloration may be brown, ochre, or gray, and sometimes it has a striking pattern. The garden tree boa uses an accordion-like climbing technique. The snake wraps the front of its body around a thin part of the tree trunk and then pulls itself higher, only to re-anchor the body again and climb a bit more.

Boa Constrictor (Boa constrictor). This snake usually will reach a maximum length of 4 to 4.5 meters (13.1 to 14.8 feet) and will weigh up to 60 kilograms (132 pounds). This snake is probably the most familiar of the boids, although by no means the largest. It is distributed from Mexico to northern Argentina. Three closely related species occur on the West Indies islands and the plains of western Argentina. Boa constrictors, whose pattern varies from one individual to the next, are among the most beautiful of snakes. They are ground dwellers and are particularly prevalent in mountain forests. These snakes live chiefly on small mammals, birds, tegus, and iguanas.

Anacondas (Eunectes). These boas are more aquatic than those just described. The *anaconda* (*E. murinus*) can attain a length of 9 to 9.6 meters (29.5 to 31.5 feet) and the large ones are the longest of reptiles in the world today. The *yellow anaconda* (*E. notaeus*) is considerably smaller.

Contrary to popular perceptions, most boids (excepting sand boas and a few others) cannot tolerate extremely severe heat. They prefer temperatures of 20–30 °C. Many species hibernate or estivate and can survive unfavorable seasons in a dormant state.

Colubrid Snakes

The colubrid family (*Colubridae*) contains more species than any other snake family. The relationship between the presence or absence of grooves and the individual species is evident when one inspects the venom gland, a structure that is necessarily found in every venomous snake. Venom

glands probably developed through a process of adaptation from upper lip and salivary glands. The venom glands consist of the upper lip gland (which only produces mucus) and a poison-transporting venom gland. As early as 1894, investigators demonstrated that the secretion of a single venom gland from a ringed snake is potent enough to kill a guinea pig. The mucous gland lubricates the prey; the venom gland helps prepare it for digestion.

The number of species of colubrid snakes is extensive, as is obvious from the table, and only a few of the more interesting species can be highlighted here.

Ringed Snake (Natrix natrix). These snakes reach a length of about 1 meter (3.2 feet) on the average, but some species are longer. Ringed snakes are distributed across a large area, including most of Europe and a bit of northern Africa. The snake is named for the two fairly distinct orange, yellow, or whitish moonshaped spots on the rear of the head, which look something like a ring. It is difficult today to find a ringed snake more than 2 meters (6.5 feet) long. The longer ones are usually more cautious and therefore more difficult to catch. Due to their large size, they are forced to traverse a greater area and to visit many ponds in order to find sufficient nutrition. Females wander about seeking favorable egg-laying sites (often in dung heaps). Their enemies include cats, hedgehogs, raptorial birds, and humans. Many are killed on modern highways.

When ringed snakes are threatened, they usually respond with a series of stereotyped defensive behavior patterns — flicking the tongue and hissing; releasing the content of their stink gland; defecating; or regurgitating food. Only rarely do they actually bite, and a ringed snake bite has no harmful effects for humans.

Diced Snake (Natrix tessellata). These snakes are found in central Europe and the Near East. They can achieve a length of between 75 and 100 centimeters (29.5 and 39 inches), but eastern species may be as long as 150 centimeters (59 inches). The diced snake is rather slender with a narrow head. The eyes are medium in size, are situated slightly high, and have round pupils. The top of the neck often has a dark V-shaped spot. The underside is whitish or yellowish, or it may have reddish and black spots. Some authorities believe that the diced snake is a relic from the warmer postglacial period. It is even more dependent on water than the ringed snake. It consumes a larger amount of fishes and often lies for hours or days underwater near the shore on low rocks, under which it flees when people approach. The eyes of the diced snake are well adapted to a highly aquatic life. While ringed snakes can be found considerable distances from water, the diced snake occurs in the immediate vicinity of water.

Viperine Snake (Natrix maura). This species achieves a length of over 80 centimeters (31.5 inches). Distribution is similar to that of the ringed and diced snakes. The viperine name arises from the zigzag band extending along its back, giving it a similar appearance to the common viper. The snake is harmless. Viperine snakes can be distinguished from vipers by the round pupils of the viperines. The stripe on the back of this snake sometimes appears as two rows of spots, but usually forms the aforementioned zigzag pattern. Dark spots or rings run along both sides of the central stripe, and they enclose a white or yellowish spot. Viperine snakes feed on fishes and amphibians.

Water Snakes (Natrix spp.). There are many water snakes in North America, mainly in the United States. The *diamond-back water snake* (*N. rhombifera*) is about 1.4 meters (4.6 feet) long when fully grown. The back is brown or olive-brown, with a chain of rhomboid figures. The belly is yellow and has halfmoon-shaped brown spots. Distribution is from the midwestern United States southward into Mexico. The *plain-bellied water snake* (*N. erythrogaster*) also reaches a length of about 1.4 meters (4.6 feet). The upper side is uniform black to redbrown and the underside is reddish. This snake occurs in the southeastern United States. The *queen snake* (*Regina septemvittata*) attains a length of about 50 centimeters (19.6 inches) and is similar to the plain-bellied water snake except it is more slender. This species occurs from Pennsylvania to Wisconsin. The *brown water snake* (*Natrix taxispilota*) on the average has a length up to 1.3 to 1.5 meters (4.3 to 4.9 feet) and is the largest North American water snake. It is heavy and plump and has a clearly distinguishable head. It is brown to rust-brown, with large rectangular spots. This species occurs in the southern United States. The *Brazos water snake* (*N. harteri*), reaching a length of about 90 centimeters (35.4 inches) and is known only in the Palo Pinto region on the upper Brazos River in Texas. *Kirtland's water snake* (*Clonophis kirtlandii*) reaches a length of about 45 centimeters (17.7 inches) and is a light-brown to gray snake with roundish black spots. Distribution is from the midwestern United States to Pennsylvania and New Jersey. *Graham's water snake* (*Regina grahami*) attains a length up to 60 centimeters (23.6 inches). It is dark brown with a broad yellow band on the first three rows of scales, bordered below by a narrow dark stripe. A pale stripe lined on both sides with black extends across the back, and the belly is yellowish with dark splotches. This snake occurs from Illinois to Louisiana and eastern Texas.

Water snakes generally live on fishes, anurans, and urodele amphibitans, crustaceans, and insects. Mating occurs in April and the young are born live between August and early October. Newborn common water snakes are about 22 centimeters (8.7 inches) long. With their plump body, dependence on water, and vigorous defensive behavior, the common water snake may be confused with water moccasins.

Garter Snake (Thamnophis). These snakes achieve a length of 50 to 150 centimeters (19.7 to 59 inches) and are the most prevalent colubrid snakes in North America. They are small, slender, and often considered "cute." There are several species. These ground-dwelling colubrid snakes are found throughout the 48 contiguous United States, as well as in southern Canada and northern Mexico. They are sometimes observed in urban areas. They differ from water snakes in having an undivided anal scute, and many species have three light stripes. All garter snakes are live-bearers. Some feed chiefly on earthworms, while others living near water concentrate on frogs.

Smooth Snakes (Coronella). These snakes have a small head, which is distinct from the neck. The medium-size eyes have round pupils. The scales are smooth and are arranged in rows. The group includes small to medium-size species of ground-dwelling, nonvenomous colubrid snakes distributed in Europe and Asia. Smooth snakes occur mostly in woods, inhabiting clearings, paths, forests, and particularly piles of wood and of rocks and shrub-covered ground, where they can sun themselves. That same habitat supports sand lizards, common lizards, and blind snakes and mice on which they feed. Like king snakes, smooth snakes also feed on other snakes.

Common King Snake (Lampropeltis getulus). These snakes attain a length up to 2 meters (6.6 feet). They prey upon other snakes, even poisonous ones. Their diet also includes small mammals, lizards, and fishes. When a king snake seizes another snake, it wraps its body firmly around the other animal and chokes it. Interestingly, rattlesnakes do not assume their typical position when they are brought face to face with a king snake. Instead, they press the front of the body against the ground and try to hit the king snake with another part of the body. The king snake has a light chain pattern on the back. Distribution is in the southern United States and northern Mexico.

Dwarf Snakes (subfamily Calamarinae). These small snakes are only from 25 to 30 centimeters (9.9 to 11.8 inches) long. The head is small and passes into the round, firm trunk without any noticeable neck section. There are some seven genera with approximately eight species, all from the Southeast Asian tropics, chiefly Indonesia and the Philippines. They feed primarily on earthworms and insects. They spend all their lives on the ground, concealing themselves in the soft earth beneath fallen tree stumps and rocks. Defenseless and slow, they are often eaten by other snakes.

Flying Snakes (Chrysopela). These snakes do not fly, but they drop from one branch to a lower one so quickly that it appears as though they are gliding. They attain a length up to 1.5 meters (4.9 feet). They have a longitudinal ridge on each side of the belly. The *C. ornata* has brilliant coloration with a complex pattern. These snakes are found in Indonesia and southeastern Asia.

Cobras and Sea Snakes

The cobra family contains some of the most greatly feared snakes, about which so much has been written: cobras, which perform before snake charmers; the legendary black mamba; and the colorful, red-yellow-and-black ringed American coral snakes. Two members of the family are usually thought of as being among the most venomous snakes in the world — the Southeast Asian king cobra and the Australian taipan. Cobra

species occur in every continent except Europe. The family is particularly diverse in Australia, with about 75% of all Australian snakes being in the cobra family.

There are four dangerous venomous snake families known: cobras, sea snakes, vipers, and pit vipers. These four families form two major groups. The fangs are always in front of the mouth, but in cobras and sea snakes, they have a groove, which indicates how the originally open venom canal developed over many centuries of adaptation.

The *Elapidae*, like other venomous snakes, arose from nonvenomous snakes. Their anatomy is much more like that of the colubrids than is that of the plump, short-tailed vipers. Also, in cobras the fangs are firm, relatively short structures, while in vipers the short, vertical upper jawbone and fangs are rotated back against the palate when the mouth is closed. Thirdly, cobra fangs have a closed groove, but it has a deep indentation. Finally, cobras as a rule produce neurotoxins in their venom, while viper venom generally has a hematoxic (blood poisoning) action.

Elapids are generally slender, highly agile snakes with a colubrid-like head that is not very distinct from the neck, and which bears large, colubrid-like scutes. The fangs are short, so the mouth does not have to open very wide for them to be useful. There are no other upper teeth in the highly developed species (mambas and coral snakes), while others have one or more small, ungrooved teeth behind the fangs in the upper jaw. Additional teeth are found on the palate, the pterygoid bone, and the lower jaw.

The length of these snakes varies from 30 centimeters (11.8 inches) in the bandy-bandy to over 5 meters (16.4 feet) in the king cobra. The body often has stripes that may be very colorful. Many cobras can flatten their body when they are excited, and *Naja* cobras can spread their neck ribs, forming the familiar hood. Cobras and sea snakes share a similar fang anatomy, but they differ in that cobras have a round tail. Their chief prey are small vertebrates. Several species prefer to feed on other snakes. They are ovoviviparous (live bearing, particularly in the Australian species) or oviparous (egglayers). Elapids do not constrict their prey.

The *Elapidae* contains more venomous snakes than does any other snake family. Most of them are ground-dwellers, often secreting themselves in rodent dens or burrowing in loose earth (coral snakes). A few are arboreal (mambas, cobras, and Gold's cobra), and one genus (winged water cobra) inhabits standing and slowly flowing water. Most elapid snakes are active at dusk and night and they avoid bright sunlight. There are 41 genera with approximately 180 species and 300 subspecies.

King Cobra (*Ophiophagus hannah*). This is the largest poisonous snake in the world. Specimens as long as 4 meters (13.1 feet) are not unusual, and the current record is 5.58 meters (18.3 feet). Whether the species is also the most dangerous poisonous snake is still being debated. The very large venom glands do produce a huge quantity of venom, and fatalities from king cobra bites have been recorded in Burma, India, and China. However, one should regard phrases, such as "the most dangerous venomous snake" with some skepticism. The effect of any individual bite on a human will vary with the conditions under which the incident occurs. The metabolic reactions of the person involved (death from shock has occurred, but not in every case) and the degree to which the snake is excited (usually exaggerated in reports) both play a role in the effect of a bite. It is not correct to measure potency of a snake's venom by using the number of people it has bitten. Actually, the most toxic snakes bite the least often (H.G. Petzold, 1972). Experimental studies have revealed that coral snake venom is much stronger than pit viper venom, but many more deaths are caused by pit vipers than by coral snakes because of the life habits and the prevalence of the species. See Fig. 2.

King cobras are much less aggressive than many other, smaller snakes, although one might not guess this when seeing a king cobra's hooded threat display. This display usually has a powerful effect on humans. The king cobra inhabits India, but not the nearby island of Sri Lanka. Distribution extends into southern China as far as Shanghai, Malaysia, the Sunda Islands to Bali, the Andaman Islands, and the Philippines. The head of the king cobra can grow to be near the size of a human head and coloration varies with habitat from olive-brown or gray to a deep, shining black. Forty to fifty narrow, irregular light stripes extend across the back. The eyes have a bronze hue. The two fangs are never more than 10 centimeters (4 inches) long, and there are usually three smaller upper teeth behind each of them.

The snake generally leads a secretive life. However, it feeds by day as well as by night. It prefers dense highland jungle, often near water, and in the Nilgiri Mountains of India it occurs as high as 2000 meters (6562 feet). King cobras often flee into water when they are pursued. Unlike most other venomous snakes, the king cobra is very agile and excitable. Its threat posture is almost universally known; the front of the body is raised and the loose neck skin is stretched wide as the movable neck ribs spread out. The king cobra's hood is not the disk-like rounded form of the smaller Asian cobra (also known as the Indian cobra), and the king cobra lacks the eyeglass markings. An upright king cobra can sway its forebody for several minutes, but it never does so in the swanlike manner of *Naja* cobras. However, only cobra species can move forward while it is in the threat posture. Hardly anyone would easily dismiss an encounter with a threatening king cobra, which not only assumes that characteristic posture, but also emits a high, penetrating hiss through the nasal openings.

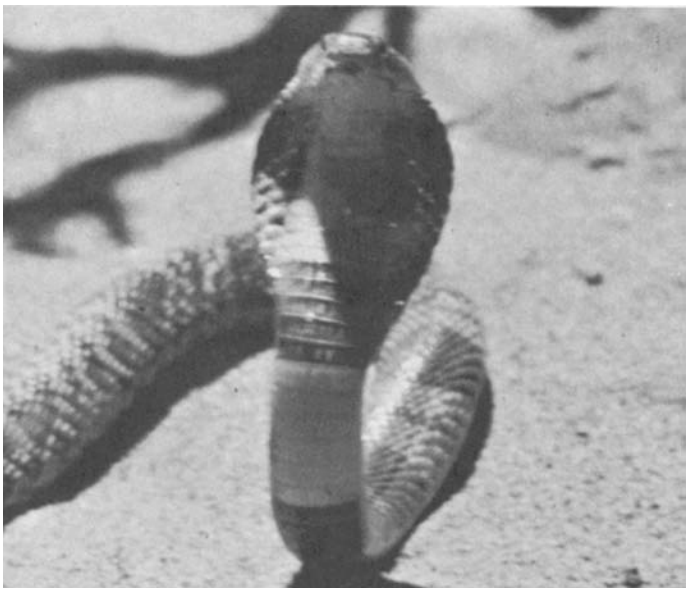

Fig. 2. Cobra. (*A.M. Winchester.*)

King cobras are especially feared during the mating season, and in India, paths and streets may be closed off by officials if a cobra nest is discovered nearby. This leads to a fascinating aspect of king cobras. The eggs are incubated. The characteristic "two-story" nest, made of foliage, was first described early in the nineteenth century. The first "story" contains the 18 to 40 white eggs; the female coils her body around them, while the male is usually stationed near the nest. Until recent years, it was believed that the snakes randomly gathered twigs that were blown about by the wind. Definitive observations were made at the Bronx Zoo (New York) of a breeding pair of king cobras. The 4-meter (13.1-foot) female grabbed bamboo shoots, branches, and foliage by slinging her forebody around them, and in two days, she had constructed a nest nearly 1 meter (3.2 feet) wide. In their Indian habitat, newborn king cobras are about 0.5 meter (1.5 feet) long and are deep black with yellowish-white stripes. Later the coloration becomes lighter and the contrast between the various hues diminishes.

King cobra venom is extremely potent. A human can die within 15 minutes after being bitten unless treated with the proper antivenin. The symptoms for king cobra poisoning are typical for the neurotoxic action of elapid venom. Victims suffer from vision disabilities and severe dizziness. This is followed by a slowing down of the reflexes and respiratory difficulties. Work elephants are sometimes killed by king cobras in India and Thailand if the snake manages to bite a tender spot, such as the tip of the trunk or the area where the toenail meets the skin. An elephant bitten by a king cobra usually will die within 3 to 4 hours.

Not every king cobra strikes at humans without provocation. In terms of the "art" of snake charming, few king cobras are used in such performances, and those that are used are generally limited to religious performances, as in Burma. The Egyptian cobra and the Asian or Indian cobra are the more typical performing snakes. Snake charming is an ancient art; the snake that Aaron charmed before the pharaoh was an Egyptian cobra. Although many charmers work with artificially cooled-down snakes

or fangless cobras, masters of the art use normal cobras. Snakes are deaf and do not dance in their baskets to the tune of their charmer's flute. With their eyes and forebody, they follow the movements of the tip of the flute and the swaying body of their master, who merely needs to move with the rhythm of his music to make it appear that the snake is dancing. The charmer knows the striking distance of the cobra as well as any professional herpetologist and adjusts himself to the snake accordingly.

True Cobras (Naja). These snakes are less surrounded by myths, but are more prevalent. The *Asian* or *Indian cobra* (*Naja naja*) is the most prevalent and occurs over a large region from central Asia through India and southern China to the Sunda Islands and the Philippines. Coloration varies more within this species than in any other; there are light-brown, brown, olive-gray, and completely black common cobras, which may have lighter stripes. Asian cobras generally reach a length of 1.5 meters (4.9 feet), with the largest ones being found on Sri Lanka.

They inhabit a number of places — from the thickest jungle to open rice paddies, city parks and gardens, sheds, bazaars, and village streets. The proportion of the body that is raised when a cobra threatens depends upon the degree that the animal is excited and varies from one-fifth to one-third of the total body length. Raising of the hood is a sign of threat and defense and, together with raising the body, shows that the snake is prepared to attack. A threatening cobra does not bite upward; its strike is not directed higher than the mouth is at the time the snake is in the upright position.

Cobras are visually oriented animals; they show little response to mechanical manipulation.

The first attempts to develop immunology and serum therapy for snake bite occurred as early as 1891. Calmette was the first to collect cobra venom for injection into small animals. The first snake serum was available in 1895. When cobras are "milked," an expert holds the snake at the edge of a Petri dish and lightly massages its venom glands with thumb and middle finger. This releases about half the venom stored in the glands; only about one-fifth of the contents are released when a cobra bites. Cobra venom is extremely potent. As little as 0.00002 gram of dehydrated cobra venom can kill a guinea pig. Theoretically, one gram of the dehydrated cobra venom is sufficiently potent to kill 140 dogs, 167,000 mice, or 165 humans. The mongoose is reputed to be immune to snake bite, but this is not true. However, a mongoose can tolerate a dose of cobra venom that is eight times the quantity that would kill a rabbit.

Mambas (Dendroaspis). This snake is more feared and infamous in Africa than the resident cobras. The most familiar is the *black mamba* (*D. polylepsis*), which attains a length of about 4 meters (13.1 feet) and is the largest venomous snake in Africa. It is characterized by lightning-quick, elegant movements in branches and by the vigor of its reactions. This large, slender snake has a narrow head, smooth scales arranged in diagonal rows, very large eyes with round pupils, and enlarged lower teeth, which, together with the poison fangs of the upper jaw, grab a firm hold onto prey, usually birds, arboreal lizards, and tree frogs.

Contrary to their reputation, mambas do not make wild attacks on harmless travelers. The snakes are shy and will flee into the foliage when people approach. Some mambas are highly territorial, and will stay in the same small area for months.

Banded Krait (Bungarus fasciatus). This is a lacquer-black snake with shiny yellow bands on a strangely ridged back, a coiled snake that lies in the shade. The slender head is hardly distinctly different from the rest of the body. The krait achieves a length of 1.5 to 2 meters (4.9 to 6.6 feet). Kraits are nocturnal and sensitive to light. They are specialists and eat almost nothing but other snakes, and they readily attack the large, powerful rat snakes, cobras, and even smaller conspecifics. The poison fangs are only 2 to 3 millimeters long and the amount of venom released (30–40 milligrams, based on measurements of dehydrated venom taken at East Berlin's zoo) is not great. However, the venom contains extremely potent neurotoxic material that paralyzes the respiratory center and can kill a human being in 30 minutes. However, it is extremely unusual for a human being to be bitten by a krait. Kraits are egg-layers.

Coral Snakes (Micrurus, Micruroides, and Leptomicrurus). These snakes usually range between 60 and 80 centimeters (23.6 and 31.5 inches) in length, seldom up to 1 meter (3.3 feet). They are characterized by their bright coloration and pattern. In the majority of American coral snakes (*Micrurus*), the only teeth in the upper jaw are the two small poison fangs, an indication that this genus is a phylogenetically recent one. Little venom is released with each bite; the maximum for the Brazilian species (*Micrurus corallinus*) is 50–200 milligrams of liquid (i.e., 60 milligrams dehydrated). Most coral snakes are in Mexico, which has about 30 species. Colombia has 28 and Central America, excluding Mexico, contains 26 species. The number of species is reduced as one moves further north or south; there are just three coral snake species in the United States; Argentina contains only four.

Coral snakes feed chiefly on lizards and small snakes and, less often, on young birds, frogs, and insects. When they bite, they "chew" several times in succession, a behavioral pattern that is rare in venomous snakes. Repeated biting increases the amount of venom injected. The swallowing of prey is a slow process, because the jaws are not very flexible. Coral snakes do not have a strong tendency to bite, and cases of bitten humans are unusual, but when they occur they are serious injuries.

The *eastern coral snake* (*Micrurus fulvius*) achieves a length up to 60 centimeters (23.6 inches) and occurs from southeastern United States to Mexico and is one of the most prevalent species. It often inhabits rodent dens, where its bright coloration makes it stand out. The snout is black. This species assumes a curious defensive position when it is irritated. The head is hidden; the short tail is raised several centimeters and moved back and forth.

The *Arizona coral snakes* (*Micruroides euryxanthus*) also attain a length of about 60 centimeters (23.6 inches). These snakes inhabit arid terrain. Arizona coral snakes have a small, smooth tooth behind each poison fang. This species has red, yellow, and black bands. It is interesting to note that nonpoisonous colubrid snakes in North, Central, and South America bear the same red, yellow, and black ring markings as the poisonous coral snakes. However, the distinction between the harmless and dangerous snakes is rather easy to make in the case of North American snakes. In the coral (dangerous) snakes, a yellow (or white) ring is always bordered by a red one, while in the harmless colubrid snakes, such as the brilliantly colored milk snake (*Lampropeltis doliata syspila*), red and yellow are separated by a black ring. The problem of identification is more difficult in South America because of the presence of "true" and "false" coral snakes, which have nearly identical markings.

In Australia, where elapids are particularly prevalent and diverse, there are numerous small, primitive, slightly potent species. There are as well some species that are among the most dangerous members in the entire family. Their bite can be fatal to humans. They include the *taipan* (*Oxyuranus scutulatus*), which attains a length of 3 to 4 meters (9.8 to 13.1 feet). This is the most poisonous of Australian snakes. It inhabits remote coastal stretches of northern Australia and New Guinea, as well as the islands of the Torres Strait. The snake is brown to brown-black, and melanistic individuals have been found in New Guinea. About 80% of taipan bites are fatal unless antivenin is administered in time. Even with serum injections, many people die. It has been reported that a riding horse in northern Queensland died within five minutes after being bitten by a taipan. The species has long poison fangs. The venom not only paralyzes the central nervous system, but also destroys red blood corpuscles.

When preying (chiefly on rats), the taipan makes several bites in rapid succession. The snake often remains in rat holes and is active early in the morning and late in the evening.

The gray-brown, dark-banded *death adder* (*Acanthopis antarcticus*) is a large Australian elapid, which attains a length of about 80 centimeters (31 inches). It is one of the more prevalent elapids in Australia and New Guinea. The appearance is much like that of a viper. It has keeled scales and, unlike nearly every other cobra species, has a broad, clearly distinct, nearly triangular head (usually a characteristic exclusive to vipers). When excited, the death adder can inflate itself into a sausage shape. Its venom (up to 236 milligrams of liquid per milking) is more potent than cobra venom. Although the bite of a death adder leaves practically no mark, about half of all untreated bites in humans result in death due to respiratory arrest. Death adders are chiefly active at dusk. Australian farmers intensely dislike the species, because their sheep are in areas where the snake is most prevalent (central and western Australia), and a sheep that steps on a death adder will probably die, because the snake reacts by biting the animal. Female death adders bear from 10 to 12 live young.

Sea Snakes (Hydrophiidae). These snakes have the same basic characteristics as the *Elapidae*. However, they have some unique features that

reflect their marine existence; the tail is laterally compressed and forms a rudder-like structure. The trunk, particularly the rear portion, also is often laterally compressed. The scale covering is nearly uniform. These highly specialized marine inhabitants have lost the broad ventral scutes seen in terrestrial snakes, so the scales are nearly the same all over the body. The external nasal openings are on the top of the head and can be closed by a valve. Sea snakes have salt glands in the head for eliminating excess salt.

Most sea snakes belong to the subfamily *Hydrophiinae*, which contains 13 genera. Members of this subfamily share the paddle-shaped tail with all other sea snakes. These snakes have lost all dependence upon terrestrial life, and never go on land. Body musculature is degenerate. The strong current in the water takes over much of the work that the muscles would otherwise have to provide. Heavy specimens are rather helpless on land and can suffocate since their vestigial supporting muscles cannot even fill the lungs with air. One of the biological puzzles is the striking similarity in body shape, coloration, and patterning between several moray-like fishes and various sea snakes of the Indian and Pacific Oceans.

Vipers

Two snake families, whose venom apparatus has reached an impressive degree of effectiveness, are at the peak of phylogenetic development of the large suborder of snakes. Their poison fangs have no sign of grooves; they are solenoglyph teeth, which means that they actually have enclosed canals within the fangs that transmit the venom out of the body, very much like a hypodermic needle. Furthermore, members of these two families, excepting just a few species, have lost the large head scutes found in colubrid snakes and cobras and instead have many small scales on the head. These families are the vipers or adders (*Viperidae*) and the pit vipers (*Crotalidae*). Pit vipers are considered to be a distinct family because of their unique pit organs.

Vipers are found only in Europe, Asia, and Africa. Australia lacks both vipers and pit vipers, an indication that both families are phylogenetically recent, developed after the Australian continent became a separate land mass. Whether vipers developed from cobra-like ancestors or directly from nonvenomous colubrid snakes remains obscure. It has been well established that vipers arose somewhere in western Asia.

The most important distinguishing characteristic of the venom apparatus in vipers is that the two upper jaws, which bear the fangs, are greatly shortened. Each upper jaw has a special joint that permits the jaw, along with the fang anchored firmly within it, to rotate 90 degrees. If the viper closes its mouth, the fangs lie back, tips inward, and are covered by a fold in the mucous membrane. When the mouth is opened, a lifting mechanism is activated, putting the fangs into a vertical position. The fangs (or more precisely, the upper jaw bones) are laid back with the same action as when a pocket knife is snapped together. The adaptation of folding back the fangs permits them to be extremely long, far exceeding the length of those in cobras. The fangs of the giant king cobra are not much longer than those of the rather small adder. The long fangs enable vipers to bite deeply into the tissues and cause the victim to suffer severe necrosis. The fangs snap back into the mouth after they are withdrawn from the victim.

Viper venom contains mainly hematoxic materials (substances that injure the blood and associated vessels). Thus, a viper bite has a very different effect from a cobra or mamba bite (their venoms being neurotoxic). Viper bites are accompanied by prominent local irritation and symptoms of severe blood poisoning, with burning pain, inflammation, pronounced discoloration, sudden drop in blood pressure, internal bleeding, degeneration of the tissues, and the formation of an abscess. Death ensues because the heart stops, not as the result of respiratory arrest as in the case of cobra bites.

Vipers or adders are generally compact, sturdy snakes. The head is triangular and is distinct from the rest of the body. Their length ranges from 30 centimeters (11.8 inches), as in the case of the dwarf puff adder, to about 180 centimeters (5.8 feet), as in the Gaboon viper. The pupils are usually vertical and elliptical. All face bones are movable. Each of the two shortened, retractile upper jaw bones bears only the tubular venom fang (which can only be activated for a short period) and often one to several significantly smaller reserve teeth of various sizes, none being a firmly positioned poison fang. The tail is short, and coloration is usually drab. In the genus *Vipera*, it is often of a dark zigzag pattern or a rhomboid band along the back. Desert species are sand-yellow, while jungle vipers often have a colorful carpet marking. There are 10 genera with 60 species and 110 subspecies.

Some vipers inflate their bodies into sausage shapes when excited. Almost all vipers assume a plate-shaped coiled position as a threat gesture, in which they lift up the neck and hold it in an S-shape. Other threat behaviors include loud hissing and rapid, forward jerks of the head. Some sand dwellers, such as the saw-scaled viper, create a particularly impressive sound by rubbing their scales together. Vipers feed chiefly on small vertebrates, particularly rats, mice, and lizards and less often on frogs and birds, paralyzing or killing their prey by biting it. Some of the smallest vipers prefer locusts. Many vipers are useful for controlling rodent pests.

The true vipers (*Vipera*) are distributed in Europe and Asia, with 8 species and, in Africa, with 4 species. The *adder* (*Vipera berus*) attains a length of 50 to 60 centimeters (19.7 to 23.6 inches), seldom over 80 centimeters (31.5 inches). The adder can tolerate the coldest climates of any viper species. Its distribution essentially follows that of deciduous forests, mixed forests, northern pine forests, and high-altitude forests. In Europe, the species occurs as far north as the Arctic Circle and also inhabits the Carpathian, Balkan, and Caucasus Mountains. The *asp viper* (*V. aspis*), about the same size as the adder, occurs chiefly in the Mediterranean region, extending northward as far as the southernmost part of the Black Forest of Germany and moving from there into central France and western and southern Switzerland.

Adders do not have the compact appearance of many other vipers. The head is only slightly broadened toward the rear and it is covered with rather large scales. Basic coloration in males is gray; in females, brown. Adders hibernate underground at a site which is moist, but protected from flooding. Live-bearing (ovoviviparity) permits the adder to penetrate far north and high up on mountains. The number of young varies between 6 and 20. Two vipers are seldom found together outside the mating season, although their home territories overlap and they may live within several meters of each other. Vipers hunt by lying in wait and grabbing appropriate prey that passes within striking distance. The chief enemies of European vipers are serpent eagles and the hedgehog.

Attempts to find snake antivenins were being made in antiquity, but truly effective venom antidotes were not developed until the end of the 19th century with the work of Calmette, as previously mentioned in connection with cobra antivenom, and the work of Phisalix and Bertrand, who produced asp viper antivenin at about the same time. Asp viper antivenin became available in 1896. The *sand viper* (*Vipera ammodytes*), which attains a length up to 90 centimeters (35.4 inches), is found in southeastern Europe and is the most dangerous (venomous) snake in Europe. Sand viper bites cause fatalities in remote parts of the Balkans. However, its venom does not compare with the potency of that in cobras or rattlesnakes.

The Gaboon viper, from the jungles of western, central, and eastern Africa is the largest of all vipers. It is the most prevalent of venomous snake species in the mountains of Cameroon. Its patterning is like that on ornate Oriental carpets; the deep purple-brown background has geometrical patterns in yellow, light brown, and blue, usually in an hourglass arrangement along the sides with long, rectangular, deep-purple bordered rings. The pale-brown head with its dark medial line has a chocolate-colored wedge-shaped spot whose tip extends to the eyes. With most exceptions, Gaboon vipers are docile and do not readily bite.

Pit Vipers

Pit vipers and vipers share a common extinct ancestor. Pit vipers probably arose once the egg-laying vipers had evolved and were developing along that line. Pit vipers survived because their new organ, the pit organ, was biologically successful, and this recent snake group is still evolving. More than two-thirds of all pit vipers inhabit the Americas, but their origin is probably in tropical Asia, where vipers and pit vipers occur together. There are no pit vipers in Africa or Australia, but the species has reached the southeastern edge of Europe, on the Caspian Sea.

In pit vipers, the pupils are vertical and elliptical. The fangs are long and solenoglyph (tubular). They often remain inside the prey, and may be excreted in the pit viper's feces. Fangs are replaced two to four times annually by reserve teeth. Contractions of the muscles surrounding the venom glands control the amount of venom released and direct the venom via a mucous membrane covering to the teeth. Their length varies

from 40 centimeters (15.7 inches) to 3.75 meters (12.3 feet). Coloration is typically gray, brown, or olive with a distinctive light-dark diamond pattern or dark spots. There is often a dark band extending from each eye to the corner of the mouth. Arboreal pit vipers (with prehensile tails) are green or yellowish. Behaviorally, pit vipers resemble vipers, but the threat posture consists of slightly flattening the body and rolling it together into a spiral, and then lifting the forebody from the ground and bending it into an S-shape. The end of the tail is also raised, and tail shaking occurs even in those pit vipers lacking rattles. The rattling is a warning reaction. The diet is the same as that of the vipers.

Venom in most pit vipers contains hematoxins like that of vipers. The tropical rattlesnake is an exception. Since pit vipers play a more significant role in North and South America than vipers do in Europe, organized medical aid for bitten people is more extensive in the Americas. The Instituto Butantan, near São Paulo, Brazil, was the pioneer establishment for dealing with the treatment of venomous snake bites. In 1901, Mineiro, who had gained fame by combating typhoid and pestilence epidemics in Brazilian ports, was assigned the task of establishing a serum therapeutic institute for the State of São Paulo.

All pit vipers have a deep pit between the nostril and the eye; its opening is larger than the nostril but smaller than the eye. The pit, which has been depicted in old Indian drawings, lies in an indentation of the upper jaw bone. Scientists puzzled for decades over the meaning of these pits. As early as 1824, it was known that tiny nerves lead to them, and that the pits were therefore sensory organs. But there were arguments over just what sense modality they served. It was not until the late 1930s that most of the mysteries were cleared up. It is now established that the pit organs are heat-detecting sensors. They do not function like a thermometer, as once thought, but respond to temperature differences between the inside of the snake and the outside. Sensitivity has been suggested as being a small fraction of one degree Celsius. With this organ, the pit viper can sense the presence of warm-blooded prey at a distance up to 50 centimeters (19.6 inches). The pit organ is particularly helpful at night when the difference between the temperature of the prey and the ambient temperature is the greatest.

Rattlesnakes (Crotalus). These snakes are among the best-researched and most impressive snakes known. All rattlesnakes have the rattle at the tip of the tail. The biological function of the rattle was discussed for many years. The hard, dry, chain-like, loosely jointed rattle elements at the tail tip are the remains of previous moltings. See Fig. 3. In newborn rattlesnakes, the tail ends in a spherical scale. While all other snakes cast off this terminal scale at every molt, rattlesnakes do so only at their first molt, which occurs 7 to 10 days after birth. This last scale hardens into a piston-like hollow structure before the onset of the second molting; it has a ring-like construction. During subsequent molts, this last scale loosens like all the others, but it is not cast off. In the meantime, a new terminal scale has developed from inside this first one, and the new one has a greater diameter and holds the first one. Another terminal scale develops at the next molt, and so it goes, adding more and more rattles to the chain. Each of the hollow, pod-like scales in the chain of rattles was, at one time, the closest to the snake's body. Thus, contrary to widespread popular concepts, the number of rattles does not indicate the rattlesnake's age in years. They show how many times the snake has molted and rattlesnakes molt at an average of three times each year. Rattles tend to break off and with an irregular molting schedule, there is no direct connection between number of rattles and a snake's age. Rattlers can shake their tails much faster than a human eye can perceive — up to forty or 60 cycles per second. The sound is more like a hissing buzz or whir than a rattle. The rattlesnake does not hear its own rattling because it is deaf. The most likely meaning of rattling is that it is a warning sound used to intimidate enemies — a tool for upsetting the enemy. One exception to the foregoing is the Santa Catalina rattlesnake (*Crotalus catalinensis*), which does not have rattles.

Most species of rattlesnakes prefer dry, rocky, shrub-covered terrain, where they can conceal themselves inside crevices in the rocks or in mouse holes. Forest dwellers are more active during bright daylight hours than are species that inhabit more open country. Northern species often hibernate in large groups. A single mass winter quarter can support rattlesnakes from a large region and usually the same site will be used year after year. Northern populations of prairie rattlesnakes have been known to form groups numbering 200 to 300 on the average, but sometimes up to a thousand snakes. Rattlesnakes often share their quarters with nonvenomous snakes. Symbiotic relationships also occur among rattlesnakes, burrowing owls, and prairie dogs.

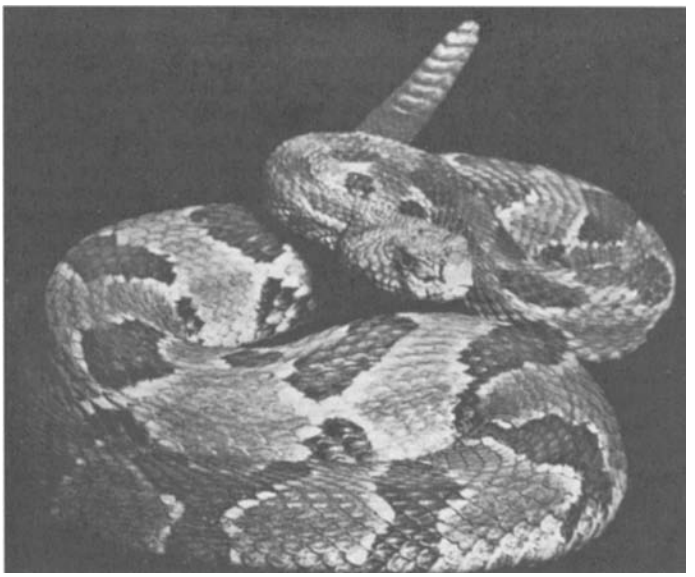

Fig. 3. Rattlesnake. (*A.M. Winchester.*)

The diet of American rattlesnakes consists of mammals, primarily white-footed mice, pocket mice, voles, wood rats, and chipmunks. Large rattlers also may feed on ground squirrels and wild rabbits. Birds, such as domestic chicks and quail, are eaten less frequently.

Mating occurs in the spring in the southern United States. All rattlesnakes bear live young, born between August and October. Further north, especially in Canada, litters are born every other year in June and July. Most species bear 8 to 15 young per clutch.

Eastern Diamond-Back Rattlesnake (Crotalus adamanteus). This is the largest of all rattlesnakes and achieves a length up to 2.5 meters (8.2 feet) and a weight of 10 kilograms (22 pounds). This massive snake with its light-edged diamond figures is one of the most dangerous venomous snakes, chiefly because of the large amount of venom it produces. In a single 'milking,' this snake can yield 1050 milligrams of liquid venom (equal to 300–500 milligrams of dehydrated venom).

Western Diamond-Back Rattlesnake (Crotalus atrox). This snake attains a length of 2.2 meters (7.2 feet), but usually is somewhat shorter. The snake is aggressive and easily excitable and causes the majority of fatalities from snake bite in the United States. The species is useful in controlling rodents. The species is highly fertile, bearing 10 to 20 young at a time.

Prairie Rattlesnake (Crotalus viridis). This is a greenish-olive snake with longitudinal rows of round, brown spots. It is one of the most widely distributed of the rattlesnakes and exists in many subspecies. It is found in the Sierra Nevada mountains in California up to 4,000 meters (13,124 feet) and extends as far north as Canada. These snakes live primarily on mice.

Sidewinder (Crotalus cerastes). This small rattlesnake achieves a length of 60 to 70 centimeters (23.6 to 27.6 inches). Its sidewinding movement is an adaptation to desert life. Sidewinders can move at speeds of 3–4 kilometers (1.8–2.5 miles) per hour, making it one of the speediest of all rattlesnakes. It is almost purely nocturnal. Sidewinders are not particularly venomous; their prey includes other reptiles, especially smooth-throated lizards and whiptail lizards.

Tropical Rattlesnake (Crotalus durissus). Also called the cascaval or South American rattlesnake, this is probably the most dangerous of the rattlesnake species. Its venom contains substantial amounts of neurotoxic material. It is estimated that a cascaval bite is about as potent as a puff adder and cobra bite combined. A very special antivenin was developed in order to lower the death rate from bites in South America, particularly in Brazil. Approximately 75% of all untreated adults bitten die from a cascaval bite. A peculiar aspect of a cascaval bite is paralysis of the neck muscles of the victim. This causes the head to suddenly drop to one side. Severe neural

disturbances later appear, including auditory and visual impediments that lead to blindness and unconsciousness.

The Agkistrodon Snakes. Much more is known about American *Agkistrodon* snakes than about the Asian species. They are as familiar to Americans living in the southern and eastern United States as are rattlesnakes. The most important of the American *Agkistrodons* include the cottonmouth or water moccasin, and the copperheads.

Cottonmouth or Water Moccasin (Agkistrodon piscivorus). This is a compact, powerful snake and is treated with great respect when it is encountered in rice fields in the southern United States. A cottonmouth bite is seldom fatal, but it has extremely unpleasant consequences. The popular name is due to the white inside of the jaw, which is visible when the snake is irritated, the open mouth being a threat gesture. Large cottonmouths are a deep blue-black, quite unlike the juveniles, which have jagged, red-brown, light-edged bands on a flesh-colored background. Five to 15 young are born after a long gestation period. Females reproduce every other year.

Cottonmouths often stay in swamps and on low branches overhanging the water. They swim well and flee into the water when alarmed. The species is not a true aquatic snake, since it does not catch most of its prey (frogs and fishes) while swimming, but rather by lying in wait on the shore. Cottonmouths apparently form pairs frequently, as shown by studies on several islands off Florida. Like rattlesnakes, they often winter in groups.

Copperhead (Agkistrodon contortrix). Although the fatalities from snake bites in the United States are mainly attributed to the western diamond-back rattlesnake, the number of incidents is greater from copperhead bites. The copperhead attains a length up to 1 meter (3.2 feet) and is distributed in four subspecies across many eastern and southern states. Copperheads are strikingly colored, beautiful snakes whose bands, arranged in an irregular zigzag, may be narrow or broad and red-brown or cinnamon on a gray or pinkish background. The top of the head is a light reddish-brown. This may be an adaptation to their favorite habitat, which is foliage-covered forest floors. They adapt their coloration to their background. Copperheads are extremely adaptable snakes. In some heavily populated areas where rattlesnakes disappeared many years ago, such as along the Hudson River in New York State, copperheads are still prevalent. Copperheads winter in groups, frequently with rattlesnakes. A female bears 8 to 12 live young, which have sulfur-yellow tail tips.

SNAPPERS *(Osteichthyes).* Of the order *Percomorphi*, family *Lutianidae*, snappers prefer tropical shallow inshore waters and usually occur in large schools. They possess bright, iridescent coloration, usually of blue, red, and yellow shades. They are known to migrate over great distances in search of food. They are carnivorous. They are an abundant fish and particularly in the Indo-Pacific region. The *Ocyurus chrysurus* (yellowtail snapper) is found in the tropical Atlantic and attains a length of about 2 feet (0.6 meter). The *L. synagris* (spot snapper) and *L. analis* (muttonfish) are found in American Atlantic waters. The established reputation of snappers as good food fishes has been tarnished from time to time by outbreaks of tropical fish poisoning, largely attributed to certain species of snappers. The poisonous qualities, however, appear to vary with particular region and time of year. Snappers considered in the poisonous category include: *Lutjanus bohar* (onespot snapper); *L. gibbus* and *L. vaigiensis* (red snappers); and *Aprion virescens* (blue-gray snapper). See also **Foodborne Diseases**.

SNELLEN EYE CHART. The Snellen Eye Chart is the standard used in measuring the eye's ability to distinguish detail and shapes (visual acuity). The chart is based on the work of a Dutch ophthalmologist, Dr. Hermann Snellen, who in 1862 designed this system for describing human vision.

The Snellen Chart is made up of a series of letters, numbers or symbols of progressively smaller size, the largest at the top. "Normal" vision is 20/20. A person who can clearly read a one-inch letter at a distance of 20 feet is considered to have normal vision. All measurements obtained from use of the Snellen Chart are a comparison to that standard. Persons who have 20/40 vision, for example, can read at 20 feet what people with normal vision can read at 40 feet.

Visual acuity is normally checked before proceeding with any other part of an eye examination, including administering any medications to the patient's eyes. The patient is allowed to keep on any eyeglasses or contact lens and is positioned 20 feet in front of the Snellen Eye Chart. Covering one eye at a time, the patient is asked to read progressively smaller letters until it is no longer possible to read the small letters. Then the test is repeated with the other eye.

The Snellen Eye Chart measures only visual acuity. It does not prove the absence of an eye disease or any other eye problem. See also **Visual Acuity**.

SNELL, GEORGE DAVIS (1903–1996). George Snell was an American immunogeneticist who discovered the major histocompatibility complex (MHC), which governs tissue transplantability and plays an essential role in the lymphocyte-mediated recognition of foreign antigens.

Snell was born in Minnesota, the youngest of three children, but moved to Massachusetts as a young man. Science, mathematics, astronomy and physics were his favorite subjects during his school years. His lifelong interest in genetics was ignited by his teacher, Professor John Gerould at Dartmouth College. On his advice, Snell enrolled as a graduate student with Harvard Professor Castel, the first American biologist to study Mendelian inheritance in mammals. Two years as a postdoctoral fellow in the laboratory of Herman Muller, who received the Nobel Prize for discovering the mutagenic effect of X-rays, prompted Snell's decision to devote himself to the genetics of the most readily accessible mammal, the mouse. In the early 1930s Snell joined the Roscoe B. Jackson Laboratory in Bar Harbor, Maine, where the first highly inbred strains of mice were developed, after more than a decade of brother sister mating. See also **Muller, Hermann Joseph (1890–1967)**.

Experiments were performed on the role of genetic factors for the development of cancer. Tumor cells were also transplanted from cancerous to healthy mice. Snell found that transplanted tumors grew progressively in all mice of the same strain, but were rejected in foreign strains. Crossing experiments showed that the tumors could grow only if the donor and the recipient shared certain dominant genes. He called them *histocompatibility genes* or H genes. In the absence of such identity, the tumor cells were killed by host lymphocytes. Snell also realized that the transplantability of normal tissues was regulated by the same genes. The mouse has at least 30 different H genes. Their identification and analysis was entirely based on Snell's monumental work on developing a spectrum of "congenic resistant" (CR) substrains that differed from the standard inbred line by only a single H gene.

Differences at some H loci generated stronger rejection responses than others. The strongest gene, which played the dominating role for rejection, was called H-2. Together with the English immunologist, Peter Gorer, Snell developed serological methods for the study of H-2. The system was highly polymorphic in the mouse. Jean Dausset, with whom George Snell shared the 1980 Nobel Prize in Medicine, applied similar methods to study the human counterpart of H-2, designated HLA. Later, H-2 and HLA were collected under the term MHC (major histocompatibility complex). In addition to its role as the most important gene for tissue rejection, MHC was found to be decisive for lymphocyte-mediated (CTL, cytotoxic T-cell) recognition of antigenic cells of all kinds, including virally infected and cancer cells. MHC differences also play an important role in determining susceptibility to certain diseases. See also **Immunology (The History)**.

After his retirement, Snell turned to his second major interest. During his summer stays at Woods Hole Oceanographic Institution, Massachusetts in the beginning of his career, he became interested in the evolution of social insects. This prompted his later interest in the question whether Christian ethics can provide a biological advantage to the human species after it has reached a certain level of organization. This was the main topic for his work after retirement.

SNIPE FLY *(Insecta, Diptera)*. A two-winged fly with long legs and a conical abdomen. It belongs to the family *Rhagionidae*, sometimes called *Leptidae*. Some of the species suck blood, and in the western part of the United States are very annoying to human beings. This insect receives the name deer fly in the west, a term applied to a small horsefly in the east.

SNOW. See **Precipitation and Hydrometeors**.

SNOW AND SNOWMELT. Snow is a solid form of precipitation. The formation of snow crystals inside a cloud depends on the presence of ice nuclei, water vapor, motion of the cloud, and the temperature of the cloud. Snow crystals are formed when the cloud temperature is below freezing. These crystals experience diffusional, accretional, and aggregational growth inside the cloud. At temperatures greater than about $-5\,^{\circ}\mathrm{C}$ ($23\,^{\circ}\mathrm{F}$), crystals usually stick together, and aggregation of ice crystals forms snowflakes. Snowflakes obtain their maximum size when the temperature of a cloud is near $0\,^{\circ}\mathrm{C}$ ($32\,^{\circ}\mathrm{F}$). Aggregation of ice crystals ceases at temperatures below $-20\,^{\circ}\mathrm{C}$ ($-4\,^{\circ}\mathrm{F}$). Due to changes in the ambient condition of the cloud, the size and form of the crystals change when they descend through a cloud. In a typical cloud, a snowflake of 1 mm (0.04 in) diameter can grow to 10 mm (0.39 in) in about 20 minutes. Because of the irregular shapes of snowflakes, measurement of their linear dimensions is difficult. The maximum diameter of snowflakes may range from 0.1 mm (0.01 in) to several centimeters (1 in).

Snow falls from the clouds mainly in the form of branched hexagonal crystals or stars. Other observed shapes include hexagonal rods, needles, and plates. Snowflakes have a large surface area and fall slowly compared with raindrops. Therefore, snowflakes scavenge more atmospheric aerosols than rain. Precipitation as snow occurs when the atmospheric temperature is near $0\,^{\circ}\mathrm{C}$ ($32\,^{\circ}\mathrm{F}$) or less. Compared to rainfall, snowfall occurs more uniformly, but its distribution on the ground is highly influenced by wind. To obtain the water equivalent of snow, the actual depth of snow unaffected by wind and its density are needed.

Accumulation of snow on the ground leads to the development of a snowpack, which stores water in the form of snow. Depending upon climatic conditions, snow on the ground can stay for a period as long as several months. The global distribution of snow shows that a major portion of the Northern Hemisphere is covered by snow during winter. Snow has great scientific interest because of its practical importance and utility in many fields, especially, in water resources, climate, and winter sports. For many countries, such as the United States, Canada, India, China, Pakistan, Afghanistan, Russia, Nepal, and European countries, snowmelt runoff is a vital source of water for drinking, irrigation, and hydropower generation. Several important rivers, such as the Columbia River in the United States and Canada, the Rhine River in Europe, and the Indus River in Asia, get substantial contributions from snowmelt runoff. Melting snow provides more than 70% of the water supply for the western United States.

In general, snow starts melting in the spring when the temperature begins rising. The depth and extent of the snowpack is reduced due to snow melting, and water is released from the snowpack. Snowmelt runoff estimates are needed for forecasting seasonal water yields, river regulation, reservoir operation, determination of design floods, design of hydrologic and hydraulic structures, and planning flood control programs. The snowmelt is estimated either using the energy balance approach or the temperature index method. The energy balance method requires information on radiation energy, sensible and latent heat, energy transferred through rainfall onto the snow, and heat conduction from the ground to the snowpack. When all the components for an energy balance computation are known, the melt rate can be expressed as

$$M = \frac{1000 Q_m}{\rho_w L \beta} \tag{1}$$

where M is the depth of melt water (mm d^{-1}), Q_m is the net energy flux available for melting (kJm^{-2} d^{-1}), L is the latent heat of fusion (333.5 $\mathrm{kJ\,kg}^{-1}$), ρ_w is the density of water (1000 $\mathrm{kg\,m}^{-3}$), and β is the thermal quality of the snow. The thermal quality of snow depends on

the amount of free water content (generally 3–5%) and the temperature of the snowpack. Assuming $\beta = 0.97$ for a thermally ripened snowpack, Equation 1 reduces to

$$M = 0.0081\,Q_m \tag{2}$$

Snowmelt follows an almost diurnal pattern of energy availability, and thus, it is possible to determine the diurnal variation in snowmelt by applying the diurnal distribution of energy received on the snow surface. The albedo, the most important parameter controlling the absorption of solar radiation, is very high for snow. For fresh snow, the albedo is about 0.80–0.90, suggesting that most of the short-wave radiation is reflected back to the atmosphere from the snow surface.

In the absence of detailed energy data for computing snowmelt, the temperature index method is considered the best substitute for the energy balance and is widely used. The air temperature, expressed as degree-days, is used for snowmelt computation. Temperatures are the most readily available data; therefore, the temperature index method is extensively used. The most common expression for estimating snowmelt using temperature is given as

$$M = D(T_i - T_b) \tag{3}$$

where M is the depth of melt water (mm d^{-1}) produced in unit time, D is the degree-day factor (mm $^{\circ}C^{-1}$ d^{-1}), T_i is the index air temperature ($^{\circ}C$ (32 $^{\circ}F$), and T_b is the base temperature (usually, 0 $^{\circ}C$ (32 $^{\circ}F$). Daily mean temperature is most commonly used as an index of temperature for snowmelt. The degree-day factor is used to convert the degree-days to the depth of snowmelt. A wide range of degree-day factors (0.7–9.2 mm $^{\circ}C^{-1}$ d^{-1}) has been reported in the literature. However, the majority of the reported values of the degree-day factor range from 3–5 mm $^{\circ}C^{-1}$ d^{-1}. The degree-day factor is influenced by the physical properties of the snow and, therefore, changes with time. Usually, temperature data used for melt estimation are available at a few locations in a basin. These available temperatures can be interpolated/extrapolated to different altitudes using the temperature lapse rate (usually, 0.65 $^{\circ}C$/100 m).

Snow melts on the upper surface of the snowpack exposed to the atmosphere. In some cases, a little melting is also possible from the lower surface of the snowpack due to ground heat transfer. Snow is a porous medium, and melt water generated on the surface percolates through the snowpack before appearing as runoff. In the beginning of the melt season, the upper part of the snowpack may be warm (0 $^{\circ}C$ (32 $^{\circ}F$), but the lower part may be cold (subfreezing). Under such conditions, melt water produced on the surface may freeze in the snowpack to raise the temperature to 0 $^{\circ}C$ (32 $^{\circ}F$). Unless the whole snowpack is isothermal at 0 $^{\circ}C$ (32 $^{\circ}F$), no melt runoff is produced.

SNOWFLAKE. Colloquially an ice crystal, or more commonly an aggregation of many crystals that falls from a cloud. Simple snowflakes (single crystals) exhibit beautiful variety of form, but the symmetrical shapes reproduced so often in photomicrographs are not found frequently in snowfalls. Broken single crystals, fragments, or clusters of such elements are much more typical of actual snow. Snowflakes made up of clusters of crystals (many thousand or more) or crystal fragments may grow as large as three to four inches in diameter, often building themselves into hollow cones falling point downward. In extremely still air, flakes with diameters as large as 10 inches (25 centimeters) have been reported.

SOAP. See **Colloid System**.

SOAPS. Chemically, a soap is defined as any salt of a fatty acid containing 8 or more carbon atoms. Structurally a soap consists of a hydrophilic (water compatible) carboxylic acid which is attached to a hydrophobic (water repellent) hydrocarbon. Soap molecules thus combine two types of behavior in one structure; part of the molecule is attracted to water and the other part is attracted to oil. This feature underlies the function of these materials as surface active agents, or surfactants. Soaps are one class of surfactants. The other classes generally are called detergents. See also **Detergents**.

Soap is one of the oldest known manufactured chemical substances and was first produced over two thousand years ago through the reaction of animal fats with the ashes from plants. Initially soaps were used primarily for the cleansing of clothing. The earliest documentation of their use as a medicament and for personal hygiene did not appear until the beginning of the second century. Details of the subsequent development of soap making are rare but by the Middle Ages soap making was prevalent across Europe. By this time soap-making had moved on from a cottage industry into an industrial process. Two types of soap were available depending on location. Coastal producers used ash from sea weeds which was rich in sodium carbonate, and hence made hard soap directly. In contrast, central European makers used wood ash which was rich in potassium carbonate, and produced soft soaps or used salt to convert this into hard soap. This situation prevailed until the late eighteenth century when Leblanc developed a low cost process for the manufacture of soda ash which removed the restriction of cost on hard soap production.

By the late nineteenth century the basic chemistry of soap making was understood and the principles of kettle soap-making were essentially in place. The next major developments had to wait until the early twentieth century when physical chemists studied the detailed phase behavior of soap and in parallel Wigner identified a quantitative approach to soap making. In combination these activities paved the way for continuous soap making operations using a wide range of oils/fats.

Current mass market soap manufacturing is based primarily around continuous soap making using either fat saponification or by fatty acid neutralization, utilizing a wide variety of natural and synthetic feedstocks. The soap chips produced are then usually finished using a high speed soap line comprised of refiner mill, extruder, and stamper. Batch processing is much rarer and is mainly confined to speciality soaps which often sell at a considerable premium. Examples of such products are high transparency cast bar products.

The strict definition of the term "soap" includes all compounds formed by interaction of either an inorganic or organic base with an organic fatty acid. This general description hence covers chemicals with a wide range of physical properties spanning water soluble to water insoluble. For instance the use of heavy metals or alkaline earth metals produces water insoluble soaps, many of which have industrial uses. However the most important sub-group of soaps are those that display surface activity (such molecules are known as "surfactants" from the description surface active). These soaps are usually based on combinations of alkali metals such as sodium and potassium and linear alkyl chain carboxylates. These simple metal alkyl carboxylates represent the oldest surfactants known. The term surfactant describes molecules which are comprized of two separate groups, one which is water-loving and the other which is water-hating. This combination of properties is responsible for classical surfactant behavior such as interfacial adsorption, lather and emulsion stabilization, detergency and surface wetting. All of these phenomena are due to the balance of hydrophilic/hydrophobic characteristics operating in surfactant molecules.

In the twentieth century, many new synthetic surfactants were developed. These can be manufactured from either the traditional oils and fats used for soap making or from petrochemicals. These surfactants may have advantages over soap, including mildness to skin, high water solubility and most importantly they may not be precipitated by calcium and magnesium ions. The first two of these have led to the growth of liquid products such

as shampoos, shower gels and body washes where the use of soap can lead to precipitation at low ambient temperatures. The precipitation of soap by calcium and magnesium ions is a major issue for soap since these ions are present to some degree in all surface waters. The common term for these ions is water hardness. Thus in hard water which contains significant amounts of both calcium [CAS: 7440-70-2] and magnesium [CAS: 7439-95-4] ions, soap is precipitated as scum. This reduces cleaning efficiency and also lays down an insoluble layer of these precipitates on solid surfaces known as lime-scale. This problem has led to full or partial replacement of soap by new synthetic surfactants in formulations for use in hard water conditions in personal washing, and particularly in laundry washing where build-up of the precipitated soaps will change both fabric appearance and feel over time. In contrast in the bar form products, the move to synthetics has been minimal due to the immense difficulty in incorporating high levels of synthetic surfactants which are either liquids or have paste-like rheology in their anhydrous state.

Properties

A surfactant is a bipolar surface active molecule composed of hydrophilic and hydrophobic groups. For soap molecules, the carboxylate head group, negatively charged, is hydrophilic and interacts with water. The long hydrocarbon chain is hydrophobic and therefore prefers air or an oil phase. Large polymeric surfactants can have more than two hydrophilic blocks separated by a hydrophobic block or another way around.

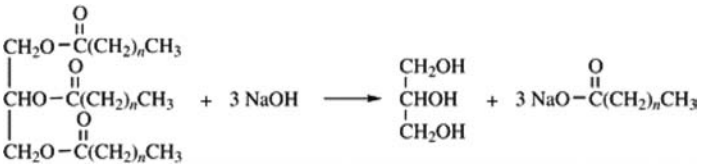
There are generally four types of surfactants. They are anionic, cationic, zwitterionic, and non-ionic based on the type of charges that the surfactant molecules possess in a solvent, usually water. Anionics are negatively charged; cationics positively charged; non-ionics are not charged; and zwitterionics possess both negative and positive charges in different parts of the molecule but overall the molecule is neutral. In practice mixed surfactants are often used in commercial formulations. For example in shampoo and shower gels an anionic and a zwitterionic are mixed to enhance the micelle and foam stability. It is, however, not usual to mix anionic and cationic surfactants together since the molecules couple together due to the charge interaction and precipitate.

Surfactants can be crystalline or liquids and dissolve preferentially in water or an oil phase depending on the balance of hydrophobic and hydrophilicity characteristics within the surfactant. In solution, a range of aggregates may form together with the solvent depending on the surfactant concentration and the temperature. A monolayer of the surfactant molecules normally forms between any two phases of dissimilar polarity, eg, water and oil, or water and air. The hydrophilic portion preferentially solubilizes in the polar or higher polarity phase whereas the hydrophobic portion preferentially solubilizes in the nonpolar or lower polarity phase. The presence of surfactants at the interface provides stability to the interface by lowering the total free energy associated with maintaining the boundary. Thus, surfactants facilitate stabilization of intermixed, normally immiscible phases, such as oil in water, by decreasing the free energy necessary to maintain the large interfacial region associated with mixing. For example, in the absence of surfactants, oil in water dispersions rapidly separate into two distinct layers to minimize the surface or contact area between the two phases. The ability of surfactants to lower this interfacial energy between the oil and water allows the formation and stabilization of smaller oil droplets dispersed throughout the water, forming stable dispersions called emulsions.

Another property of surfactants is their ability to aggregate in solution to form various composite structures or phase states, such as micelles and liquid crystals, as a function of concentration and temperature. At very low surfactant levels, the surfactants exist as individual molecules in solution associating primarily with water molecules. They also concentrate or partition to form a monolayer at the interfacial regions as described above. However, as the concentration of surfactant in solution is increased, a point is reached where the molecules aggregate to form micelles. This concentration is defined as the critical micelle concentration (CMC). The micellar structure minimizes system free energy through surfactant self-association; the micelle in water is typically characterized with the hydrophobic tails pointing to the centre and the hydrophilic head groups pointing out toward the water in spherical superstructures. As the concentration of surfactant in solution is further increased, the micelles elongate into long tubules which align with each other to form a hexagonal arrangement when viewed end-on. These structures are commonly referred to as hexagonal liquid crystals. As the surfactant concentration is further increased, the tubules expand in a second direction to form large, stacked lamellar sheets of surfactants, commonly referred to as lamellar liquid crystals. These liquid crystals are very important in soap making and the washing properties of the soap. In a soap bar, the soap concentration is very high and liquid crystals exist in the soap bar. During washing as the water concentration increases the soap crystal concentration decreases therefore the soap molecules form micelles or individual molecules which stabilize the water and air interface and lead to the formation of foam or lather. In the rinsing stage the soap concentration decreases significantly which causes the collapse of foam. See also **Surfactants**.

Raw Materials and Their Processing

Principal Raw Materials. Carboxylate soaps are most commonly formed through either direct or indirect reaction of aqueous caustic soda, ie, NaOH [CAS: 1310-73-2], with oils and fats from natural sources, ie, triglycerides. Oils and fats are typically composed of both saturated and unsaturated fatty acid units containing between 8 and 20 carbons randomly linked through ester bonds to a glycerol backbone. Overall, the reaction of caustic soda with triglyceride yields glycerol and soap in a reaction known as saponification. The reaction is shown in equation 1.



(1)

Saponification can proceed directly as a one-step reaction as shown above, or it can be achieved indirectly by a two-step reaction where the first step generates fatty acids through simple hydrolysis of the oils and fats and the second step forms soap through the neutralization of the fatty acid with caustic soda. There are practical considerations which must be addressed when performing this reaction on a commercial scale. Compositional differences in the oils and fats give rise to their significantly different physical properties and those of the resulting fatty acids and soaps. The main compositional difference is the chain length distribution of the fatty acids associated with the oils or fats.

Fats and Oils Used in Soap Making. Oils and fats used in soap making have traditionally been classified as either lauric or nonlauric oils/fats. A typical toilet soap will contain a blend of both of these types of oils and fats. This broad classification is based on the fact that oils and fats tend to contain either extremely low levels of C_{12} alkyl chain material or high levels (typically ca 50% by weight). The lauric oils are relatively rare commercially with only two (coconut and palm kernel oil) accounting for the bulk of lauric oil use in soaps world-wide. The nonlauric oils are numerous but again there are two that account for the bulk of nonlauric use in soaps world-wide, these being tallow and palm oil. Many soaps also contain blends of nonlaurics with either tallow or palm oil being blended with harder materials such as palm stearines or softer oils such as soya bean. Examples of typical chain length distributions of a number of commonly used oils and fats for toilet soaps are given in Table 1 along with their measured iodine value (IV). The latter is a measure of the degree of unsaturation of the oils and fats. Although this is a single number it can be used to predict the effects of individual or blends of oils and fats on the hardness of a soap blend.

The lauric oils shown in Table 1 all have similar levels of C_{12} with only minor differences in other chain lengths. None contain high levels of C_{16} or C_{18} in the form of saturates or unsaturated materials. In contrast the two main nonlaurics (tallow and palm) contain only low levels of short chain lengths (ie, <=C12) and have high levels of C_{16} and/or C_{18} as both unsaturated and saturated materials. A key point to note is that an oil name defines the general chain lengths present, but there is some variability in quantities of individual chain lengths; an example of this effect is shown in Table 1 for tallows sourced from South America and the UK. Other sources of nonlauric oils are of two types; hard and soft oils. The hard oils are classed as stearines and are produced either by fractionating

TABLE 1. TYPICAL FATTY ACID CHAIN LENGTH DISTRIBUTIONS FOR OILS AND FATS USED IN SOAP-MAKING[a]

tallow or palm or by hardening oils or fats. The extent of this hardening is defined by their iodine value; the lower the IV, the harder the material. An additional consideration for oils and fats which have been hardened catalytically is that some trans-esterification of the double bonds often occurs. The resulting trans-isomers produce soaps with markedly different solubilities from their cis-isomers, which must be taken into consideration during blending for achieving acceptable processing and in-use properties.

Toilet soaps manufactured by extrusion require both minimum and maximum product hardness and this imposes limits on the level of soft and hard oils and fats that can be used in a blend. However blending of soft and hard oils can achieve the target hardness and it is obvious that many combinations of oils and fats could be produced to meet this requirement. In addition to the process requirement of product hardness, there are a number of product in-use properties which influence the choice of the oil and fat blend. These variables are quite numerous, but the main ones can be summarized as (*1*) lauric oil content which controls lather and (*2*) the amount of unsaturated chain lengths, which due to their high water solubility can improve speed of lather generation but can also negatively affect bar economy if they are present at too high levels. Conversely, high levels of stearines that are relatively insoluble in water can improve bar economy, but can reduce lather if present at too high a level. The main factor limiting soft oil use is the chemical instability of the unsaturated chain lengths, particularly for di-, tri- and polyunsaturated materials. The blending of oils and fats to achieve the target hardness for processing and acceptable in-use properties is, thus, a complex balancing operation. One widely employed approach is to use the blend iodine value, in combination with a constant level of lauric oil to identify blend options that will have similar process and in-use behavior. A final consideration is the chemical state of the oils and fats. The effects of storage conditions, impurities and processing can lead to significant differences between nominally identical oils or fats and this is usually reflected in an industry-standardized specification known as a *grading value* being associated with an individual oil or fat. This in turn influences the oil price with higher grade oils and fats being more expensive, but having less undesirable effects on product properties such as color and odor. This overall approach allows manufacturers to select blends of oils and fats to minimize raw material costs while maintaining processing and product user properties.

In the last ten years the increased use of chemical splitting of oils and fats has widened the range of feedstocks for soap making to include "non-natural" chain length blends. This provides soap makers with additional opportunities to cost optimize their blends. A further consequence of this is that soaps made from distilled fatty acids tend to contain lower levels of impurities which in natural oils and fats can have deleterious affects on color and odor. This offers the potential for further cost savings by reduction in levels of minor ingredients such as whiteners and antioxidants.

Other Sources. The most commonly used oils and fats in soap making around the world are tallow, palm oil, and their stearines and the two lauric oils, coconut and palm kernel oil. However over the years local shortages in these oils and fats have led to a plethora of alternative oils/fats being used as nonlauric and lauric oil substitutes. For instance until the 1990s, India relied on blends of local oils such as linseed, rice bran, and castor which with appropriate hardening, dehydroxylation, etc could produce a nonlauric blend that mimicked the process and in use behavior of palm oil. Similarly in South America partially hardened soya bean oil has been used as a partial replacement for tallow. Other oils/fats occasionally used as nonlauric replacements include lard (pig fat) and a number of soft oils such as sunflower and groundnut oil. Alternatives to the common lauric oils are extremely limited but include rosin and a range of synthetic surfactants.

Raw Material Pretreatment. The quality, i.e., level of impurities, of the crude oils and fats used in the manufacture of soap is important in the production of commercial products. Oils and fats are isolated from various vegetable and animal sources and contain different intrinsic impurities although both will contain free fatty acids and mono and diglycerides. These crude oils and fats typically contain a range of nonsaponifiable contaminants some of which affect color and odor of the oil or fat and also that of the finished soap product. For animal fats these will include blood, mucilage, and other proteinaceous material, phosphatides, and bone. For plant-derived oils, typical contaminants include sterols, carotenoids, phosphatides, tocopherols, etc. In addition both will contain physical dirt, water, rust, and other material picked up during their extraction and storage.

For commercial soaps, it is desirable to keep these impurities at the absolute minimum for both storage stability and finished product quality considerations.

There are a number of processing steps that can be used to improve the quality and stability of the oils and fats raw materials. These include water washing, alkali refining, physical (steam) refining, deodorization, bleaching, and hydrogenation. Water washing, also called degumming when dealing with vegetable oils, is an effective means of improving the color of oils and fats through the elimination of proteinaceous solids, phosphatides, and other water-soluble impurities. Hot water, possibly containing some phosphoric acid or sodium phosphate, is mixed with the oils or fats. The water layer is allowed to separate either statically or by using centrifugal force. Many of the solids and other impurities become either solubilized or suspended in the water and removed. Alkali and physical (steam) refining can be utilized to decrease the amount of free fatty acid and other color bodies present in oils and fats. Alkali refining washes the oils and fats with alkaline water and converts fatty acids into soap. The resulting soap is removed with the alkaline aqueous phase through settling or centrifugation. In physical refining, volatile impurities including low boiling fatty acids are vaporized and removed from the oils and fats by steam-heating the material. Deodorization, also called steam

stripping, is another steam distillation process. For deodorization, however, the distillation is performed under vacuum that allows for more efficient removal of the less volatile odour bodies. Bleaching is most commonly done using a physical adsorption process in which activated clay, eg, fullers earth, is slurried with the dry oil under vacuum at temperatures around 90 °C (194 °F). The color bodies adsorb onto the clay, which is subsequently removed through a filtration process at a lower temperature to minimize oxidative damage. Hydrogenation is also frequently utilized in the processing of oils and fats to improve their storage stability through reduction in the amount of polyunsaturates and unsaturates present. This is achieved by contacting the oils and fats in a reactor containing a catalyst, eg, Ni or Pt, and hydrogen gas under pressure so that hydrogen adds across the double bonds.

Industry uses a number of analytical methods to characterize oils and fats, in terms of a number of parameters which include moisture, titre (solidification point), free fatty acid, unsaponifiable material, iodine value, peroxide value, and color. Moisture content of the oils and fats is an important measure for storage stability at elevated temperature because it facilitates hydrolysis which in turn impacts odour and color quality. Titre is a measure of the temperature at which the material begins to solidify, signifying the minimum temperature at which the material can be stored or pumped as a fluid. Free fatty acid is a measure of the level of hydrolysis the oils and fats have undergone. Increased fatty acid content usually negatively impacts product color stability because fatty acids are more susceptible to oxidation. Unsaponifiable material is a measure of the nontriglyceride fatty material present, which affects the soap yield of the material. The iodine value is a measure of the amount of unsaturation present in the oils and fats. Peroxide value is a measure of the amount of oxidation the oils and fats have undergone and indicates the potential for further degradation.

Bar Soap Manufacture

Direct Saponification of Oils and Fats. Direct saponification of oils and fats is the traditional process utilized for the manufacturing of base soap. Commercially this is done through either a kettle (pan) boiling batch process or a continuous process. In both cases there are three key stages required to produce a neat soap, (lamellar liquid crystal containing ca 70% soap) suitable for further processing into bar products. These stages are saponification, washing and fitting. See also **Saponification**.

Kettle Boiled (Pan) Process. This process produces soap in large, open steel tanks known as kettles or pans, which can hold up to 130,000 kg (286,601 lbs) of material. Kettles are cylindrical tanks with conical bottoms, which contain open steam coils for heating and agitation. The traditional batch making process carries out the three essential stages, known as saponification, washing, and fitting in the same vessel. To initiate the saponification, oils and fats, caustic soda, salt and water are simultaneously added to the kettle. Effective mixing is important in this process because of the low miscibilities of the oils and fats and caustic lye. The addition of steam to the system facilitates mixing and the saponification reaction. In some systems, the reaction is enhanced through the use of specially designed saponification jets, which allow for intimate mixing of the two components during the charging of the kettle. Care must be taken when blending the oils and fats with caustic soda, salt, and water to ensure a consistent reaction rate for forming the desired neat soap. It is common practice to leave some previously formed soap in the kettle before charging the kettle with the new batch of saponification. This soap, through its surfactant properties, helps disperse the fats and oils and water phases through better emulsification, thus, increasing the reaction rate. To complete the saponification process, the soap batch is boiled for a period of time using steam sparging (via open steam coils).

Upon completion of the saponification reaction, additional salt is added to the kettle while boiling with steam to initiate the washing stage by converting the single phase neat-soap (lamellar liquid crystal) into a two-phase lamellar liquid crystal-aqueous lye composition. This process is also called opening the grain of the soap. The lye layer (located at the bottom of the kettle) is an aqueous phase containing a high level of salt, glycerol, and only small amounts of soap due to its low solubility in saturated salt solution. This two-phase mixture is allowed to separate for several hours, after which the aqueous solution (lye) is removed from the bottom of the kettle. This lye contains most of the glycerol produced during the saponification process and can be transferred to a glycerol recovery system, where the glycerol is recovered, purified, and used for other purposes. It is common to use several washing stages to optimize glycerol removal. The soap remaining in the kettle now contains a high level of salt and so a fitting stage is initiated. This stage involves the addition of dilute caustic soda solution to the soap. This mixture is then given time to separate into two layers, with a pure neat soap at ca 70% concentration in the upper layer containing only low levels of salt and glycerol and other impurities. The lower layer (nigre), will contain most of the salt and any water-soluble colored impurities. After separation of the nigre layer, the upper neat soap is ready for further processing via drying and finishing. This overall three-stage kettle process requires considerable practical expertise, is time-consuming and requires several days to complete.

Continuous Saponification Process. There are a wide variety of commercial systems for continuous soap-making; details of a number of these and their operation are given in the Woollatt reference. However all rely on high speed saponification using intense mixing followed by separate units to continually wash and fit the soap to produce the desired neat soap required for further drying/finishing. All of these routes are less labor intensive and faster than the previous batch process and hence provide improved manufacturing efficiency. Although commercial systems may differ in design aspects or specific operations, they all saponify fats and oils to finished soap using the same general process.

In a continuous saponification system, blended oils and fats feedstocks are continuously and accurately metered into a pressurized, heated vessel, commonly referred to as an autoclave, along with the appropriate amount of caustic, water, and salt. The concentrations of these ingredients are adjusted to yield a mixture of neat soap and a lye phase. At the temperatures (~120 °C (~248 °F) and pressures (~200 kPa), the saponification reaction proceeds quickly (<30 min). A recirculation system ensures a residual level of soap in the autoclave to improve contact between the oil and water phases and provides additional mixing. After a relatively short resident time in the autoclave, the neat soap and lye phase reaction blend is pumped into a cooling mixer where the saponification reaction is completed and the reaction product is cooled to below 100 °C (212 °F). The reaction product is pumped next into a static separator, where the lye phase containing a high level of glycerol (25–30%) is separated from the neat soap through gravitational force or settling. The neat soap is then washed with a lye and salt solution using a counter-current flow process. This process is often done in a vertical column, which might be an open tube or contain mixing or separation stages. The neat soap is introduced into the bottom of the column and the lye/salt (washing) solution is pumped into the top. The less dense neat soap rises up in the column while the lye/salt solution falls to the bottom. The washing solution removes impurities and allows for further collection of the glycerol. As with the kettle process, it is important to have a proper level of electrolyte (salt and lye) for effective removal of the glycerol. Final separation of the lye layer from the neat soap is commonly achieved using centrifugation. After centrifugation, the remaining caustic or residual alkalinity in the separated neat soap is neutralized through the accurate addition of fatty acid in a steam-jacketed mixing vessel (crutcher). The soap is now ready for use in the manufacturing of soap bars.

Fatty Acid Neutralization Process. This route produces soap via a two stage process. In the first stage (hydrolysis) the oils and fats are split into fatty acids using steam/water and separated from the glycerol and other impurities. These fatty acids can then be blended if necessary to the target soap charge required and then neutralized in the second stage with alkali. This process normally produces a neat soap, which is then dried and finished using identical processing to the conventional direct soap-making route previously described.

Comparison of Base Soap Manufacturing Routes. Direct saponification of oils and fats is well known, characterized, and straightforward; requires conventional equipment; and is relatively energy-efficient. However, it imposes practical limitations with regard to changes in the oils and fats ratio desired for finished soap bar formulations. Furthermore, direct saponification has the drawbacks of lower glycerol yields, limited flexibility toward formation of mixed counterion soaps, and requires higher quality feedstock for good quality soaps. In contrast, the hydrolyzer/neutralizer system is more flexible with regard to formation of mixed counterions and

formula changes and provides better glycerol recovery. In addition, the ability for both distillation and post-hardening provides greater flexibility in oils and fats feedstock selection; lesser grades can be utilized to yield comparable quality base soap. However, this process is extremely energy-intensive and requires more specialized process equipment, eg, hydrolyzer columns, stills, a hydrogenation system, and neutralizer, and necessitates the use of stainless steel on account of the corrosive nature of fatty acid.

Formulation

The formulation of bar soaps has become increasingly complex with changing consumer bathing habits and expectations. In the past, consumers' bathing habits were such (e.g., once-a-week baths) that simple lye soaps were acceptable. However, it is not uncommon nowadays to shower everyday, which puts greater demands on the performance properties of a soap bar, for example, mildness to skin and prevention of bathtub ring. Manufacturers of bar soaps have developed a variety of formulation approaches to deliver products that better meet current consumer needs. This is achieved through the proper balancing of soap components, inclusion of various additives, or the blending of synthetic surfactants into the formula. In addition, new forms of cleansing products have been introduced to address these changing habits and consumer needs, eg, liquid handsoaps and shower gels or body washes. For personal cleansing products, including bar soaps, performance is measured by such tests as amount and creaminess of lather, wet cracking, economy, water uptake (mush), rinsability (the amount of residue left on surfaces after rinsing with hard water), and mildness to skin. It is through use of these measures and exhaustive consumer research that modern soap-makers develop better products for consumer needs.

Soap Bars. In soap bars, the primary surfactant is predominantly sodium salts of fatty acids. These products typically contain between 70 and 85% soap. Occasionally, potassium soap (~5–30%) is included in the formulation to increase the solubility of the soap and, hence, the bar's lathering properties. The low Krafft temperatures for potassium soap are the basis for the lather enhancement, but also limits their content in bars, making them softer and poor in economy.

Soap performance can be controlled through the proper blending of oils and fats to specific ratios, and the formation of the proper phase and colloidal structure. It is common to produce soap using a blend of tallow or palm and coconut or palm kernel oils, generally in a ratio of between 85:15 and 50:50. As the amount of coconut oil is increased in the bar, the lathering profile of the product typically increases as a result of the inherent higher solubility of the soaps formed from coconut (shorter chain length soaps). However, this higher lather comes at the expense of poor economy and increasing water uptake which results in the formation of an expanding outer soft layer known as mush, which increases for the same solubility reasons. Furthermore, the higher content of sodium laurate in these high coconut soaps can negatively impact the mildness of the product, because laurate soaps are intrinsically more irritating to skin than other chain lengths.

Additionally, soap bars typically contain between 8 and 20% water, 0.5 to 1% NaCl, and low levels of glycerol. Both salt and glycerol modify the processability of soap during milling and plodding, as well as being carryover ingredients from the manufacture of the base soap. Similarly the water content is critical in controlling bar hardness and hence processability.

Bar Soap Additives. There are a variety of additives that may be formulated into soap bars to provide additional consumer benefits or modify the performance of the products. In all cases a key consideration must be the mode of addition of the additive. If additives are mixed using low shear then it is likely that they will exist within the product as macroscopic domains and as such will not impact the overall bar soap phase chemistry. However the presence of such large defects is liable to disturb bar macrostructure and produce effects ranging from bar cracking, insoluble lumps, uneven bar wear and poor economy. The actual behavior will depend both on the physical nature and chemistry of the additive and its domain size in the bar. Conversely if the additive is mixed using high shear then it has the potential to disturb the soap phase chemistry which is liable to impact all of the aforementioned bar properties, but the magnitude and type of effect will be different for any particular additive.

Free Fatty Acid. Soap bars are intrinsically alkaline in nature on account of the physical properties of soap in water and the process utilized in its manufacture, which yields base soap having a very slight excess of free caustic. Low levels of free fatty acid are often added to the neat soap prior to drying to neutralize this slight excess of caustic. These low levels have no effect on processability or in-use properties. However, addition of higher levels of free fatty acid provided they are molecularly mixed into the soap, typically in the range 2–10% can significantly affect processability and in-use properties. This approach is known as super-fatting and this term was even used in advertising for Lux soap in the 1950s with the slogan "Super-fatted Luxury". The basis for this claim is that the addition of fatty acids (usually as coconut or palm kernel fatty acids) leads to an increase in both the amount of lather and its creaminess. However a downside of this is that if processing temperature is not carefully controlled, both bar economy and water uptake (mush) can increase, the latter leading to extremely soft bars.

If free fatty acids are added to soap without being molecularly mixed, the resulting soap bars will have a gritty feel and will wear unevenly, and will not exhibit any improvements in lather. However, irrespective of the degree of mixing, the presence of high levels of free fatty acids can also decrease the odor and color stability of the final product because oxidative degradation of fatty acids is faster than for the analogous soaps.

Glycerol. Although glycerol is normally present at low levels in soap due to incomplete removal during the soap-making process, it is often added to soaps at higher levels either to support skin-mildness claims based on its known humectancy or to promote bar translucency. For example glycerol, at levels of 10%, has been shown to change significantly the consumer skin softness and smoothness perception. Similarly levels in the range 5–10% are often used in milled translucent soaps. However, care must be taken when adding glycerol at such levels because it can severely affect both bar processability, bar appearance and in-use properties.

Perfume. A key aesthetic for consumer acceptance of personal cleansing products is how the product smells. Perfume is utilized by manufacturers of soaps as one of the primary means of targeting products for specific user groups and connoting different product marketing positions. A secondary purpose of perfume is to mask the fatty base odor of the soap. Product odor instability results from both the loss of perfume during storage and the propensity for oxidation of perfume and soap components. Hence, a product may change from an acceptable to an unacceptable odor profile during its lifetime if not properly formulated.

Commonly, perfume development is performed by perfume houses who focus their development on product appeal needs. For example, perfumes used for deodorant products tend to be impactful and residual to skin to provide long-lived perfume on skin. A number of products are appearing on the market that are designed for individuals with sensitive skin. The perfume levels used in these sensitive-skin products are usually lower than for other soaps and are selected to mask the base odor of the soap while providing some soft perfume notes during use, reinforcing their mildness to or compatibility with skin. Irrespective of market position, perfume levels in soaps are typically in the range of 0.2 to 1.5%.

The perfume is usually added during the finishing operation using a low shear device although in some products, a high shear stage may occur later in the finishing operation. However the effect of perfume on processing is always to make the soap mass slightly softer. The effect of perfume on in-use properties is also negligible.

Mildness and Skin Additives. The increased frequency of bathing and the changing consumer need has necessitated the development of products having skin care benefits. In addition to the two most common additives, fatty acid and glycerol, there is a wealth of other additives which are frequently used. Examples include lanolin [CAS: 8006-54-0], vitamin E [CAS: 59-02-9], aloe vera gel, mineral oil [CAS: 8012-95-1], and baking soda [CAS: 144-55-8].

Inert materials are sometimes used in soap bars as a means of improving the skin mildness of the product by decreasing the level of soap and surfactant in the bar. The cleansing agents at high concentrations can sometime dry and irritate skin. Varieties of inert materials, both inorganic and organic, have been reported in the literature, including oatmeal, dextrin [CAS: 9004-53-9], starch [CAS: 9005-25-8], wax [CAS: 71808-29-2], and

talc [CAS: 14807-96-6]. These materials may also deposit on the skin during washing, further modifying the rinsing properties of the soap bar and impacting the consumer perception of the product and its aesthetic properties.

Newer technologies have been used in the manufacture of bar soaps, which truly improve the clinical mildness-to-skin of these products. One approach relies on minimising the overall levels of the more irritating soap species such as the laurates and unsaturated species through appropriate balancing of feedstocks. Another approach is the incorporation of quaternary amine compounds into the formula, which effectively complexes the soap during the wash-rinse process, reducing its potential to remove oils from or interact with the skin. The amines commonly take the form of cationic polymers based on natural materials such as cellulose [CAS: 9004-34-6], guar gums, and proteins.

Much of the development of new soap bar technologies has been focused on products containing some level of synthetic surfactants. The primary benefits of synthetic surfactants over soaps are their intrinsic lower sensitivity to water hardness, which improves their rinsing profiles, their lathering ability, and their effects on skin feel and mildness. Anionic, nonionic, and zwitterionic surfactants have all been formulated into bar soaps. In most bar soaps, the synthetic surfactant serves the purpose of a secondary surfactant modifying the lathering, rinsing, or skin effects profile. A major challenge has been how to incorporate relatively high levels (i.e., >10%) of these highly soluble synthetic surfactants into soap bars without significantly affecting both processability and in-use properties and this need has produced numerous patent filings covering specific approaches.

Anionic surfactants are the most commonly used class of surfactant. Anionic surfactants include sulfates such as sodium alkylsulfate and the homologous ethoxylated versions, sodium monoglycerol sulfate and also the sulfonates, eg, sodium alkylglycerol ether sulfonate and sodium cocoyl isethionate.

Nonionic surfactants include the alcohol ethoxylates, also the sugar-based surfactants such as alkyl polyglycosides. Zwitterionic surfactants, such as cocoamidopropyl betaine and cocoamphoacetate, are more recent surfactants in the bar soap area and are typically used at low levels (<2%) as secondary surfactants. These materials can have a dramatic impact on both the lathering and mildness of products.

These surfactants, in conjunction with soap, produce bars that may possess superior lathering and rinsing in hard water, greater lather stability, and improved skin effects. Beauty and skin care bars are becoming very complex formulations. A review of the literature clearly demonstrates the complexity of these very mild formulations, where it is not uncommon to find a mixture of synthetic surfactants, each of which is specifically added to modify various properties of the product.

An extension of the soap-coactive approach has been the production of ultra-mild bars which contain only low levels of soap, with the primary surfactant being a synthetic anionic.

One common theme throughout all of these products and patent filings is that the synthetic surfactant(s) are always molecularly mixed with the other product components. Failure to ensure the formation of a homogeneous product results in major processing problems and poor product in-use appearance and behavior.

Antimicrobial Agents. Antimicrobial agents have been used for a number of years in soap bars as a means of providing additional deodorant protection through their residual effectiveness on suppressing the growth of odor-causing bacteria. These materials may deposit on skin during the washing process and provide a reservoir of active ingredient that is effective at suppressing bacterial growth between washings. It is widely believed that these soaps may provide additional benefits on account of their ability to control the microflora on the skin surface. One such benefit may be the reduction in the level or frequency of minor skin infections by controlling the *Staphlyococcus aureus* level on the skin surface. Only two active ingredients are commonly used in bar soaps: trichlorocarbanalide or TCC (Triclocarban) [CAS: 101-20-2] and trichlorohydroxydiphenyl ether or TCS (Triclosan) [CAS: 3380-34-5]. These compounds are typically used at concentrations of 0.25 to 1.5% in the final product and have activity against a wide range of micro-organisms. They are usually added using low shear and have no effect on either processability or product in-use properties.

Specialty Soaps. There are a variety of specialty soaps that require certain additives to deliver the special consumer needs for which they were developed. Examples include scouring soaps that contain an abrasive agent homogeneously distributed throughout the soap to aid in the cleaning properties of the product. The abrasives are extremely small particles of insoluble material such as pumice. Similarly encapsulated oils or perfumes can also be incorporated into conventional milled soap bars. Bars with visual effects include striated soap bars, which can be produced using two soap streams with different colorant systems that are intentionally poorly mixed during extrusion through the plodder. Alternatively a single soap stream can be used and a dye injected during extrusion. If a true striped bar is required, this can be manufactured using separately colored soap streams and a specialized extruder. The other common visual effects are translucency and transparency. Each of these has its own specific formulation space and process requirements, with the former being accessed either via a milled-process route or a cast process and the latter being accessed solely by a casting process.

Milled Translucent Soaps. A semiconventional finishing line can be used to make translucent toilet soap. The formulation and processing of these soaps differs from conventional opaque soaps in that the water content must be high (typically 14–20%) and either glycerol and/or a polyol (e.g., sorbitol, sucrose) must be present at level of 4–10%. This type of formulation can also include other additives such as potassium soap. Irrespective of the exact formulation, the one additional requirement for achieving translucency is high shear. This can be achieved either by pre-blending all materials prior to drying or by utilizing a high shear device (eg, batch Z-blade mixer) during the finishing operation. If throughput is an issue, a continuous high shear mixer such as a CTM should be used. If a low shear finishing line is used the resulting poorly mixed mass will be soft and difficult to process into bars, and the in-use properties will be poor. In contrast, high shear processing will yield bars with good translucency, which will improve further during storage (due to moisture loss). These bars will also have acceptable in use properties although with a tendency to form thick mush layers if exposed to humid conditions.

Transparent Soaps. The early commercial transparent soap bars were based on conventional fat charges of tallow and coconut and also contained solubility enhancers such as potassium soap and rosin [CAS: 8050-09-7], in addition to glycerol and ethanol [CAS: 64-17-5]. These products were cast into molds and allowed to set and then stored for an extended period of time to allow the ethanol to evaporate. It is only after evaporation of the ethanol that transparency is achieved. This overall process can take several weeks and coupled with the alcohol evaporation is a slow and costly process. The best known product of this type still exists today and is sold by Unilever under the name “Pears soap”.

In recent times there has been much interest in this product form due to the high consumer appeal of glass-clear bars. Much work has been carried out to eliminate the alcohol evaporation stage of the process to produce a high quality bar at high throughput. This goal has been achieved by several manufacturers, using a range of formulations but in essence a single approach which is to reduce the soap content and replace this with high levels of polyols and other solvents. Common solvents include ethanol, propylene glycol [CAS: 57-55-6], dipropylene glycol [CAS: 25165-71-8] and triethanolamine [CAS: 102-71-6]. These are combined with blends of polyols such as glycerol, sorbitol [CAS: 50-70-4], and sucrose [CAS: 57-50-1]. These components along with water often make up at least 50% of the product. The process involves pre-blending all ingredients at elevated temperature and pouring into molds where the product is allowed to set. The bars can then be either extracted from the mold and packaged or sold in-the-mold. A successful formulation is one that forms an isotropic solution at elevated temperature and does not form any liquid crystalline phases during the cooling phase. This minimizes formation of large solid crystals, which would reduce the transparency of the final product. The solvents and polyols also aid the formation of a clear product by retardation of crystal growth.

There are many examples of these types of product on the market especially in Japan where mild products based on synthetic surfactants have also been developed using the same principles outlined here. One of the best known European products is Neutragena which is based on a triethanolamine soap.

Liquid Soaps and Body Washes. In the late 1970s and early 1980s a new form of soap product emerged, commonly referred to as liquid handsoaps. These liquid soaps were offered as a practical replacement of soap bars for use at sinks in the bathroom and kitchen. Manufacturers have taken two basic approaches to the formulation of these products: soap-based and synthetic-based formulations. Soap-based formulations typically use potassium soaps which because of their high solubility are unlikely to precipitate out at low ambient temperatures. These soaps have typically been of either short-chain lengths, such as coconut soap, or a blend of short-chain lengths and unsaturated soaps such as oleic. More recently, these soap-based formulations have been replaced by synthetic surfactant-based formulations. Synthetic surfactant formulations have the advantages of being milder-to-skin, cleaner rinsing, higher lathering, and less sensitive to water hardness. A typical synthetic surfactant formulation is around 80% water and contains sodium alkylethoxy sulphate as the primary surfactant, a non-ionic surfactant such as lauramide DEA, and potentially a lather-building amphoteric surfactant such as cocoamidopropylbetaine [CAS: 61789-40-0]. The global market has evolved significantly since the initial introduction of liquid handsoaps, and most products now often contain some form of benefit agent such as an antibacterial agent (usually TCS) and/or a moisturier (typically glycerol or a polyol).

Body washes are another more recent introduction into the marketplace. These products have become a mainstay in the global market. Body washes can be simple formulas similar to those used for liquid handsoaps or complex 2-in-1 oil-in-water emulsion, moisturising formulations. These products contain a wide range of synthetic surfactants not typically found in bar soaps or liquid handsoaps, such as sodium monoalkyl phosphate and alkyl aminocarboxylates. It is not uncommon to find over 20 different components in these formulations, with no less than six or seven different surfactants. These products can also contain skin benefit agents, such as cholesterol, fatty alcohols, fatty acids, cationic polymers, and emollient oils to provide even milder-to-skin cleansing and in-use moisturization.

Bar Soap Manufacture

The conversion of wet base soap into consumer-acceptable soap bars can be achieved using one of two commonly utilized manufacturing routes: casting-molding and milling-extrusion forming, both of which use a variety of processing unit operations or finishing steps. These steps include wet mixing or crutching, drying, dry mixing or compounding, and bar forming also known as finishing. A number of recent innovations in the two basic routes have been reported eg, the hot-extrusion process and the continuous casting processes, the latter of which has largely replaced the older cast-mature process.

Casting in Frame. The most commonly used casting process is the so-called *framed bar process.* This is by far the oldest and the most straightforward process utilized in the production of bar soaps. The wet soap base is pumped into a heated, agitated vessel commonly referred to as a crutcher. The minor ingredients used in soap bars such as fragrance or preservative are added to the wet soap in the crutcher or injected in-line after reduction of product stream temperature. The hot mixture is then pumped into moulds and allowed to cool.

These molds can be either finished bar-shape molds or large blocks. Finished bar-shape molds can be either a mated two-piece design or a five-sided, open-top design. Upon cooling the solid bar is removed from the mould and packaged as desired. For the large blocks, the mold is pulled apart and the block of solid soap is removed. Wire cutters are employed to cut the blocks first into slabs, then into stripes, and finally into rectangular bricks representing the finished size of the bar. The rectangular brick is finished by a final stamping step which typically embosses the logo and any minor shape modifications into the brick. This large-block approach is only suitable for brick-like shapes, whereas the finished bar-shape molds allow for the production of much more complex shapes.

Traditionally, this process has been utilized primarily for low cost soap bars because it produces bars with limited shape options. A derivative of this approach has been utilized for many years to make transparent bars by the so-called cast-mature process.

Cast-Mature. The cast-mature process was an early attempt to make high quality transparent soap, with the best known product, “Pears soap”. The process is similar to the framing process except for the inclusion of high levels of alcohol and the need for extending ageing times. The initial melt which is based on a semiconventional tallow: CNO blend with added solubilizers is poured into longitudinally bar-shaped molds and allowed to cool. After cooling, the opaque product is cut into individual bars and each is embossed with the logo and placed in ovens to evaporate off the alcohol. After a number of weeks the bars are removed from the oven at which stage they are transparent. The bars can then be surface-cleaned to optimize transparent appearance and packaged as for normal soap bars.

Continuous Casting. Improvements to the basic cast-mature process appeared initially in Europe and Japan where premium quality high transparency bars were able to demand a considerable premium over conventional toilet soaps. Two major advances were made the first being the identification of new formulation spaces which no longer required maturation times and the second being the automation of the process. Using these combined advances, throughputs approaching conventional milled soaps can now be achieved. A number of different machine designs exist but in all cases the same basic process is used: the hot melt is injected into individual molds, and these are then either passed through a cooling tunnel after which the bars are removed from the molds and packed or the molds act as primary packs in which case these are simply sealed and allowed to cool/set post-processing. In the case of the latter process, the molds are typically made from transparent plastic hence allowing consumers to perceive the excellent transparency.

Milling/Extrusion Forming. The most common process for the production of bar soaps is the milled bar process. The process has two separate stages, a drying stage followed by a finishing stage. Typical production rates on high-speed lines achieve the order of 400 bars/min. The limiting step in this is usually the bar-stamping rate, which has been the subject of many technological advances in recent times.

Milled soap is a high-grade soap in which critical crystal-phase changes have been brought about through the use of mixers, milling rolls, and plodders. The milled soap is made by drying a good grade of neat soap to about 15% moisture content, breaking up the crystalline structure that develops during drying and cooling, plasticizing and converting a sufficient portion of the soap to a desirable phase condition, de-aerating and compacting the resulting mass, and forming it into bars. Perfume, coloring matter, preservatives, and special additives are incorporated prior to the milling operation. A milled bar is particularly hard, dense, and smooth, and it lathers freely without forming excessive soft soap on the surface of the bar.

Drying. Liquid base soap is dried from a 30% water liquid form to a solid of about 15% water content. If desired, some minor ingredients may be blended into the soap stream prior to drying. Methods of drying used in common practice are (1) chip drying, (2) atmospheric flash drying, and (3) vacuum flash drying.

Chip Drying. Sometimes called *ribbon drying*, this process involves spreading a thin layer of hot base soap on a large chilled drum, which cools and firms up the soap. Drying is promoted primarily by the difference in water vapor pressure between the soap chips and the air surrounding them. No attempt is made to increase drying rate by heating the soap itself.

Atmospheric Flash Drying. A tower similar to a synthetic-granules spray-drying tower is used. The heat for drying, however, is put into the soap by heating it under high pressure before flashing it into the tower. During flashing, the pressure on the soap is abruptly relieved and soap moisture flashes to steam. Air to the tower is used for cooling. The soap temperature as it enters the flashing nozzles determines the final moisture of the dried soap.

An alternative method involves flashing the soap from the nozzle onto the surface of a chilled drum. The resultant solid soap is scraped off in flake form. This process called *chill flake drying*, is the method of choice for drying sticky soap/synthetic combination formulas.

Vacuum Flash Drying. In this most recent technique, drying takes place in a vacuum vessel similar to an atmospheric tower but smaller. The soap is similarly heated before flashing but under less pressure, so that boiling (actually drying of the soap) occurs in the heat exchangers. Since there is boiling in the heaters, the moisture of the dried soap depends primarily upon soap flow rate, soap pressure, and steam pressure to the heater and to a minor extent on the absolute pressure in the vacuum chamber. The

final temperature of the soap depends entirely upon the absolute pressure in the vacuum chamber.

Mixing. After drying, the soap noodles or flakes are mixed with all additional ingredients required by the final product formula. Mixing is done in batch processes or continuously. These ingredients include dye, perfume, preservatives, deodorants, opacifier, and special purpose items. The type and proportion of these materials is largely what makes one brand of milled soap different from another.

In batch mixing, dried soap and additives are measured and dumped into a dry blender, where macro-mixing occurs. The batch process is cumbersome and slow, and it is difficult to maintain uniform quality. Continuous mixing operations for improving economy and efficiency of mixing include precision metering devices to measure the additives into the soap noodles as they are pulverized and conveyed through the mixer. Although these ingredients constitute but a small portion of the total product, their effect on the physical properties, e.g., softness, resistance to cracking, lathering, and resistance to dissolving, are considerable.

Milling. The three objectives of milling are: (1) thorough and intimate final mixing of the soap, perfume, and other ingredients without overheating; (2) crushing lumps of overdried soap and pulverizing them into pieces too small to appear as lumps or hard specks in the finished bar; and (3) conversion of a sufficient portion of the soap into the waxy, plastic phase of cold working. Soap is milled by forcing it through a series of rolls, thus subjecting it to a strong shearing action. This cold working at the proper moisture content changes the crystalline structure or phase of the soap. Temperature control during milling is important. If the temperature is too low, the wrong crystal structure will be formed, resulting in soft soap or a hard, brittle structure prone to cracking. If the temperature is too high, the soap will become sticky and difficult to process further.

Another method for complete mixing and working uses multiple plodding and screening, in which the soap and additives are pushed together through finer and finer mesh screens.

Plodding. After milling, it is necessary to form the soap into a shape for making the final bar. This usually is accomplished with a plodder, which essentially is a large-size meat grinder with a barrel that terminates in a cone. The plodder functions to compact the pellets or flakes of soap into a solid mass, squeeze out any pockets of entrapped air, and extrude it as a firm, uniform, and continuous strip.

Operations that follow include cutting, stamping, wrapping, and packing.

Transparent Bar Manufacture. Most milled bars are opaque and contain a whitening agent (titanium dioxide) to create a uniform appearance. By eliminating this whitener and carefully controlling processing conditions, a bar that is transparent can be produced. This transparency results when the soap crystals are reduced to microscopic size which then allows light to pass through the structure. It is also important to achieve the correct soap phase. The control of soap phase is a function of the ratio of tallow to coconut soaps, the milling temperature, and soap moisture which must be maintained within very rigid limits.

Floating-Bar Manufacture. Base soap made from the desired blends of fat and oil first is flash-dried to a moisture content of about 22%. It then enters a mechanical mixer called a *crutcher*, where it is thoroughly mixed with perfume, preservatives, and air. The amount of air controls the density of the final product, giving the bar a density of less than one and making it floatable.

From the crutcher, the mix goes to a freezer to reduce the temperature of the soap to the point where it will hold its shape when extruded. In the earlier steps, the soap mix is in liquid form. Rapid chilling is required to put it into a solid state. The machine is similar to a commercial ice-cream freezer, consisting of a horizontal cylinder surrounded by a jacket and housing a rotating shaft (mutator) on which scraping blades are mounted. The liquid soap mix from the crutcher is pumped into one end of the cylinder. A refrigerated brine solution is circulated through the jacket to chill the soap. The scraping blades on the mutator remove the chilled soap from the cylinder walls and maintain uniformity of the mix. The nose of the freezer is equipped with an oblong orifice through which the soap is extruded, after chilling, in the form of a continuous ribbon, which has the same cross section as the final bar. There follows a series of cooling, storing, stamping, and packaging operations.

Health and Safety

The manufacture of soap poses some material handling concerns because of the reaction of strong caustics with either neutral fats and oils or fatty acids at relatively high temperatures. The caustics, ie, sodium hydroxide and potassium hydroxide, represent the primary hazard. At around 50% concentrations, these caustics are extremely corrosive and may cause serious body burns and eye injuries if not removed quickly through rinsing with copious amounts of water. Appropriate protective clothing is strongly urged when handling these materials.

Soap as used in personal cleansing products has a long safe history of use. Modern soaps have been specifically formulated to be compatible with skin and to be used on a daily basis with minimal side effects. However excessive use of soap for skin cleansing can disrupt the natural barrier function of skin through the removal of skin oils and disruption of the lipid bilayer in skin. This can result in imperfect desquamation or a dry appearance to skin and cause an irritation response or erythema, ie, reddening of the skin. Neither of these is a permanent response; and the elicitation of this type of skin reaction depends on the individual's skin type, the product formulation, and the frequency of use.

There is a considerable amount of research into the compatibility of cleansing products with skin. Modern soap manufacturers improve the skin compatibility of their products through a variety of chemical testing methods. These methods are often used to evaluate the mildness (irritation potential) of test formulations in comparison to other formulations on the basis of the dry skin and irritated (red) appearance of skin. There are many reports of comparative studies of various formulations and their mildness-to-skin; however, the results of these overly exaggerated test methods may not reflect consumer experience with products. Upon direct contact with other sensitive membranes such as eyes, soap may also cause irritation in the form of stinging. Again, this is a temporary response which can be rectified through rinsing with water. Ingestion of soap poses little risk at the levels of materials usually ingested. Typically, temporary minor irritation of mucous membranes and gastrointestinal disorders, eg, nausea, vomiting, and diarrhoea, may be experienced.

SOCIETY (Ecology). A group of individuals of the same species living together for mutual benefit, with some division of labor. The society is a high expression of colonial organization in the animal kingdom, and is not sharply separated from simpler forms of colonies.

In the simplest type of colony, as found among the 1-celled animals, the associated individuals are similar and each is capable of complete existence in itself. In the same group a slight division of labor appears, accompanied by structural differentiation of the individuals for different tasks. This form

of organization persists in the coelenterates, bryozoans, and ascidians, with varying degrees of structural continuity in the colony and varying degrees of differentiation and division of labor.

Among the more highly organized animals the possibility of association of individuals in a complex society involving division of labor is expressed only among the social insects and man. The insect society, or colony as it is often called, continues the associated principle of structural specialization of the individual for its particular duties, with the resulting castes exemplified in a simple form by the queen, drone, and worker honeybees. Among the termites and ants the differentiation is much more extreme and complex. To a moderate degree the honeybee colony also shows specialization of behavior among the workers, which may engage in various activities within their powers according to the requirements of the colony at different times.

The human society differs from that of insects in the restriction of inherent fitness for special duties to less evident details of organization. While inherent fitness undoubtedly exists among men, they are structurally of approximately the same form and their specialization is largely a result of training. In other words, specialization of the individual in human society is conspicuously a specialization of behavior. Lack of structural specialization is compensated by the use of tools.

In all cases, the society is an extension of the prevailing biological principle that biological units of any degree of complexity can be associated together as component parts of a larger coordinated unit.

SODALITE. An isometric mineral, a sodium aluminum silicate [CAS: 73987-94-7] containing sodium chloride [CAS: 7647-14-5], with the chemical composition Na_4Al_3 $(SiO_4)_3Cl$, potassium [CAS: 7440-09-7] sometimes replacing a small amount of sodium [CAS: 7440-23-5]. It is commonly found as dodecahedrons or simply massive. When observed sodalite has a dodecahedral cleavage; conchoidal to uneven fracture; brittle; hardness, 5.5–6; specific gravity, 2.14–2.30; luster, vitreous to greasy; color grayish to greenish or yellowish, may be white. It is often a beautiful blue and may sometimes be red. It is transparent to translucent; streak, white. Sodalite is found in igneous rocks of nephelite-syenite type which have been produced from soda rich magmas. Sodalite is a member of the sodalite group and together with hauyne, nosean and lazurite is a common constituent of lapis lazuli. The mineral derives its name from the fact of its soda content.

Discovered in 1806 in Greenland, sodalite did not become important as an ornamental stone until 1891 when vast deposits of fine material were discovered in Ontario, Canada. It has since been named **Princess Blue** after Princess Patricia who, upon visiting Ontario some time after its discovery, chose sodalite as interior decoration for Marlborough House in England.

Occurring typically in massive form, sodalite is found as vein fillings in plutonic igneous rocks such as nepheline syenites. It is associtated with other minerals typical of undersaturated environments, namely leucite, cancrinite and natrolite.

Significant deposits of fine material are restricted to but a few locales: Bancroft, Ontario and Mont-Saint-Hilaire, Quebec in Canada; and Litchfield, Maine and Magnet Cove, Arkansas in the USA. Smaller deposits are found in South America (Brazil and Bolivia), Portugal, Romania, Burma and Russia. Hackmanite is found principally in Mont. Saint-Hilare and Greenland, the latter locale producing a green specimen nicknamed "chameleon sodalite."

Euhedral, transparent crystals are found in northern Namibia and in the lavas of Vesuvius, Italy. These rare specimens are highly prized by collectors.

SODA NITRE. The mineral soda nitre or Chile saltpeter is naturally occurring sodium nitrate [CAS: 7631-99-4], $NaNO_3$. Its hexagonal crystals are rare, this mineral usually being found in crystalline aggregates, crusts or masses. It is soft; hardness, 1.5–2; specific gravity, 2.266; vitreous luster; colorless or white to yellow or gray; transparent to opaque. Soda nitre is a most important mineral commercially, being used in the manufacture of nitric acid [CAS: 7697-37-2], other nitrates and fertilizers. The chief soda nitre deposits of the world are those found in the Atacama and Tarapaca deserts of northern Chile, although others exist in the Argentine and Bolivia. Some small deposits have been found in California, New Mexico and Nevada. The origin of these nitrate deposits is far from being well understood. They have been regarded as nitrates formed originally by oxidation of organic matter and subsequently leached out. Guano, the excrement of birds, might be the original source of the nitrates. Ground water and ancient marine deposits have been suggested as well as the possibility of derivation from nitric acid produced in the atmosphere during electrical storms. Some investigators consider that the nitrates may have come from volcanic sources.

SODA PULP PROCESS. See **Pulp (Wood) Production and Processing**.

SODDY, FREDERICK (1877–1956). Frederick Soddy was an English radiochemist who conceived the concept of isotopes. An aspiring scientist from an early age, Soddy took a first-class honors degree in chemistry at Oxford in 1898. Two years later he became a demonstrator at McGill University in Canada, where he worked with physicist Ernest Rutherford to identify the gas given off by radioactive elements. In 1903 they proposed the disintegration theory of radioactivity: some of the heaviest elements achieve stability by losing mass and charge, forming in the process other elements. Soddy's Radioactivity (1904) presented an introduction to the subject. See also **Rutherford, Ernest (1871–1937)**.

Appointed to the University of Glasgow in 1904, Soddy spent the next ten years working to clarify the relationship between numerous radioelements' and the periodic table. His research, and that of others, showed that radioelement's could be chemically inseparable and yet have different physical properties. From this Soddy concluded that such elements were chemically identical (having the same atomic number) but of different atomic weights, and coined the term 'isotope' to describe them. Then he showed that radioactive substances decay to a final stable product (lead) following his displacement law, which locates an element's place in the periodic table following emission of alpha- and beta-particles. The new subject was clearly presented in The Chemistry of the Radioelement's (1911–1914); a few years later Soddy predicted the use of isotopes in geological dating. In 1921 he received the Nobel Prize for Chemistry.

After becoming Dr Lee's Professor of Chemistry at Oxford in 1919, Soddy gradually abandoned scientific research, developing instead little-supported political and economic ideas directed to the social consequences of science.

SODIUM. [CAS: 7440-23-5]. Chemical element, symbol Na, at. no. 11, at. wt. 22.9898, periodic table group 1 (alkali metals), mp 97.82 °C (208 °F), bp 882.9 °C (1621 °F), density 0.971 g/cm^3 (solid at 0 °C), 0.9268 g/cm^3 (liquid at mp). Elemental sodium has a face-centered cubic crystal structure.

Sodium is a silvery-white metal. It can be readily molded and cut by knife. It oxidizes instantly on exposure to air, and reacts with water

violently, yielding sodium hydroxide and hydrogen gas, consequently is preserved under kerosene, and burns in air at a red heat with yellow flame. Discovered by Davy in 1807.

There is only one naturally occurring isotope, ^{23}Na. There are five known radioactive isotopes, ^{20}Na through ^{22}Na, and ^{25}Na, all with short half-lives except ^{22}Na with a half-life of 2.6 years (Table 1). See also **Radioactivity**. In terms of abundance, sodium ranks sixth among the elements occurring in the earth's crust, with an average of 2.9% sodium in igneous rocks. In terms of content in seawater, the element ranks fourth (due mainly to excellent solubility of its compounds), with an estimated 50,000,000 tons of sodium per cubic mile of seawater. First ionization potential 5.138 eV. Oxidation potential $Na \rightarrow Na^+ + e^-$, 2.712 V.

TABLE 1. RADIOISOTOPES OF SODIUM

Isotope	CAS Registry Number	Half-life, s
sodium-20	[14809-59-7]	0.4
sodium-21	[15594-24-8]	23.0
sodium-22	[13966-32-0]	2.58[a]
sodium-24	[13982-04-2]	15.0[b]
sodium-25	[15760-13-1]	60.0
sodium-26	[26103-12-8]	1.0

[a] Expressed in years.
[b] Expressed in hours.

Other important physical properties of sodium are given under **Chemical Elements**.

Sodium does not occur in nature in the free state because of its great chemical reactivity. Sodium occurs as sodium chloride in the ocean (1.14% Na); in salt deposits (salt, halite, NaCl), e.g., in Michigan, New York, Louisiana, in Great Britain, and in Germany; in salt lakes, e.g., the Dead Sea (3% Na), Great Salt Lake; in common rocks (average of the solid shell of the earth 2.75% Na) as sodium nitrate (Chile saltpeter, $NaNO_3$) in Chile; as sodium borate (rasorite, kernite, $Na_2B_3O_7 \cdot 4H_2O$, in California; tinkal, $Na_2B_4O_7 \cdot 10H_2O$, in Tibet); and as sodium carbonate Na_2CO_2 and sulfate Na_2SO_4 in certain salt lake areas. See also **Sodium Chloride**.

Although sodium metal was isolated in 1807, it remained a laboratory curiosity until Oersted discovered in 1824 that sodium metal will reduce aluminum chloride to produce pure aluminum metal. This discovery led to the development of a commercial process for the manufacture of sodium. The first cell was designed by Castner in 1886 and a plant was built in Niagara Falls, N.Y., because of availability of low-cost electric power, for the electrolysis of fused NaOH. This process was made obsolete in 1921 by introduction of the Downs process in which a mixture of fused sodium chloride and calcium chloride is electrolyzed to produce metallic sodium. The modern cells have four anodes (graphite) surrounded by a steel cathode. Wire mesh diaphragms extend down into the electrolysis zone to prevent recombination of product sodium and chlorine. The use of calcium chloride in the cell significantly lowers the melting point of the mix. Sodium chloride has a mp 800 °C (1472 °F), calcium chloride, mp 772 °C (1422 °F), the two-salt eutectic, mp 505 °C (941 °F). Calcium has limited solubility in sodium. The excess calcium reacts with the sodium chloride present, $Ca + 2NaCl \rightarrow 2Na + CaCl_2$, and thus does not contaminate the sodium metal to a large degree. The sodium, which is saturated with calcium, is cooled in a riser pipe. This reduces the solubility of Ca in Na, precipitating Ca, which falls back into the cell, where it reacts to form more Na. The Na that overflows at the top of the riser pipe contains 1% or less of Ca. The Na is further purified by filtration at a temperature near its melting point, reducing the Ca content to about 0.05%. The cells operate at about 8 V, with groups of 25 to 40 cells connected in series.

Uses. Like so many of the chemical elements, the compounds of sodium are far more important than elemental sodium — by several orders of magnitude.

Among the attractions of molten sodium metal as a heat-transfer medium are: (1) low density compared with other metals and combinations of salts, contributing to low cost per unit volume and thus relative ease of pumping, sodium being about one-half that of the more commonly applied nitrate-nitrite heat-transfer salts; (2) relatively low vapor pressure even at temperatures as high as 550 °C (941 °F); (3) greater heat capacity than most common metals in liquid form, the thermal conductivity being 5 to 10 × greater than the conductivities of lead or mercury and 50 × higher than for most organic heat-transfer media; and (4) the viscosity of molten sodium is quite low. Despite these fine qualifications, however, the use of sodium as a heat-transfer medium has enjoyed a mixed reception over the years, partially attributable to a lack of marketing thrust in its behalf. Sodium is fifth among the metals in terms of electrical conductivity — hence bus bars are constructed from steel pipe filled with sodium. The characteristic yellow sodium light, created by the passage of an electric current through sodium vapor, is used for commercial and industrial lighting. Sodium is used to modify aluminum-silicon alloys. Normally coarse and brittle, such alloys can be transformed into fine-grained alloys with good casting properties through the addition of a fraction of 1% of sodium. Sodium also has been used as a hardening agent in bearing metals. When added with an alkaline-earth metal, such as calcium, sodium increases the hardness of lead. The German alloy "Bahnmetal" is an alloy of this type.

Generally, plain carbon steel containers are sufficient for handling metallic sodium at temperatures not in excess of the metal's boiling point. All-welded pipeline construction and bellows-sealed packless valves are usually used. Because of the metal's violent reactivity with H_2O, conventional fire extinguishers, including CO_2 and chlorinated hydrocarbons, should not be used. The preferred fire-retarding agents are salt, graphite, and soda ash, but they must be dry. Sand usually is not recommended because it is difficult to obtain perfectly dry sand in an emergency. In manufacturing operations involving sodium, particularly at reasonably high temperatures, an apron, leggings, and a complete face covering should be used. At normal temperatures, or where only small quantities of the metal are required, as may be the case in a research laboratory, conventional protective gear and goggles and gloves usually suffice.

Chemistry and Compounds. Sodium metal is obtained by electrolysis of fused sodium chloride or hydroxide out of contact with air. Its uses are limited in extent, but important in particular cases, as in the liberation of a metal from its chloride by reaction of sodium to form sodium chloride, and in certain reactions of organic chemistry.

The ionization potential of sodium (5.138 eV) is second to that of lithium and higher than those of the other alkali metals. However, the measured value of its oxidation potential against a normal aqueous solution of its ion is 2.712 V, the lowest of the group. Potassium is more electropositive in many of its reactions, even with water; though both react vigorously to produce the hydroxide and hydrogen, the reaction of potassium is more vigorous. With bromine, sodium reacts only slowly without heating and with iodine scarcely at all even on heating; potassium reacts violently with bromine, and with iodine on heating.

Because of the ease of removal of its single 3*s* electron (5.138 eV) and the great difficulty of removing a second electron (47.29 eV), sodium is exclusively monovalent in its compounds, which are electrovalent. Some experimental work indicates that the sodium alkyls may be covalent, but even they form conducting solutions in other metal alkyls.

Sodium Atoms Confined. In an interesting experiment conducted at the National Bureau of Standards in 1985, Migdall and colleagues trapped slow-moving neutral Na atoms in a magnetic field that created an energy well for the atoms. Robinson 1985, reported that approximately 10^5 sodium atoms in a trap volume of 20 cubic centimeters were stopped for a brief instant of time. For many years, spectroscopists have visualized the ideal sample where a collection of atoms or molecules would reside motionless in space for a period of time. Because of this experiment, researchers are closer to this goal. In the experiment, it was found that the particles gradually leak out, with time constants ranging from 0.1 to 1 second. Similar experiments have been conducted at AT&T Bell Laboratories (Holmdel, New Jersey). The theoretical trapping time in a perfect vacuum has been estimated as greater than 1000 seconds. The importance of these experiments is explored in considerable detail by Robinson in the reference listed.

Like lithium, sodium and its compounds have been studied extensively in solution in liquid NH_3. Sodium metal in such solutions slowly or with catalysis forms the amide, $NaNH_2$. The solution of the metal is a powerful reducing agent, reacting with metallic salts to free the metal, with which

it may form an intermetallic compound

$$Na + AgCl \longrightarrow NaCL + Ag$$

$$9Na + 4ZnCN)_2 \longrightarrow 8NaCN + NaZn_4$$

Sodium chloride also forms the amide, or at low temperatures the pentammoniate, $NaCl \cdot 5NH_3$.

Like the other alkali metals, sodium forms compounds with virtually all the anions, organic as well as inorganic. These compounds are remarkable for their great variety and for the fact that the reactivity of sodium bicarbonate with many metallic oxides permits preparation of many compounds that are unstable in aqueous solution. While other alkali bicarbonates react similarly, the general discussion of these compounds, and of the inorganic alkali salts generally, is appropriately given in this book under this entry for sodium, from which such a great number of inorganic (as well as organic) salts has been prepared.

Thus, normal (ortho) sodium arsenates $Na_3AsO_4 \cdot xH_2O$ and acid arsenates exist both in solution and in the solid state, whereas the meta- and pyroarsenates exist only as solids, but are readily prepared by heating arsenic pentoxide, As_2O_5, and sodium bicarbonate in correct proportions to produce the primary and secondary sodium arsenates, whence the meta- and pyroarsenates are obtained by heating

$$NaH_2AsO_4 \longrightarrow HeatNaAsO_3 + H_2O$$

$$2Na_2HAsO_4 \longrightarrow HeatNa_4AsO_2O_7 + H_2O$$

Similarly, the boron salts include metaborates, $NaBO_2 \cdot xH_2O$, tetraborates, $Na_2B_4O_7 \cdot xH_2O$, other polyborates, $Na_2B_{10}O_{16} \cdot xH_2O$, at least one orthoborate, Na_3BO_3, and peroxyborates, such as $NaBO_3 \cdot H_2O$. See also **Boron**. Other important sodium salts include the carbonates, cyanides, cyanates, hexacyanoferrates, $Na_4Fe(CN)_4$ and $Na_3Fe(CN)_6$, halides, polyhalides, hypohalites, halites, halates, perhalates, permanganates, ortho-, pyro-, meta-, fluoro-, and peroxyphosphates, hyposulfites, sulfites, sulfates, thiosulfates, peroxysulfates, polythionates, tungstates, vanadates, uranates, etc.

In addition to the simple compounds, sodium forms double salts of various types, although because of the relatively small size of the Na^+ ion, the number of sodium alums (see also **Alum**) is relatively small.

In addition to the inorganic salts, sodium forms such binary compounds as a phosphide, Na_3P, by direct union with phosphorus, a nitride, Na_3N, by direct union with nitrogen when activated electrically (which decomposes partly to give sodium amide, NaN_3, also obtained by heating sodium nitrate with sodium amide) and the oxides. Sodium monoxide, Na_2O, is obtained by heating the nitrite with the metal, displacing the nitrogen. Sodium peroxide, Na_2O_2, is the most stable oxide, obtained by reaction of the elements. Sodium superoxide is known, NaO_2, and one other oxide, Na_2O_3, has been reported. Sodium hydroxide, NaOH, is very soluble in H_2O and soluble in alcohol. It is almost completely ionized in water at ordinary concentrations, although its basic character is less than those of the higher elements in the group ($pK_B = -0.70$).

The detailed chemistry and applications of some of the more important compounds, other than those already discussed, follow.

Aluminate. Sodium aluminate, [CAS: 11138-49-1], $NaAlO_2$, white solid, (1) by reaction of aluminum hydroxide and NaOH solution, (2) by fusion of aluminum oxide and sodium carbonate, the solution reacts with CO_2 to form aluminum hydroxide. Used as a mordant, and in water purification. See also **Aluminum**.

Aluminosilicate. Sodium aluminosilicate [CAS: 73987-94-7] is used as a water softener for the removal of dissolved calcium compounds.

Amide. Sodamide, sodamine, [CAS: 7782-92-5], $NaNH_2$, white solid, formed by reaction of sodium metal and dry NH_3 gas at 350 °C (662 °F), or by solution of the metal in liquid ammonia. Reacts with carbon upon heating, to form sodium cyanide, and with nitrous oxide to form sodium azide, NaN_3.

Bromide. Sodium bromide, [CAS: 7647-15-6], NaBr, white solid, soluble, mp 755 °C (1427 °F). Used in photography and in medicine. See also **Bromine**; and **Sodium Bromide**.

Carbonates. Sodium carbonate (anhydrous), soda ash, [CAS: 497-19-8], Na_2CO_3, sodium carbonate decahydrate, washing soda, sal soda, $Na_2CO_3 \cdot 10H_2O$, white solid, soluble, mp 851 °C (1564 °F), formed by heating sodium hydrogen carbonate, either dry or in solution. Commonly bought and sold in quantity on the basis of oxide Na_2O determined by analysis (58.5% Na_2O equivalent to 100.0% Na_2CO_3). See also **Sodium Carbonate**.

Soda ash is a very-high-tonnage chemical raw material and approaches a production rate of 10 million tons/year in the United States. About 40% of soda ash is used in glassmaking; approximately 35% goes into the production of sodium chemicals, such as sodium chromates, phosphates, and silicates; nearly 10% is used by the pulp and paper industry; the remainder going into the production of soaps and detergents and in nonferrous metals refining. The first process for preparing soda ash was developed by Leblanc during the first French Revolution. In the Leblanc process, sodium chloride first is converted to sodium sulfate and subsequently the sulfate is heated with limestone and coke: (1) $Na_2SO_4 + 2C \rightarrow Na_2S + 2CO_2$; (2) $Na_2S + CaCO_3 \rightarrow Na_2CO_3 + CaS$. During the mid-1800s, the Solvay process was introduced. In this process, CO_2 is passed through an NH_3-saturated sodium chloride solution to form sodium bicarbonate, then followed by calcination of the bicarbonate: (1) $NH_3 + CO_2 + NaCl + H_2O \rightarrow HNaCO_3 + NH_4Cl$; (2) $2HNaCO_3 +$ heat$+Na_2CO_3 + CO_2 + H_2O$. A large proportion of soda ash now is derived from the natural mineral trona, which occurs in great abundance near Green River, Wyoming. Chemically trona is sodium sesquicarbonate, $Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$. After crushing, the natural ore is dissolved in agitated tanks to form a concentrated solution. Most of the impurities (boron oxides, calcium carbonate silica, sodium silicate, and shale rock) are insoluble in hot H_2O and separate out upon settling. Upon cooling, the filtered sesquicarbonate solution forms fine needle-like crystals in a vacuum crystallizer. After centrifuging, the sesquicarbonate crystals are heated to about 240 °C in rotary calciners whereupon CO_2 and bound H_2O are released to form natural soda ash. The crystals have a purity of 99.88% or more and handle easily without abrading or forming dust and thus assisting glassmakers and other users in obtaining uniform and homogeneous mixes.

Chlorate. Sodium chlorate, chlorate of soda, [CAS: 7775-09-9], $NaClO_3$, white solid, soluble, mp 260 °C (500 °F), powerful oxidizing agent and consequently a fire hazard with dry organic materials, such as clothes, and with sulfur; upon heating oxygen is liberated and the residue is sodium chloride; formed by electrolysis of sodium chloride solution under proper conditions. Used (1) as a weedkiller (above hazard), (2) in matches, and explosives, (3) in the textile and leather industries.

Chloride. Sodium chloride [CAS: 7647-14-5], common salt, rock salt, halite, NaCl, white solid, soluble, mp 804 °C (1479 °F). See also **Sodium Chloride**.

Chromate. Sodium chromate, [CAS: 7775-11-3], $Na_2CrO_4 \cdot 10H_2O$, yellow solid, soluble, formed by reaction of sodium carbonate and chromite at high temperatures in a current of air, and then extracting with water and evaporating the solution. Used (1) as a source of chromate, (2) in leather tanning, (3) in textile dyeing, (4) in inks.

Citrate. Sodium citrate, [CAS: 68-04-2], $Na_3C_6H_5O_7 \cdot 5\frac{1}{2}H_2O$ white solid, soluble, formed (1) by reaction of sodium carbonate or hydroxide and citric acid, (2) by reaction of calcium citrate and sodium sulfate or carbonate solution, and then filtering and evaporating the filtrate. Used in soft drinks and in medicine.

Cyanide. Sodium cyanide, [CAS: 143-33-9], NaCN, white solid, soluble, very poisonous, formed (1) by reaction of sodamide and carbon at high temperature, (2) by reaction of calcium cyanamide and sodium chloride at high temperature, reacts in dilute solution in air with gold or silver to form soluble sodium gold or silver cyanide, and used for this purpose in the cyanide process for recovery of gold. The percentage of available cyanide is greater than in potassium cyanide previously used. Used as a source of cyanide, and for hydrocyanic acid.

Dichromate. Sodium dichromate, [CAS: 10588-01-9], $Na_2Cr_2O_7 \cdot 2H_2O$, red solid, soluble, powerful oxidizing agent, and consequently a fire hazard with dry carbonaceous materials. Formed by acidifying sodium

chromate solution, and then evaporating. Used (1) in matches and pyrotechnics, (2) in leather tanning and in the textile industry, (3) as a source of chromate, cheaper than potassium dichromate.

Dithionate. Sodium dithionate, "sodium hyposulfate," [CAS: 7775-14-6], $Na_2S_2O_6 \cdot 2H_2O$, white solid, soluble, formed from manganese dithionate solution and sodium carbonate solution, and then filtering and evaporating the filtrate.

Fluorides. Sodium fluoride [CAS: 7681-49-4], NaF, white solid, soluble, formed by reaction of sodium carbonate and hydrofluoric acid, and then evaporating. Used (1) as an antiseptic and antifermentative in alcohol distilleries, (2) as a food preservative, (3) as a poison for rats and roaches, (4) as a constituent of ceramic enamels and fluxes; sodium hydrogen fluoride, sodium difluoride, sodium acid fluoride, $NaHF_2$, white solid, soluble, formed by reaction of sodium carbonate and excess hydrofluoric acid, and then evaporating. Used (1) as an antiseptic, (2) for etching glass, (3) as a food preservative, (4) for preserving zoological specimens.

Fluosilicate. Sodium fluosilicate, [CAS: 16893-85-9], Na_2SiF_6, white solid, very slightly soluble in cold H_2O, formed by reaction of sodium carbonate and hydrofluosilicic acid. Used (1) in ceramic glazes and opal glass, (2) in laundering, (3) as an antiseptic.

Formate. Sodium formate, [CAS: 141-53-7], $NaCHO_2$, white solid, soluble, formed by reaction of NaOH and carbon monoxide under pressure at about 200 °C (392 °F). Used (1) as a source of formate and formic acid, (2) as a reducing agent in organic chemistry, (3) as a mordant in dyeing, (4) in medicine.

Hydride. Sodium hydride, [CAS: 7646-69-7], NaH, white solid, reactive with water yielding hydrogen gas and NaOH solution, formed by reaction of sodium and hydrogen at about 360 °C (680 °F). Used as a powerful reducing agent.

Hydroxide. Sodium hydroxide, caustic soda, sodium hydrate, "lye," [CAS: 1310-73-2], NaOH, white solid, soluble, mp 318 °C (604 °F), an important strong alkali, not as cheap as calcium oxide (a strong alkali) nor sodium carbonate (a mild alkali), but of wide use. Formed (1) by reaction of sodium carbonate and calcium hydroxide in H_2O, and then separation of the solution and evaporation, (2) by electrolysis of sodium chloride solution under the proper conditions, and evaporation. Commonly bought and sold in quantity on the basis of oxide Na_2O determined by analysis (77.5% Na_2O equivalent to 100.0% NaOH). Used (1) in the manufacture of soap, rayon, paper ("soda process"), (2) in petroleum and vegetable oil refining, (3) in the rubber industry, in the textile and tanning industries, (4) in the preparation of sodium salts, (a) in solution, (b) upon fusion. See Fig. 1. See also **Sodium Hydroxide**.

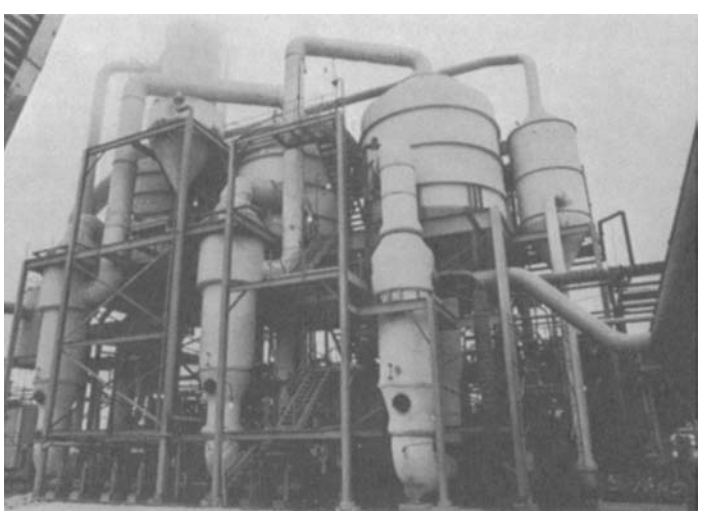

Fig. 1. Triple-effect evaporator used in concentrating soda solutions and preparation of solid sodium hydroxide.

Hypochlorite. Sodium hypochlorite, [CAS: 7681-52-9], NaOCl, commonly in solution by (1) electrolysis of sodium chloride solution under proper conditions, (2) reaction of calcium hypochlorite suspension in water and sodium carbonate solution, and then filtering. Used (1) as a bleaching agent for textiles and paper pulp, (2) as a disinfectant, especially for water, (3) as an oxidizing reagent. See also **Bleaching Agents**.

Hypophosphite. Sodium hypophosphite, [CAS: 7681-53-0], $NaH_2PO_2 \cdot H_2O$, white solid, soluble, formed (1) by reaction of hypophosphorous acid and sodium carbonate solution, and then evaporating, (2) by reaction of NaOH solution and phosphorus on heating (poisonous phosphine gas evolved).

Hyposulfite. Sodium hyposulfite [CAS: 7772-98-7], sodium hydrosulfite (not sodium thio sulfate), $Na_2S_2O_4$, white solid, soluble, formed by reaction of sodium hydrogen sulfite and zinc metal powder, and then precipitating sodium hyposulfite by sodium chloride in concentrated solution. Used as an important reducing agent in the textile industry, e.g., bleaching, color discharge.

Iodide. Sodium iodide, [CAS: 7681-82-5], NaI, white solid, soluble, mp 651 °C (1204 °F), formed by reaction of sodium carbonate or hydroxide and hydriodic acid, and then evaporating. Used in photography, in medicine and as a source of iodide. See also **Sodium Iodide**.

Manganate. Sodium manganate, Na_2MnO_4, green solid, soluble, permanent in alkali, formed by heating to high temperature manganese dioxide and sodium carbonate, and then extracting with water and evaporating the solution. The first step in the preparation of sodium permanganate from pyrolusite.

Nitrate. Sodium nitrate, nitrate of soda, Chile saltpeter, "caliche," [CAS: 7631-99-4], NaNO3, white solid, soluble, mp 308 °C (586 °F), source in nature is Chile, in the fixation of atmospheric nitrogen HNO_3 is frequently transformed by sodium carbonate into sodium nitrate, and the solution evaporated. Used (1) as an important nitrogenous fertilizer, (2) as a source of nitrate and HNO_3, (3) in pyrotechnics, (4) in fluxes. See also **Sodium Nitrate**.

Nitrite. Sodium nitrite, [CAS: 7632-00-0], $NaNO_2$, yellowish-white solid, soluble, formed (1) by reaction of nitric oxide plus nitrogen dioxide and sodium carbonate or hydroxide, and then evaporating, (2) by heating sodium nitrate and lead to a high temperature, and then extracting the soluble portion (lead monoxide insoluble) with H_2O and evaporating. Used as an important reagent (diazotizing) in organic chemistry. See also **Sodium Nitrite**.

Oleate. Sodium oleate, [CAS: 143-19-1], $NaC_{18}H_{33}O_2$, white solid, soluble, froth or foam upon shaking the H_2O solution (soap), formed by reaction of NaOH and oleic acid (in alcoholic solution) and evaporating. Used as a source of oleate.

Oxalates. Sodium oxalate, [CAS: 62-76-0], $Na_2C_2O_4$, white solid, moderately soluble, formed (1) by reaction of sodium carbonate or hydroxide and oxalic acid, and then evaporating, (2) by heating sodium formate rapidly, with loss of hydrogen. Used as a source of oxalate; sodium hydrogen oxalate, sodium binoxalate, sodium acid oxalate, $NaHC_2O_4 \cdot H_2O$, white solid, moderately soluble.

Palmitate. Sodium palmitate, [CAS: 408-35-5], $NaC_{16}H_{31}O_2$, white solid, soluble, froth or foam upon shaking the H_2O solution (soap), formed by reaction of NaOH and palmitic acid (in alcoholic solution) and evaporating. Used as a source of palmitate.

Permanganate. Sodium permanganate, permanganate of soda, [CAS: 10101-50-5], $NaMnO_4 \cdot 3H_2O$, purple solid, soluble, formed by oxidation of acidified sodium manganate solution with chlorine, and then evaporating. Used (1) as disinfectant and bactericide, (2) in medicine.

Phenate. Sodium phenate, sodium phenoxide, sodium phenolate, [CAS: 139-02-6], $NaOC_6H_5$, white solid, soluble, formed by reaction of sodium hydroxide (not carbonate) solution and phenol, and then evaporating. Used in the preparation of sodium salicylate.

Phosphates. Trisodium phosphate, tribasic sodium phosphate, [CAS: 7601-54-9], $Na_3PO_4 \cdot 12H_2O$, white solid, soluble, formed (1) by reaction of sodium hydroxide and the requisite amount of phosphoric acid, and then evaporating, (2) by reaction of disodium hydrogen phosphate plus sodium hydroxide, and then evaporating. Used (1) as a cleansing and laundering agent, (2) as a water softener, (3) in photography, (4) in tanning, (5) in the purification of sugar solutions; disodium hydrogen phosphate, dibasic

sodium phosphate, $Na_2HPO_4 \cdot 12H_2O$, white solid, soluble, formed (1) by reaction of dicalcium hydrogen phosphate and sodium carbonate solution, and then evaporating the solution, (2) by reaction of sodium carbonate and the requisite amount of phosphoric acid, and then evaporating. Used (1) in weighting silk, (2) in dyeing and printing textiles, (3) in fireproofing wood, paper, fabrics, (4) in ceramic glazes, (5) in baking powders, (6) to prepare sodium pyrophosphate; sodium dihydrogen phosphate, monobasic sodium phosphate, $NaH_2PO_4 \cdot H_2O$, white solid, soluble, formed (1) by reaction of sodium carbonate and the requisite amount of phosphoric acid, and then evaporating, (2) by reaction of calcium monohydrogen phosphate and sodium carbonate solution, and then evaporating the solution. Used (1) in baking powders, (2) in medicine, (3) to prepare sodium metaphosphate; sodium pyrophosphate, $Na_4P_2O_7 \cdot 10H_2O$, white solid, soluble, mp about 900 °C (1652 °F), formed by heating disodium hydrogen phosphate to complete loss of water, followed by crystallization from water solution. Used in electroanalysis; sodium metaphosphate, $NaPO_3$, white solid, soluble, mp 617 °C, formed by heating sodium dihydrogen phosphate or sodium ammonium phosphate to complete loss of water, is an easily fusible phosphate forming colored phosphates with many metallic oxides, e.g., cobalt oxide. The hexametaphosphate, $(NaPO_3)_6$, is an important water-conditioning agent forming soluble complex compounds with many cations, e.g., Ca^{2+}, Mg^{2+}. Many polyphosphate compounds are known; their various uses include water softening and ion exchange. They are widely formulated in detergents, as are several of the simpler phosphates.

Phosphites. Disodium hydrogen phosphite, $Na_2HPO_3 \cdot 5H_2O$, white solid, soluble, formed by reaction of phosphorous acid and sodium carbonate, and then evaporating at a low temperature, mp of anhydrous salt is 53 °C (127 °F), at higher temperatures yields sodium phosphate and phosphine gas; sodium dihydrogen phosphite, $NaH_2PO_3 \cdot 2\frac{1}{2}H_2O$, white solid, soluble, formed by reaction of phosphorous acid and NaOH cooled to −23 °C when the crystalline salt separates.

Salicylate. Sodium salicylate, [CAS: 54-21-7], $NaC_7H_5O_3$, white solid, soluble, formed by reaction of sodium phenate and CO_2 under pressure. Used as a source of salicylate and for salicylic acid.

Silicate. Sodium silicate, sodium metasilicate, "water glass," [CAS: 6834-92-0], Na_2SiO_3, colorless (when pure) glass, soluble, mp 1,088 °C, formed by reaction of silicon oxide and sodium carbonate at high temperature; solution reacts with CO_2 of the air, or with sodium carbonate solution or ammonium chloride solution, yielding silicic acid, gelatinous precipitate. Sodium silicate solution is used (1) in soaps, (2) for preserving eggs, (3) for treating wood against decay, (4) for rendering cloth, paper, wood noninflammable, (5) in dyeing and printing textiles, (6) as an adhesive (e.g., for paper boxes) and cement. Sold as granular, crystals, or 40° Baumé solution.

Silicoaluminate. (See **aluminosilicate**, above.)

Silicofluoride. (See **fluosilicate**, above.)

Stearate. Sodium stearate, [CAS: 822-16-2], $NaC_{18}H_{35}O_2$, white solid, soluble, froth or foam upon shaking the water solution (soap), formed by reaction of NaOH and stearic acid (in alcoholic solution) and evaporating. Used as a source of stearate.

Sulfates. Sodium sulfate (anhydrous), "salt cake," [CAS: 7757-82-6], Na_2SO_4, sodium sulfate, decahydrate, "Glauber's salt," $Na_2SO_4 \cdot 10H_2O$, white solid, soluble, formed by reaction of sodium chloride and H_2SO_4 upon heating with evolution of hydrogen chloride gas. Used (1) in dyeing, (2) along with carbon in the manufacture of glass, (3) as a source of sulfate, (4) to prepare sodium sulfide; sodium hydrogen sulfate, sodium bisulfate, sodium acid sulfate, "nitre cake," $NaHSO_4$, white solid, soluble, formed by reaction of sodium nitrate and H_2SO_4, upon heating, with evolution of HNO_3. Used (1) as a cheap substitute for H_2SO_4. (2) in dyeing, (3) as a flux in metallurgy; sodium pyrosulfate, $Na_2S_2O_7$, white solid, soluble, formed by heating sodium hydrogen sulfate to complete loss of H_2O. See also **Sodium Sulfates**.

Sulfides. Sodium sulfide, [CAS: 1313-82-2], Na_2S, yellowish to reddish solid, soluble, formed (1) by heating sodium sulfate and carbon to a high temperature. Used (1) as the cooking liquor reagent (along with sodium hydroxide) in the "sulfate" or "kraft" process of converting wood into paper pulp, (2) as a depilatory, (3) in sheep dips, (4) in photography, engraving and lithography, (5) in organic reactions, (6) as a source of sulfide, (7) as a reducing agent; sodium hydrogen sulfide, sodium bisfulfide, sodium acid sulfide, NaHS, formed in solution by reaction of NaOH or carbonate solution and excess H_2S. See also **Sodium Sulfides**.

Sulfites. Sodium sulfite, [CAS: 7757-83-7], Na_2SO_3, white solid, soluble, dilute solution readily oxidized in air, but retarded by mannitol (carbohydrates), formed by reaction of sodium carbonate or hydroxide solution and the requisite amount of SO_2, at high temperature yields sodium sulfate and sodium sulfide. Used (1) as a source of sulfite, (2) as a reducing agent, (3) to prepare sodium thiosulfate, (4) as a food preservative, (5) as a photographic developer, (6) as a bleaching agent and antichlor in the textile industry; sodium hydrogen sulfite, sodium bisulfite, sodium acid sulfite, $NaHSO_3$, white solid, soluble, formed by reaction of sodium carbonate solution and excess sulfurous acid. Uses similar to those of sodium sulfite.

Tartrate. Sodium tartrate, [CAS: 868-18-8], $Na_2C_4H_4O_6 \cdot 2H_2O$, white solid, soluble, formed by reaction of sodium carbonate solution and tartaric acid. Used in medicine; sodium potassium tartrate, Rochelle salt, $NaKC_4H_4O_6 \cdot 4H_2O$, white solid, soluble. Used (1) in medicine, (2) as a source of tartrate.

Thiosulfate. Sodium thiosulfate, "Hypo" [CAS: 7772-98-7], $Na_2S_2O_3 \cdot 5H_2O$, white solid, soluble, formed by reaction of sodium sulfite and sulfur upon boiling, and then evaporating. Used (1) in photography as fixing agent to dissolve unchanged silver salt, (2) as a reducing agent and antichlor. See also **Sodium Thiosulfate**.

Tungstate. Sodium tungstate, (sodium wolframate), [CAS: 13472-45-2], $Na_2WO_4 \cdot 2H_2O$, white solid, soluble, by reaction of NaOH solution and tungsten trioxide upon boiling, and then evaporating. Used (1) in fireproofing fabrics, (2) as a source of tungsten for chemical reactions.

Uranate. Sodium uranate, uranium yellow, Na_2UO_4, yellow solid, insoluble, formed by reaction of soluble uranyl salt solution and excess sodium carbonate solution. Used (1) in the manufacture of yellowish-green fluorescent glass, (2) in ceramic enamels, (3) as a source of uranium for chemical reactions.

Vanadate. Sodium vanadate, [CAS: 13718-26-8], sodium orthovanadate, Na_3VO_4, white solid, soluble, formed by fusion of vanadium pentoxide and sodium carbonate. Used (1) in inks, (2) in photography, (3) in dyeing of furs, (4) in inoculation of plant life.

The larger number of organic compounds of sodium are for great part derivatives of oxygen-containing compounds such as salts of organic acids (several of which are discussed above), alcoholic and phenolic compounds (carboxylates, alkoxides, phenoxides, etc.). However, in some cases, sodium derivatives of nitrogen-containing compounds, as sodium benzamide, $C_6H_5C(O)NHNa$, and sodium anilide, C_6H_5NHNa, contain sodium-nitrogen bonds, while even sodium-boron bonds exist in certain boron-containing compounds, as sodium triphenylborene, $NaB(C_6H_5)_3$, and others; and in a number of compounds sodium is carbon-connected, as in methylsodium, CH_3Na, ethylsodium, C_2H_5Na, cyclopentadienylsodium, C_5H_5Na, and sodium triphenylmethane, $NaC(C_6H_5)_3$.

The organometallic compounds of sodium may be divided into two groups, differing in properties. One group, e.g., ethylsodium, consists of compounds that are colorless, insoluble in organic solvents, and that electrolyze readily in diethylzinc solution. Another group, e.g., benzylsodium, $C_6H_5CH_2Na$, are colored, and soluble in organic solvents.

Like all the alkali metals, sodium coordinates with salicylaldehyde. Its tetracovalent compounds, with those of potassium, are the more stable of the group, for the following reasons: (1) Increasing ionic size carries with it increasing electropositiveness and ease of ionization, which diminishes the tendency to coordinate. (2) The increasing distance of the nucleus from the coordinating electrons with increasing atomic volume makes it less likely that additional electrons will be held with ease. (3) On the other hand, there is an increase in the maximum coordination number with the elements of higher atomic number. These factors are in keeping with a maximum stability for the tetracovalent compounds occurring with sodium.

Health and Safety Factors. The safe handling of sodium requires special consideration because of its high reactivity. Using properly designed equipment and strict safe-handling procedures, sodium is used in large- and small-volume applications without incident. The hazards of

handling sodium are no greater than those encountered using many other industrial chemicals, although incidents can result in very serious injury, and fatalities have been known to occur from accidental contact with molten, burning sodium, or from contact with sodium finely dispersed in inert hydrocarbons such as mineral oil [CAS: 8012-95-1] or toluene [108-88-3].

Direct contact of the skin with sodium can cause deep, serious burns from the action of sodium with the moisture present and the subsequent corrosive action of the caustic formed. Sodium can cause blindness on contact with the eyes. For these reasons, goggles, face shields, hard hat, hoods, long-gauntlet mittens, and multiple layers of flame-retardant protective clothing are recommended when working with molten sodium. All body parts should be protected and clothing needs to be designed for quick removal in case of emergencies. Contaminated clothing should first be steamed, then washed, or destroyed by burning.

Perhaps the greatest hazard presented by metallic sodium stems from its extremely vigorous reaction with water to form sodium hydroxide and hydrogen with the evolution of heat. In the presence of air this combination usually results in explosion; in a closed system where an inert atmosphere is present, the hydrogen evolved can cause a rapid increase in pressure. In the absence of air, the rate of reaction is substantially equal to the rate of mixing the reactants, and the reaction does not generally cause mechanical damage to heat-transfer equipment. In the presence of air, the results cannot be predicted. Hydrogen evolved in a closed container should not be allowed to mix with air.

Another hazard arises from the oxidation of sodium in air. Liquid sodium can autoignite at 120 °C (248 °F), although under some conditions dispersed or high surface sodium may ignite at much lower temperatures. A small local sodium fire can be extinguished by submerging the burning mass in the remaining pool of liquid sodium using an iron blade if the bulk of the sodium has not reached the ignition point. Larger fires are more difficult to handle. The common fire extinguishers, ie, water, CO_2, CCl_4, etc, should never be used. These only aggravate the existing situation by introducing additional explosion or reaction hazards. If the vessel containing the burning sodium can be flooded with nitrogen or closed to exclude air, the fire subsides and the material can be cooled. Fires that cannot be extinguished by excluding air may be quenched by large quantities of dry salts or other dry, cold, inert powder. Dry light soda ash, Na_2CO_3, is excellent for this purpose but must not be used if made damp on exposure in storage, and must be carefully protected from contact with exposure to moisture in air. Process areas and equipment should be designed to confine any sodium spills and permit recovery.

Techniques for handling sodium in commercial-scale applications have improved. Contamination by sodium oxide is kept at a minimum by completely welded construction and inert gas-pressured transfers. Residual oxide is removed by cold traps or micrometallic filters. Special mechanical pumps or leak-free electromagnetic pumps and meters work well with clean liquid sodium. Corrosion of stainless or carbon steel equipment is minimized by keeping the oxide content low. The 8-h TWA PEL and ceiling TLV for sodium or sodium oxide or hydroxide smoke exposure is 2 mg/m^3. There is no defined ALD for pure sodium, as even the smallest quantity ingested could potentially cause fatal injury.

In the laboratory, sodium is best handled in a glove box filled with nitrogen or another inert gas, or in a water-free hood. When sodium is handled on the bench top, water and aqueous solutions must be excluded from the area. Tools for cutting or handling sodium must be clean and dry. Contact of sodium with air should be kept to a minimum because moisture in the air reacts rapidly with sodium. A metal catch pan under the equipment is essential to contain any spills or fires when breaking into pipe or equipment that previously contained liquid sodium. Provision should be made for safe removal of sodium residues from equipment and for cleaning the apparatus. Residue and sodium scrap can be destroyed by burning in a steel pan in a well-ventilated hood. Equipment may be cleaned by being opened to the air and heated until any sodium present is oxidized, or by purging thoroughly with nitrogen, then slowly admitting dry steam to the system while maintaining the nitrogen purge. The burning of sodium as part of any cleaning procedure produces an irritating and hazardous smoke of sodium oxide. This should be collected by an appropriate hood or duct and scrubbed. Dilute aqueous sodium hydroxide is a satisfactory scrubbing liquid.

Other methods for safely cleaning apparatus containing sodium residues or disposing of waste sodium are based on treatment with bismuth or lead, inert organic liquids, or by reaction with water vapor carried in an inert gas stream.

Most reactions of sodium are heterogeneous, occurring on the surface of solid or liquid sodium. Such reactions are accelerated by extending the sodium surface exposed. The sodium is generally dispersed in a suitable medium or spread over a solid powder of high surface area. Dispersions in inert hydrocarbons may be briefly exposed to air and present no special hazards as long as the hydrocarbon covers the sodium. High surface sodium reacts very rapidly with air, however, and cannot be exposed without risk of fire. Dispersions of sodium spilled on cloth or other absorbent material may ignite quickly.

Sodium in Biological Systems. Sodium is essential to higher animals which regulate the composition of their body fluids and to some marine organisms. The several important roles played by the sodium cation in biological systems, frequently in concert with the potassium cation are described in the entry on **Potassium and Sodium (In Biological Systems)**.

SODIUM CHLORIDE. [CAS: 7647-14-5], NaCl, formula weight 58.44, white solid, cubic crystal structure, mp 800.6 °C (1473 °F), bp 1,413 °C (2575 °F), sp gr 2.165. Commonly called "salt," the mineral name for rock salt is *halite*. See also **Halite (Rock Salt)**. The compound is soluble in H_2O (35.7 g/100 g H_2O at 0 °C; 39.8 g/100 g H_2O at 100 °C), only slightly soluble in alcohol, and insoluble in HCl. Sodium chloride is produced in nearly all nations of the world, but some only have a sufficient supply for local needs. The leading salt-producing nations include the United States, China, the former U.S.S.R., West Germany, France, the United Kingdom, India, Italy, Canada, and Mexico. In 28 states of the United States and in several provinces of Canada, salt occurs as bedded or domed deposits. Most of the rock salt produced in the United States comes from Michigan, New York, Texas, Ohio, Louisiana, and Kansas. Purity ranges from 97% NaCl for Kansas salt to 99% purity and higher for Louisiana salt. The main impurities are calcium sulfate (0.5–2%), dolomite, quartz, calcite, and traces of iron oxides. Natural rock salt is mined much as coal and usually marketed without purification, after crushing and screening. For most industrial and consumer requirements, the impurities are harmless. There is no evidence that bacteria exist in rock salt. Additionally, there is some solar salt production in the Great Salt Lake area of Utah and on the west coast. Salt deposits date back to past geologic ages and are believed to be the results of evaporated impounded seawater.

Purified salt for table and industrial processing requirements of a special nature is made by dissolving raw sodium chloride in H_2O and then

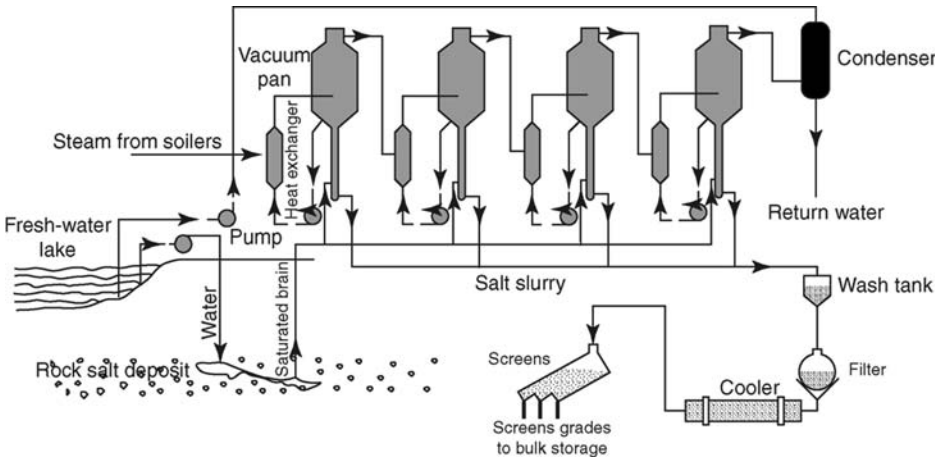

Fig. 1. Multiple-effect vacuum pans used in production of sodium chloride from brine. The saturated brine is formed by pumping fresh water directly into the rock salt deposit, leaving insoluble materials in the deposit.

evaporating the H_2O to form a final product. There are several types of evaporated salt, including *granulated salt* in which each crystal is a tiny cube, and *grainer* or *flake salt*, made up of irregularly shaped crystals, often thin and flaky and unusually soft. A process for producing evaporated salt is shown in Fig. 1. Holes are drilled into the salt deposits, after which H_2O is pumped into the beds to create a brine which then is brought to the surface for refining. In this method, all insolubles are left in the bed. After some pretreatment to remove hardness and dissolved gases, the semipure brine is evaporated in multiple-effect vacuum pans. The salt crystallizes as perfect cubes of NaCl. In the system shown, each vacuum pan performs not only as an evaporator, but also as a boiler. The vapors from a preceding pan are used to heat the contents of the following pan. This system of heat economizing is possible because each succeeding pan in the series is under less pressure — hence the contents boil at a lower temperature. See Fig. 2. The lower pressure in succeeding pans results from condensation of the vapors as well as assistance from vacuum pumps. Crystal size is controlled by evaporation rate, the latter depending on the degree of vacuum, temperature, and agitation maintained. When grown to proper size, the crystals drop to the bottom of the pans and fall into the salt legs, from which they are drawn continuously in the form of a slurry. After washing, filtering, cooling, and screening, they are packaged. See also **Evaporation**.

Grainer salt is made by surface evaporation of brine in flat pans open to the atmosphere. Heat usually is furnished by steam pipes located a few inches below the tank bottom. Crystals form at the surface of the brine and are held there temporarily by surface tension. Thus, they grow laterally for awhile and form thin flakes. But, as they grow, they tend to sink and this process imparts a peculiar, hollow pyramid-like structure to them. Such crystals are called *hopper crystals*. Ultimately, the crystals sink to the bottom where they are scraped to one end of the pan. The crystals are fragile and during handling they break up, finally assuming a flake-like shape. Thus, the term *flake salt*.

In the *recrystallizer process* for making salt, advantage is taken of the fact that the solubility of NaCl increases with temperature whereas the solubility of the principal impurity, $CaSO_4$, decreases with temperature. In *solar* facilities, the raw brine is pumped into concentrating ponds where most of the H_2O is evaporated. Some of the impurities are precipitated out in this stage, after which the saturated brine is transferred to crystallization ponds where the salt crystallizes out at a high degree of purity. Since evaporation occurs at the surface of the ponds, hopper crystals are formed as in the grainer process, with flake salt being the final product.

Uses. Sodium chloride is a very high-tonnage material. In addition to its familiar use in the diets of man and animals, representing a small part of total production, large quantities are used by highway departments to control icy road conditions, in agriculture, and as a basic chemical raw material. The chemical industry consumes about two-thirds of the salt produced, the majority of it going to electrolytic plants. Some of the basic inorganic chemicals that require salt as a starting material include soda ash, calcium chloride, caustic soda, sodium sulfate, sodium bisulfate, HCl, sodium cyanide, sodium hypochlorite, and chlorine. See also **Chlorine**; and **Sodium**.

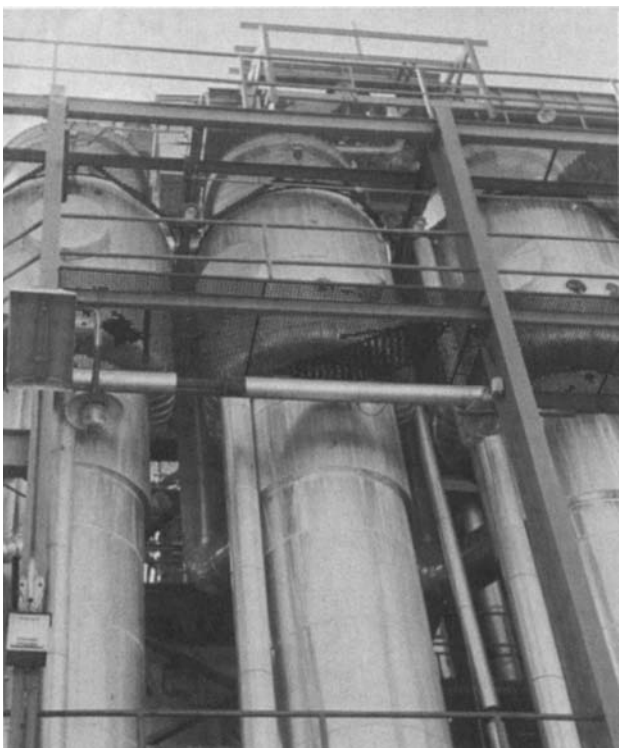

Fig. 2. Portion of train of evaporator bodies in a multiple-effect vacuum evaporation system used in production of sodium chloride.

Salt and the Diet

In food processing, the preservative and organoleptic qualities of salt are well established and it is fully appreciated why use of salt even to excess is attractive to food processors. Excessive usage is also habitual among people who "salt first and taste later." Reports show over 1 million tons (900,000 metric tons) of salt are used in foods and in connection with eating in the United States in a given year. Nearly an additional 2 million tons (1.8 million metric tons) are used in the agricultural field, much of which is consumed by livestock. The total daily intake of the North American consumer as of 1980 is estimated to be in the range of 10–12 grams of salt, which reduces to a range of 3900–4700 milligrams of sodium. Highly salted snack foods, the consumption of which has increased markedly in many parts of the world during recent years, accounts for a significant consumption of salt. In addition, certain other food ingredients, such as

monosodium glutamate and soy sauce, sometimes used in excess, also contribute to the average intake of sodium.

Sodium and chloride are not normally retained in the body even when there is a high intake. See also **Chloride (Biological Aspects)**. Amounts consumed in excess of need are excreted, so that the level in the body is maintained within very narrow limits, as is also the chloride, regardless of intake. The primary route of excretion is via the urine, with substantial amounts also lost in sweat and feces. About 50% of the sodium in the human body is located in the extracellular body fluids; 10% inside the cells; and 40% in the bones. Chloride is found mainly in the gastric juice and other body fluids.

Essential though sodium is to the normal functioning of the human body, there has been considerable concern over the last few years, about the amount of salt in the diet. This concern centers mainly on possible relationship between salt and hypertension (high blood pressure).

Hypertension afflicts more than 20% of the world population, with an estimated 24 million cases in the United States as of 1980. In 1976, Marx reported that, in about 90% of these cases, the actual causes of hypertension cannot be pinpointed. — This was in face of the fact that research on the possible role of sodium in essential hypertension had been underway for 60 years or longer. Tests of unmedicated persons with essential hypertension have been found to indicate a lowering of blood pressure when sodium intake is restricted below one gram per day — and that the blood pressure rises again if additional sodium is taken. However, in other studies, some persons have retained a normal blood pressure level even when fed substantially increased amounts of salt (or other sodium-ion-furnishing substances). In 1976, Freis reported positive correlations between estimated average salt consumption of various ethnic populations and their incidence of hypertension. But such studies are complicated by many factors, including the inability to control or eliminate other possible causes of hypertension, such as obesity, genetic predisposition, general nutritional status, and potassium intake. It also has been generally proved extremely difficult to determine differences between individuals within these cultures.

Nevertheless, the concern remains on the part of a large number of professional people who feel that someday a definitive correlation will be made. And, with considerable awareness of the lay public in this regard, very definite pressures are being exerted on food processors to reduce salt usage and to more accurately label their merchandise in this regard.

The physiology of the sodium-potassium relationship is explained in some detail in the entry on **Potassium and Sodium (In Biological Systems)**.

Concerning the sodium content (much of which is derived from salt), the following composition data may be of interest. The figures in parentheses are milligrams of sodium per 100 grams of food.

Meats Canadian bacon (2555), bacon (1077), cured ham (860), beef liver (136), pork chops (60), ground beef (48).

Cheeses Parmesan (1848), process (1421), blue (1396), brick (557), cream cheese (294).

Other dairy products Ice cream (83), whole milk (50), sherbet (45). *Miscellaneous foods*: Pretzels (7800), soy sauce (regular) (6082), dill pickles (4000–5000), soy sauce (mild) (3569), green olives (2400), soda crackers (1100), salted peanuts (groundnuts) (418), eggs (122).

Vegetables Beet greens (130), celery (126), dandelion greens (76), kale (75), spinach (60), beets (60), watercress (52), turnips (49), carrots (47), artichokes (43), collards (43), mustard greens (32), Chinese cabbage (20). Other common vegetables range between (10) and (18).

Sodium Chloride and Energy

As pointed out by Wick (*Oceanus*, **22**, 4, 28, 1980), most of the energy in the oceans is bound in thermal and chemical forms. Although thermal energy is presently commanding the most attention, within the past few years another, rather unusual, form has received notice. Where rivers flow into the oceans a completely untapped source of energy exists — represented by a large osmotic pressure difference between fresh and salt water. If economical ways to tap these salinity gradients could be developed, large quantities of energy would be available. See also **Solar Energy**.

SODIUM HYDROSULFIDE. See **Sulfur Compounds**.

SODIUM HYPOCHLORITE. See **Bleaching Agents**.

SODIUM SULFIDE. See **Sulfur Compounds**.

SODIUM THIOSULFATE. [CAS: 7772-98-7], $Na_2S_2O_3 \cdot 5H_2O$, formula weight 248.19, white crystalline solid, decomposes above 48 °C (118 °F), sp gr 1.685. Also known as "hypo" and sometimes misnamed "hyposulfite," sodium thiosulfate is very soluble in H_2O (301.8 parts in 100 parts H_2O at 60 °C), soluble in ammonia solutions, and very slightly soluble in alcohol. When sodium thiosulfate is added to an acid, thiosulfuric acid $H_2S_2O_3$ may be formed, but only for an instant, immediately decomposing into sulfur and SO_2.

Sodium thiosulfate is used: (1) to dissolve silver chloride, bromide, iodide in the photographic "fixing" bath, soluble sodium silver thiosulfate being formed plus sodium chloride, bromide, iodide; (2) in reaction with iodine in solution, sodium tetrathionate and sodium iodide being simultaneously formed, or with ferric salt solution, sodium tetrathionate and ferrous being simultaneously formed; and, (3) in reaction with chlorine as an "antichlor" forming sulfate and chloride. Sodium thiosulfate reacts with silver nitrate solutions yielding silver sulfide, brown precipitate, and with permanganate yielding manganous. Sodium amalgam changes sodium thiosulfate to sodium sulfide plus sodium sulfite.

Sodium thiosulfate is formed: (1) by reaction of sodium sulfite solution and sulfur upon warming; (2) by reaction of sodium sulfite solid and sulfur upon heating; and, (3) by complex reaction of sulfur and sodium hydroxide solution upon warming. Sulfur yields sodium sulfide plus sodium sulfite, and the latter reacts with excess sulfur, forming sodium thiosulfate. The sodium sulfide present may be converted into sodium thiosulfate by passing in SO_2 until the solution changes from yellow to colorless.

There are numerous other thiosulfates, including potassium, magnesium, calcium, barium, mercury, lead, and silver. All are soluble in H_2O except Ba, Pb, and Ag thiosulfates.

Thiosulfates are commonly identified as follows:

1. Dilute acids precipitate sulfur from thiosulfates (difference from sulfides and sulfites).
2. Zinc sulfate and sodium hexacyanoferrate(II) give no color (difference from sulfites).

SOFAR (Sound Fixing and Ranging). A system of navigation providing hyperbolic lines of position determined by shore listening stations which receive sound signals produced by depth charges dropped at sea

and exploding in a sound channel which is at a considerable depth in most areas. This system was used in Project Mercury for locating spacecraft down at sea.

SOFT. A nontechnical word used by chemists in several senses, it describes the following: (1) an acid having little or no positive charge and whose valence electrons are easily excited; (2) water that is relatively free from calcium compounds. See also **Water (Hard)**; (3) wood from coniferous trees.

SOFTENER. 1. A substance used when dry powders are added to a polymeric material (e.g., rubber or plastic) to reduce the friction of mechanical mixing and to facilitate subsequent processing. It exerts both lubricating and dispersing action, often by means of emulsification. Examples are vegetable oils, asphaltic materials, and stearic acid, the latter being especially effective with carbon black. It is difficult to distinguish precisely between softeners and plasticizers; in general, softeners do not enter into chemical combination with the polymer, and their softening effect tends to be temporary.

2. A fatliquoring agent used to soften leather.

3. A sulfonate oil, fatty alcohol, or quanternary ammonium compound used in textile finishing to impart superior "hand" to the fabric and facilitate mechanical processing.

4. A substance that reduces the hardness of water by removing or sequestering calcium and magnesium ions; among those used are various sodium phosphates and zeolites.

SOFTWARE (Computer System). The totality of programs, procedures, rules, and (possibly) documentation used in conjunction with computers, such as compilers, assemblers, narrators, routines, and subroutines. References are made to software and hardware parts of a system where the hardware comprises the physical (mechanical and electronic) components of the system. In some machines, the instructions are microprogrammed in a special control storage section of the machine using a more basic code, which is actually wired into the machine. This is contrasted with the situation where the instructions are wired into the control unit. The microprogram technique permits the economic construction of various size machines that appear to have identical instruction sets. However, microprograms are not generally considered as software. They are sometimes called firmware. See also **Digital Computer Systems**; and **Microprogram**.

SOFTWARE ENGINEERING. Engineering is the disciplined application of established principles for design and development of entities and systems. Software engineering deals with software systems. Software engineering is increasingly important because many, newer devices and systems include or are even based upon software. For example, communication systems (such as telephones and television devices and the systems that distribute phone and television data) are being changed from analog to digital information and from analog processing to software-controlled signal processing and switching. The very nature of modern business is being transformed by software tools for office automation and for electronic commerce (e.g., the network connections of businesses to businesses and organizations to individuals.)

A key point about software engineering is that engineers do different work than other information technology workers. Many people are able to write small programs, but designing larger systems requires additional skills beyond just programming. As in other fields of engineering, design encompasses issues of correctness, reliability, usability, economy, etc. Development includes issues of documentation, distribution, and maintenance, as well as management of teams of engineers and technical workers. Technicians, typically called programmers, may do may do actual coding, testing, maintenance, and customer communication and support.

The Status of Software Engineering

Software development is yet an emerging discipline. The first programming languages (FORTRAN, COBOL) date to 1960. The first use of the concept of "software engineering" dates to 1968. There is not yet a common B.S. curriculum for software engineering. Instead, professional education for information technology workers is in fields of computer science, information systems, and even business systems management. Computer science programs are reviewed and accredited by Computing Science Accreditation Board (CSAB), which is moving towards merging with ABET, which accredits other engineering programs. Within CSAB guidelines, there is little requirement for software engineering courses. Yet, within CS curricula, there is a steady shift towards more software engineering content. For example, a decade ago, core C.S. courses were programming, data structures, and analysis of algorithms. Today the beginning programming course typically includes simple design structures, the data structures course includes software engineering patterns and use of standard library packages, the third core course focuses on software architecture and design, and lastly, the curriculum concludes with a capstone one-year course on software engineering. That course emphasizes project management, software design and testing, and a group project design and implementation. Students often report that the hardest part of the project experience is the group dynamics of working together and managing a team.

At the M.S. level, several schools offer a Master of Software Engineering degree (or some similar degree) (Graduate Programs in Software Engineering). These degrees are often taught as distance education programs for persons working in the software field. There are several reasons for this pattern. First, because of good opportunities and salaries for B.S. holders, few American students continue directly to graduate work in computing. Second, students in many different disciplines of study include core courses in computer science. Later when some of these persons become involved in developing software for their discipline, the need arises for specific training in software engineering. Many master's programs are tailored for persons who have individual programming experience and who then desire to manage software development projects.

The Ph.D. degree is typically required for persons who teach or who work in research. Most Ph.D.-level work in software engineering is done within computer science departments. One exception is the Ph.D. in Software Engineering offered at Carnegie Mellon University.

There are two professional societies for computing and software professionals, the IEEE Computer Society and the Association for Computing Machinery (ACM). Both have names not associated with software, which reflects that historically, the computer itself was deemed more significant and challenging than the software.

There is yet no professional engineering certification for software engineers. Indeed, there is no official designation of who can be called a software engineer. Should it require a degree in the discipline, a degree in computer science, demonstration of specific skills and knowledge, or just experience in programming? This is significant because there have been several cases reported wherein project failure or even catastrophe has been attributed to software errors. There is effort to establish national certification for software engineers (IEEE); however, the ACM recently withdrew from support of that effort. There is a professional code of ethics for software engineers.

Because there is no well-established base of trained software engineers, it was observed that there is a need to provide assistance to companies adopting software engineering concepts. Towards that end, the Software Engineering Institute was established with grants from the U.S. Department of Defense. The SEI is a nonprofit organization that promotes software engineering by hosting conferences and by providing guidelines for education and for the software development process. One development of the SEI is the Capability Maturity Model for software development, which defines and ranks levels of industrial processes for software development.

Foundation Knowledge

What distinguishes software engineering from computer programming or information systems management? In the second case, software engineering deals with the management of the development of new software rather than the management of the operations of information systems. In the first case, the difference lies in the process and scale of software development and in the issue of control of quality, particularly correctness.

Many people today learn to write programs in some programming language. Many can develop complex functions using Rapid-Application-Development tools such as Visual Basic wizards and controls for graphic user interface and for data base access. Many can develop simple web

pages using HTML and even applets using Java. These skills are not the core of software engineering. Experience has shown the pitfalls in developing large software systems. For large systems, errors are introduced in the interactions between people and between software components. One person can easily develop a system with ten software components, whereas managing and working within a team of 200 people developing a system with 2000 components requires a different process and skills. The number of potential points of communication and hence the number of possible places for errors in communication increases with both the square of the number of persons and the square of the number of components.

From an academic point of view, the foundations of software engineering are shown in the core courses for the MSE degree. Even though there is no formal accreditation for MSE education, there is general conformity among schools that offer an MSE degree. From an industrial point of view, the foundations of software engineering are reflected in common practices, tools, and standards (Software Engineering Standard Committee). The following items correspond to core course in a MSE degree program:

- Breadth of knowledge of software development and management: For example, the text and web site by Pressman covers topics including: development process and management, measurements and planning, quality assurance, requirements analysis, architecture design, coding practices, testing, and software tools for all of these items. The web site for his book includes details of these topics, outlines, and sample assessment quizzes. Another view of the breadth of software engineering is the Software Engineering Body of Knowledge report, which is intended to identify common knowledge of the field. Professional competency in software engineering should also include the ability to read applied papers in software engineering journals, such as IEEE Transactions on Software Engineering.
- Object oriented software design and architecture: Software architecture consists of the organization of components. Design consists of defining models for both architectures and dynamic behaviors. The common notation for designs is the Unified Modeling Language.
- Formal methods in software specification: Mathematical models are used to describe properties of software. In Europe, the most accepted modeling languages are Z and VDM (Virtual Library), but these have not gained widespread use in the United States. The Object Constraint Language (OCL) component of the Unified Modeling Language seems likely to be used for such formal specification of software. Checking of properties of finite state models of software is now recognized to be effective for software verification (Formal Methods), but it is not yet widely used.
- Software project management: Managers direct and evaluate documents that define a project and its scheduling.
- Software project and portfolio: The crucial aspect of software engineering preparation is project experience with one-on-one review of all project work and documents. Such close review and feedback is not duplicated in most undergraduate classes. Major items of the portfolio are: Personal log of activities, requirements statement and use-case model; size and cost estimates and project work schedule; a software quality assurance plan (including documents to be reviewed); software design using UML; a formal model using Z or OCL; project inspection reports; test plan, including test cases and expected results, program source code; test results and analysis; project demonstration report; user documentation, including guidance for installation and use; and project evaluation, including evaluation of the size and schedule estimate.

Summary

Software engineering is a discipline distinct from just computer programming. It is concerned with software design and development and with management of teams of programmers and engineers. Most undergraduate computer science programs introduce software engineering concepts, but most training in software engineering is done through industrial training or through graduate studies.

SOFTWARE METRICS. A software metric is a rule for quantifying a characteristic or attribute of a computer software entity. That is, software metrics is an attempt to attach to software entities meaningful numbers that represent the extent that the entity has the attribute of interest.

For example, a simple metric is the FileSize metric. It is the total number of characters in the source file(s) of a program. Using the FileSize metric, one can determine the measure of a particular program, such as 3K bytes. The File Size metric provides a concrete measure of the abstract attribute of program size.

Another example of a software metric is a complexity metric. Complexity metrics are intended to provide a quantitative measure of the abstract attribute of complexity. Intuitively, if one software entity is more complex than another software entity, then it follows that the more complex entity may have more errors, may be harder to understand, or may be more difficult to maintain. Unfortunately, complexity metrics provide only an imperfect measurement of the attribute of complexity.

In addition to metrics for source programs, other metrics can be used for software entities such as requirements documents, design object models, or data base structure models.

Metrics for requirements and design documents can be used to guide decisions about development and as a basis for predictions, such as for cost and effort. Metrics for programs can be used to support decisions about testing and maintenance and as a basis for comparing different versions of programs. Ideally, metrics would be desired for the development cost of software and for the quality of the resultant program; but, lacking those, metrics for size and complexity are commonly used.

If one could attach a number (quantification) to a software entity that matches the complexity (attribute) of the software, then one could make better management decisions about the need for additional testing or the need to rewrite the software, etc. Unfortunately, it is not possible to meaningfully quantify an attribute as broad or as ill-specified as complexity.

Maurice Halstead introduced several metrics that better define program size. He found that the number of unique operators, η_1 (operators are

symbols such as "+" and function and procedure names), and unique operands, η_2 (generally operands are the variables and numbers in the program) could be used to predict software size as: $N = \eta_1 \log_2 \eta_1 + \eta_2 \log_2 \eta_2$. He also defined metrics that relate to complexity, but such metrics have not been widely used.

Thomas McCabe introduced a complexity metric for programs. It was based on the cyclomatic number used in graph theory. McCabe measured the cyclomatic number on the control flow graph of a program or design pseudo-code. He showed that the cyclomatic number was equal to one plus the number of decisions in the control graph. The cyclomatic number is commonly used as a measure of complexity. A good "rule of thumb" is that program modules with cyclomatic number greater than ten should be avoided. Whereas the cyclomatic number is intended to measure complexity of single program units (a function, procedure method, etc.), a number of metrics have been introduced to measure the complexity of object models and programs.

The earliest size metric for programs was Lines of Code (LOC). Unfortunately, LOC is not a good predictor of cost of development, likelihood of errors, etc. Additional, there is no standard way to measure LOC; variations include counting or not counting blank lines, comments, declarations, and extra lines used for formatting. Still, LOC is also commonly used.

Albrecht and Gaffney developed the Function Points (FP) metric. It is used to predict the size and cost of development of a proposed software. The developer identifies and counts all inputs, outputs, inquiries, files, and interfaces and rates each as simple, average, or complex. Additional characteristics of the project are ranked on a scale of 1 to 5.

More recent work (Baker et al.) has applied measurement theory to software metrics. Measurement theory has been used for many years in other sciences. Important ideas include the representation condition and the notion of measurement scales.

The representation condition requires that if one entity is less than another entity in terms of a selected attribute, then any metric for that attribute must associate a smaller number to the first entity than it associates with the second entity. For example, the FileSize "metric" does not meet the representation condition. If a "small" program is taken and all variables with very long names are replaced, the measure of FileSize of the "small" program can be larger than that of some "larger" program which uses short variable names.

There are five measurement scales: nominal, ordinal, interval, rational, and absolute. Every software metric must be one of the five types of scales (Gustafson and Parsed). A nominal scale just attaches numbers to entities, such as numbers on sport uniforms. Ordinal scales rank entities, like being first or second. Interval scales have a fixed difference between values. Temperature is an example of an interval scale. Rational scales have a universally accepted zero and a fixed difference. Length is an example of a rational scale. An absolute scale counts the number of items.

The type of scale determines the types of statistics that can be applied to the metric. A metric must be at least an interval scale to take averages and must be at least a rational scale to consider ratios between values. For example, the cyclomatic number is an interval scale and thus it would be correct to calculate the average cyclomatic number of a set of modules. However, one could not correctly say that one module has twice the cyclomatic number as another module. Some recent research has directed toward formal approaches to defining and identifying properties of software metrics (Gustafson and Parsed).

Dieter Rombach and Victor Basili have presented the Goal-Question-Metric (GQM). The first step in this method is to select goals that should be maximized or minimized. For example, a goal might be customer satisfaction. Next, questions are developed that are related to that goal. Such as, "Is the customer finding too many errors?" Finally, metrics are proposed that quantify answers to the questions. For example, a metric could be the number of customer reported errors. Since the metrics are closely related to the goals, use of the metrics should contribute to the achievement of the goal.

SOFTWOODS. See **Wood (or Timber; Lumber)**.

SOIL. All consolidated earth material over bedrock. Soil is approximately equivalent to regolith.[1] Agriculturally, soil is any one of many varied natural media that support or can support land plant growth outdoors; or, when in containers, indoors. The lower limit of *topsoil* is normally the lower limit of biologic activity, which usually coincides with the common rooting of native perennial land plants. The word *soil* is derived from the Latin *solum* for "ground."

The upper part of the regolith is divided into topsoil and subsoil. The topsoil is usually a relatively thin layer or zone of the more highly decomposed mineral constituents of the regolith and contains a varying proportion of organic material called *humus*. This soil zone is the habitat of the shallow-rooted plants, such as most grasses. The topsoil usually passes gradationally into the subsoil, which supplies some of the moisture and food for the deeply rooted plants and trees. The subsoil may or may not pass gradationally into the underlying bedrock. Topsoil is easily destroyed by erosion when not protected by a mantle of vegetation.

Soil serves: (1) As a foundation for holding plants in place, whether tiny grasses or huge trees; (2) as a protective covering for the root structures of plants; (3) as a source and/or medium of exchange for supplying plants with nutrients; (4) and as a reservoir for moisture upon which growing plants can draw. Soil also must be capable of allowing excessive moisture to pass through its pores and drain to a lower level so that the soil will not remain excessively wet. Properties such as permeability and strength are not only of importance to the agriculturist, but to civil engineers and construction people who excavate, drill through, and handle soil in connection with buildings, roads, tunnels, etc.

Soil is a subsystem that interacts as part of a four-element system: (1) The *climatic or environmental subsystem* prevails immediately above the ground level and thus is the microclimate for a particular location. The principal variables of this subsystem are temperature, humidity, precipitation, and solar radiation — all of which interact constantly with soil. (2) The characteristics and patterns of the *hydrologic subsystem* determine essentially how water reaches the soil, both from above and below, and how water is carried away or drained from the soil. See also **Hydrology**. (3) The *plant subsystem* reduces the nutrient and moisture

[1] A general term for the entire layer or mantle of fragmental and loose, incoherent, or unconsolidated rock material, of whatever origin (residual or transported) and of a much varied character, that nearly everywhere forms the surface of the land and overlies or covers the more coherent bedrock. It includes rock debris (weathered in place) of all kinds, volcanic ash, glacial drift, alluvium, loess and aeolian deposits, vegetal accumulations, and soils.

content of the soil, depending upon the particular uptake characteristics of a given plant. The plant subsystem also contributes in a major way to hold the soil in place and to protect it from disintegration and destruction by water and wind erosion. The plant subsystem also distributes moisture over the top of the soil so that all porous paths of the soil can be used to transport water rather than overloading and hence enlarging only some of the pores. The plant subsystem also protects the top of the soil against drying into a hard crust during periods of drought. Once disturbed, the characteristics of soil are difficult to replicate — a problem that arises when large projects, such as strip-mining, remove vast amounts of soil. See also **Revegetation**. (4) The *soil subsystem*, the properties of which are described briefly in this entry.

Lack of sufficient attention to the long-term protection of soil has caused innumerable problems and losses over the years. Although warnings of gross problems arising from soil destruction and land mismanagement were given in North America as early as the latter part of the 1600s, it required the rudest of awakenings to precipitate national interest and action in soil conservation. This came in the early 1930s in the form of the Great Dust Bowl, a national disaster that affected some 96 million acres (38.4 million hectares) of farmland in the southern part of the Great Plains region, involving parts of Kansas, Oklahoma, Texas, New Mexico, and Colorado. During just a few years of severe droughts, accompanied by frequent high winds, literally billions of tons of soil were lost. Organic matter, clay, and silt were lifted and carried for great distances. There were times when the heavily laden skies as far east as the Atlantic coast were darkened. Sand and silt dunes from 4 to 10 feet (1.2 to 3 meters) in height were formed in many locations. In some parts of the Dust Bowl, as much as 80% of the land suffered from wind erosion. Parallel situations have occurred in several other areas of the world.

The Soil Conservation Service of the U.S. Department of Agriculture was established in 1935. Concentrated and participative programs with land users in the Great Plains region from the mid-1950s to the present time have provided impressive improvements: (1) 2.4 million acres (1 million hectares) of permanent vegetative cover have been established; (2) 1.0 million acres (0.4 million hectares) of field and wind stripcropping have been introduced; (3) 169 thousand (68 thousand hectares) of grasslands have been reestablished; (4) 41 thousand acres (16.8 thousand hectares) of trees or shrubs have been placed as windbreaks; (5) 81 thousand miles (150 thousand kilometers) of terraces have been constructed; (6) 5.4 million acres (2.2 million hectares) of brush control have been provided; and (7) 9 thousand miles (16.7 thousand kilometers) of pipelines to provide water for livestock grazing lands have been installed. See also **Erosion (Geology)**.

Soil Characteristics and Classification

A soil is a naturally occurring three-dimensional body with morphology and properties resulting from effects of climate, flora and fauna, parent rock materials, topography, and time. A soil occupies a portion of the land surface, is mappable and is composed of horizons that parallel the land surface. A vertical section downward through all the horizons of the soil is called a *soil profile*. See Fig. 1.

Characterization of a soil requires selection of a representative profile that is described as quantitatively as possible, utilizing comparative charts for color, structure, and other properties, and accurately measuring soil horizons. Soils are collected from horizons and analyzed for particle-size distribution, pH, organic carbon, nitrogen, free iron oxide, calcium carbonate equivalent, moisture tension, cation-exchange capacity, extractable cations (calcium, magnesium, hydrogen, sodium, potassium), base saturation, and bulk density, among other factors.

Soil classification has been oriented to soil properties in recent years, but still is tempered with concepts of soil genesis, with external associations, and with the use of the soil. The first systematic classification was by Dokuchaiev in Russia in 1882. Based upon field and laboratory characteristics, soils were grouped into three categories — *normal soils* of the dry-land vegetative zones and moors, *transitional soils* of washed or dry land sediments; and *abnormal soils*. The system involved properties of the soil with external associations of climate and vegetation. Later, an associate (Sibirtsev) renamed the highest classes *zonal, intrazonal*, and *azonal*.

A traditional classification of soils includes three categories: (1) *Young soils*. These usually show their relationship to the parent material and are typical flood plain and hilly land deposits, when the soil surfaces are constantly being replenished or disturbed. (2) *Mature Soils*. These

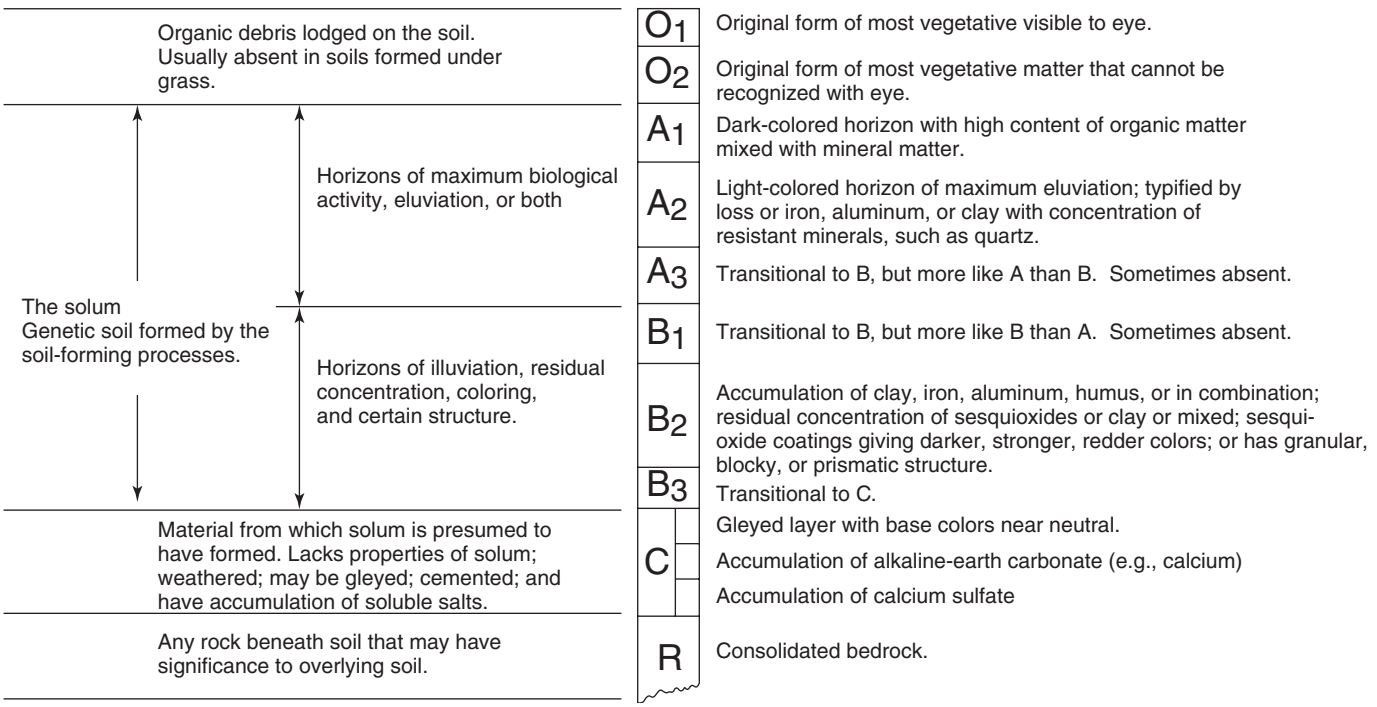

Fig. 1. Hypothetical soil profile that has all principal horizons. Not all horizons shown are present in any given profile, but every profile has some of them. Terms used in diagram: *Eluviation* is the downward movement of soluble or suspended material in a soil from the A horizon to the B horizon by groundwater percolation. The term refers especially, but not exclusively, to the movement of colloids, whereas the term *leaching* refers to the complete removal of soluble materials. *Illuviation* is the accumulation of soluble or suspended material in a lower soil horizon that was transported from an upper horizon by the process of eluviation. *Gleying* is soil mottling, caused by partial oxidation and reduction of its constituent ferric iron compounds, due to conditions of intermittent water saturation. Process is also called *gleization*. (*Adapted from USDA diagram.*)

TABLE 1. SOIL CLASSIFICATION SYSTEM (U.S.D.A.)

Order and Suborders	Definitions and Properties
Entisols	Weakly developed soils on freshly exposed rock or recent alluvium without genetic horizons. While alluvium may be rich in plant nutrients, entisols often are too shallow, too wet, or too dry for agricultural purposes.
E1	*Aquents*. Seasonally or perennially wet.
E2	*Orthents*. Loam or clay texture, often shallow to bedrock.
E3	*Psamments*. Sand or loamy sand texture.
Vertisols	Clay soils that have deep wide cracks during periods of moisture deficiency. During rainfall, vertisols swell, slide and produce warping.
V1	*Uderts*. Usually moist, with cracks open less than 90 days/year.
V2	*Usterts*. Dry and cracked more than 90 days/year.
Inceptisols	Soils that are beginning to show development of genetic horizons. Inceptisols lack evidence of weathering and usually are found in humid climates where leaching is active.
I1	*Andepts*. Soils containing amorphous or allophanic clay, often associated with volcanic ash and/or pumice.
I2	*Aquepts*. Seasonally or perennially wet.
I3	*Ochrepts*. Soil with thin, light colored surface horizons.
14	*Tropepts*. Continuously warm or hot.
15	*Umbrepts*. Dark surface horizons; medium to low base supply.
Aridisols	Soils which contain little organic matter or nitrogen. They are usually dry for more than 6 months/year. In numerous areas, salts accumulate on or near the soil surface. Since the nutrient content, except nitrogen, of aridisols is often high, these soils can be productive with irrigation and nitrogen application. Salt accumulation can be a problem with some crops.
D1	*Undifferentiated aridisols*.
D2	*Argids*. Soils with horizons of clay accumulation.
Mollisols	Soils with dark, thick, organic-rich surface horizon, high base supply. Mollisols are highly fertile and can support a variety of crops.
M1	*Albolls*. Soils with seasonally high water tables.
M2	*Borolls*. Cool or cold soils.
M3	*Rendolls*. Soils with subsurface accumulations of calcium carbonate, but no clay.
M4	*Udolls*. Temperate or warm, usually moist.
M5	*Ustolls*. Temperate or hot. Dry more than 90 days/year.
M6	*Xerolls*. Cool to warm. Moist in winter and continuously dry more than 60 days/year.
Spodosols	Soils found primarily in cool and humid forested regions. Spodosols have subsurface accumulations of amorphous materials, mainly iron and aluminum oxides. These soils are usually strongly leached, but can be used for crop support with addition of lime and fertilizer.
S1	*Undifferentiated spodosols*.
S2	*Aquods*. Seasonally wet.
S3	*Humods*. Soils with subsurface accumulations of organic matter.
S4	*Orthods*. Soils with subsurface accumulations of organic matter, iron, and aluminum.
Alfisols	Soils of middle latitudes and degraded grasslands soils. Alfisols are strongly weathered, with gray to brown surface horizons, a subsurface clay accumulation, and a medium-to-high base supply. With adequate lime and fertilizer, the alfisols will continue to produce a variety of crops.
A1	*Boralfs*. Cool soils.
A2	*Udalfs*. Temperate to hot. Usually moist.
A3	*Ustalfs*. Temperate to hot. Dry more than 90 days/year.
A4	*Xeralfs*. Temperate to warm. Moist in winter and continuously dry more than 60 days in summer.
Ultisols	Strongly weathered soils of the middle and low latitudes. Ultisols are usually moist and low in organic matter. These soils have experienced a high degree of mineral alteration and extensive leaching. With fertilizer additions and good management, ultisols can support crops.
U1	*Aqults*. Seasonally wet.
U2	*Humults*. Temperate or warm. Moist all year. High content of organic matter.
U3	*Udults*. Temperate to hot. Usually moist.
U4	*Ustults*. Warm or hot. Dry more than 90 days/year.
Oxisols	The predominant soils of the Tropics. Oxisols have experienced the greatest degree of mineral alteration and horizon development of any soil. The humus breakdown is rapid and the soils are usually deep and porous. Oxisols require fertilization to support continued crop production.
O1	*Orthox*. Hot and nearly always moist.
O2	*Ustox*. Warm or hot. Dry for long periods, but moist for at least 90 days/year.
Histosols	Bog or peat soils composed primarily of vegetative debris in various stages of decomposition.
Mountain	Soils with various temperature and moisture parameters. Altitude, aspect, steepness of slope, and relief cause these soils to vary greatly within short distances. In many places, soil will be entirely absent.
Soil-absent	Rugged mountains and icefields.

Note: Further details can be obtained from "Soil Classification, A Comprehensive System, 7th Approximation," Soil Conservation Service, U.S. Department of Agriculture, Washington, DC. (Published periodically).

usually cover relatively flat lands where there are good drainage conditions but relatively little erosion. The development of these soils has gone so far in some cases, particularly in semi-arid regions, that little relation is shown to the parent material and their nature has therefore been principally determined by climatic and organic factors. (3) *Old Soils*. These usually cover old flat surfaces that have not been disturbed by erosion or sedimentation for a long time. Such soils, due to the dominance of climatic factors in their formation, have lost many of their original characteristics and have, therefore, developed abnormal features. When soils are intensively cultivated their mineral and organic constituents are rapidly depleted and must be replenished by rotation of crops and the application of natural fertilizers. The method of allowing the land to remain fallow is now known to be inefficient. The complete removal of vegetable cover, such as may result from overgrazing, deforestation, or dry farming, exposes the soil to rapid erosion and destruction.

A more scientific classification of soils, adapted by the U.S. Department of Agriculture, is given in Table 1. Systematic classification of soils in the United States began with the work of Coffey in 1912 and resulted in the first comprehensive system by Marbut in 1936. Considering the size of the earth and the large number of soils represented, the detailed cataloging of soils for any country is a tremendous task. To simplify the task to some extent and to make findings more meaningful from a practical viewpoint, the European Commission on Agriculture (Working Party on Soil Classification and Survey) in 1966 correlated types of soils (soil units) with several regions designated by geography, geology, and climatology, and, to some extent, by the traditional use of the soils. Mixed criteria enter into soil classification schemes simply because the various physical or chemical characteristics, considered separately or together, do not fully identify a soil. The principal categories adopted by the European Commission include: Lowlands, Mountainous Areas and Highlands, Volcanic Areas, Zones of the Tundras and Fields, Zones of the Boreal Forests of Conifers and Birch, Zones of Mixed Forests of Conifers and Broadleaved Trees, Zones of the Central European Beech Forests and Oak Forests, Zones of the Oak Forests and of the Atlantic Heaths, Zones of the Continental Oak Forest, Zones of the European Grassland, Zones of the Mediterranean Sclerophyll Forests, Zones of the Juniper Forests and the Mediterranean Steppes, Zones of the Montane Mediterranean Forests, Zones of the Subalpine Mediterranean Forests, and Zones of the Arabo-Caspian Steppes.

Soil Genesis. The origin and processes of soil formation usually are inferred, by relating measured morphological, physical, and chemical properties of a part to other parts of a given soil. And, during the last several decades, laboratory experimentation has revealed a better understanding of many of these processes. A factor to be stressed is that, in general, these processes occur over very long periods of time and

frequently under multivariate conditions — conditions that are extremely difficult to duplicate and speed up in the laboratory. In the late 1950s, an interesting group of experiments revealed information concerning the formation of something similar to podzolic soil. Organic and distilled water leachates from tree leaves were passed through columns of different soil materials. Bleached surface layers and subjacent layers of stronger color formed in the columns. Effluent solutions from the base of the columns contained detectable amounts of calcium, magnesium, iron, manganese, phosphorus, potassium, and sodium. Very fine silicate clays, e.g., illite, montomorillonite, vermiculite, and chlorite, also were suspended in the effluent. Removal, transfer, and transformation were demonstrable experimentally. Examination of the columns showed that clay was partially removed from the bleached layers and was deposited in voids in the lower layers. The experiments showed removal (*eluviation*) and addition (*illuviation*) actually occurring and at a much accelerated pace.

Organic matter probably best illustrates additions to a soil and is formed in the biological decomposition of plant and animal residues by soil microorganisms. Plants supply most of the organic matter as a dry material added to the soil surface and as roots in the subsurface. It has been estimated that short grass prairie in semiarid regions may annually add 0.7 ton/acre (1.6 metric tons/hectare) of dry matter; tall grass prairie in subhumid regions, 0.8 to 1.7 tons/acre (1.8 to 3.8 tons/hectare); pine forest in more humid areas, 2.1 tons/acre (4.7 metric tons/hectare); and tropical rain forest, from 45 to 90 tons/acre (101 to 202 metric tons/hectare). Under bluegrass roots, additions may amount to 2.4 tons/ acre (5.4 metric tons/hectare) in the top 4 inches (10 centimeters) of soil.

During decomposition, plant materials are converted to carbon dioxide, water, mineral elements, and other chemically altered substances. Less-resistant materials are consumed first by soil microbes — so that more resistant plant materials remain with the new organic compounds that are synthesized by the organisms. At any time, the organic matter at a place in the soil reflects an equilibrium state of the addition of new material to the system, removal of more readily decomposable materials, and transformation to other forms by microorganisms and other agents. Organic matter also may be transferred within the soil by physical and physicochemical processes. Burrowing animals, worms, and insects turn over the soil and physically mix adjacent portions. Freezing and thawing and wetting and drying also assist in the process. Colloidal organic matter may be flushed downward or laterally and coagulate as coatings on structural aggregates in the soil.

The more unstable organic compounds are rapidly oxidized to carbon dioxide and water by various biochemical processes, while the more stable fractions accumulate. Conjugated ring compounds containing carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur and other elements in small quantities accumulate in relatively stable organic and organomineral colloidal complexes. Lignin-like, phytin-like, and nucleo-protein-like compounds are included. Sorption of the organic matter on mineral colloid surfaces, particularly layer silicates, such as montmorillonite, helps to stabilize the organic matter against biochemical oxidation. In tropical soils, high stability of soil organic matter is imparted by coatings of aluminum hydroxide and red ferric oxide. Organic and iron oxide colloids, when fairly abundant, stabilize the soil into porous aggregates through which ample air and water can circulate.

Localized spots of decomposing organic matter are important in reducing small but important quantities of iron to ferrous form and manganese to divalent form so that they become available to plants. Moderately to highly alkaline soils sometimes have inadequate activity of the reduced forms of iron and manganese, particularly in the absence of sufficient organic matter.

Radiocarbon dates of organic matter from the surface horizons of soils not only reflect the equilibrium status, but point out the turnover of the system. One example of research, for example, has shown that in the Edina soil in southern Iowa, organic matter is 410 ± 110 years old in the 6-inch (15-centimeter) top layer. In the next subjacent layer, the age is 840 ± 220 years. At depths of 23 to 25 inches (58.4 to 63.5 centimeters), the organic carbon is 1545 ± 110 years old. The entire soil has been estimated as 14,000 years old.

The four kinds of changes that develop soil horizons are dependent upon many basic processes, such as hydration, oxidation, reduction, solution, precipitation, freezing, thawing, wetting, drying, among others. These processes, in turn, are dependent upon the four fundamental factors of soil formation: (1) nature of the parent material; (2) topography; (3) climate; and (4) biological activity that occurs in the upper strata of the soil. To these factors must be added time and imposed manual and mechanical manipulation (as by tilling, planting, etc.) and chemical manipulation (as by fertilizing and use of various control chemicals that seep into the soil).

Soil is destroyed by two principal processes — *water erosion* and *wind erosion*. The word *erosion* is the physical removal of all or part of established soil by washing or blowing away. Erosion, in some instances, also brings soil to convenient locations, but usually in so doing, unless carried out over long periods as in the development of bottomlands and deltas where crops can be grown, the new muddy, fine, highly unconsolidated and disintegrated soil causes more problems than immediate benefits. The bringing in or transfer of soil by water is commonly referred to as *sedimentation*. Much research has been carried out in connection with water and wind erosion. Typical of fundamental research is the study of splash patterns as shown in Fig. 2. The lysimeter, as shown in Fig. 3, also has been effectively used. The effects of wind erosion have been extensively studied, as exemplified by Figs. 4 and 5.

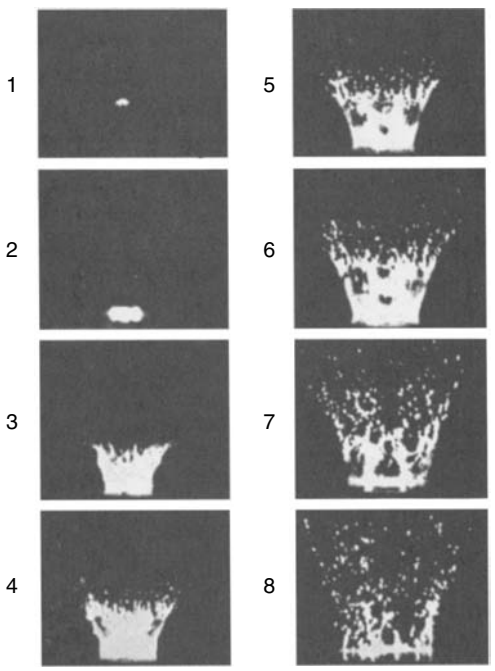

Fig. 2. Interaction of raindrops with the soil surface is an important component of the erosion process. Frames shown here were made by a 16-millimeter movie camera capable of speeds from 150 to 8000 frames per second. In the experiment, water drops are released from a tower 40 feet (12 meters) high and strike a plate glass target table. Drops from 5 to 6 millimeters in diameter are produced. Target plate is covered with water approximately 0.5 millimeter deep. (*North Central Soil Conservation Research Center, U.S. Department of Agriculture, Morris, Minnesota.*)

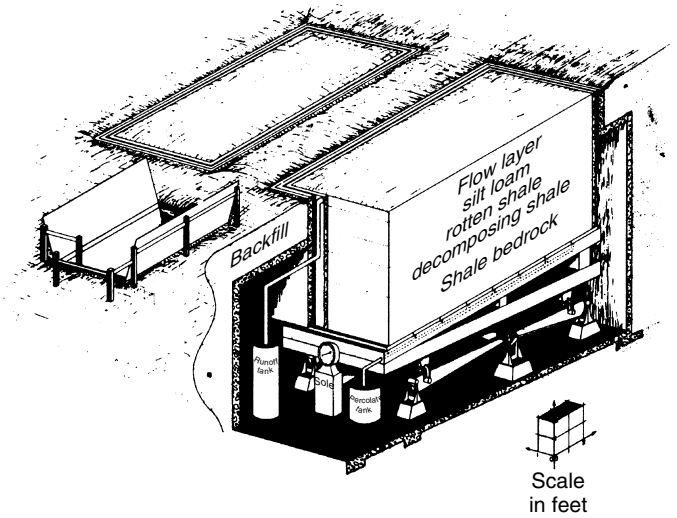

Fig. 3. A lysimeter, which provides a means for isolating soil masses and recording weight changes and water percolation. Such instruments provide accurate assessments of moisture behavior in soil. The lysimeter shown here represents $\frac{1}{500}$ acre (0.0008 hectare) and is 8 feet (2.4 meters) deep. The soil weighs 65 tons (58.5 metric tons), yet can be weighed to a precision of 5 pounds (2.3 kilograms). Soil scientists use lysimeters to study evapotranspiration, moisture consumption by crops, precipitation, water movement, and pollution. (*USDA diagram.*)

SOIL BEARING VALUE. See **Foundations**.

SOIL CHEMISTRY. This field includes all aspects of the study of soil as a chemical system. The eight chemical elements in soils which generally surpass 1% by weight are oxygen [CAS: 7782-44-7], silicon [CAS: 7440-21-3], aluminum [CAS: 7429-90-5], iron [CAS: 7439-89-6], calcium [CAS: 7440-70-2], magnesium [CAS: 7439-95-4], potassium [CAS: 7440-09-7], and sodium [CAS: 7440-23-5]; the eleven elements making up 0.2 to 1% include titanium [CAS: 7440-32-6], hydrogen [CAS: 1333-74-0], phosphorus [CAS: 7723-14-0], manganese [CAS: 7439-96-5], fluorine [CAS: 7782-41-4], sulfur [CAS: 7704-34-9], strontium [CAS: 7440-24-6], barium [7440-39-3], carbon [CAS: 7440-44-0], chlorine [CAS: 7782-50-5], and chromium [CAS: 7440-47-3]. The most abundant minerals present in less-weathered soils are quartz [CAS: 14808-60-7], feldspars, micas [CAS: 12001-26-2] and colloidal layer silicates including vermiculite [CAS: 1318-00-9], chlorite, and montmorillonite. Calcareous soils contain calcite [CAS: 471-34-1] and dolomite. More-weathered soils contain larger amounts of more resistant minerals such as kaolinite [CAS: 1332-58-7], halloysite allophane, hematite [CAS: 1317-60-8], goethite, gibbsite,

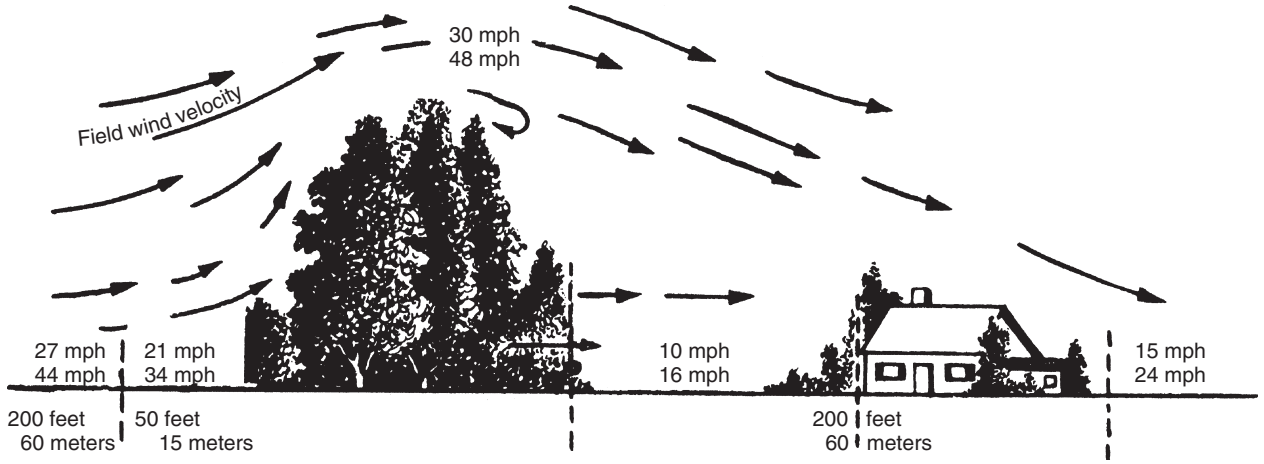

Fig. 4. Windbreaks reduce wind currents. Part of the air current is diverted over the top of the trees and part of it filters through the trees. Breaks like this reduce wind erosion of soil. Farmstead, livestock, and wildlife windbreaks should be relatively dense and wide to permit maximum protection close to the trees. Field, orchard, and garden-type windbreaks need not be so wide and dense. (*USDA diagram.*)

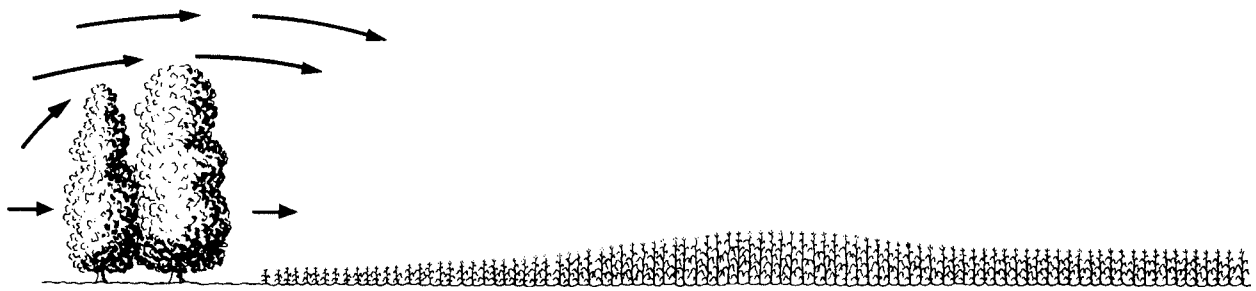

Fig. 5. Sometimes crop yields are lowest next to a tree windbreak. A common error made by some growers is to observe only the immediately adjacent area. The greatest gains are from a distance of 30 to 45 feet (9 to 13.5 meters) from the windbreak. (*USDA diagram.*)

anatase, pyrolusite, tourmaline, and zircon [CAS: 14940-68-2]. The organic matter, or humus, content of soils varies from less than 1% to over 80%. Generally, upland soils range from 1 to 8% organic matter, while less well-drained soils are frequently higher.

Soils developed under coniferous forests often accumulate acid organic matter at the surface; the resulting leaching through the soil of chelating organic acids bleaches (*podzolizes*) the mineral soil beneath. These soils are gray when plowed. Organic matter from hardwood trees and grasses which are high in bases, particularly calcium, accumulates in the soil and causes a dark color in the surface horizon. Poor drainage leads to the development of light-colored gray horizon within the soil column (*profile*), owing in part to the reduction of iron oxides to ferrous form. A bluish color is sometimes present, particularly when vivianite, $(Fe)_3(PO_4)_2 \cdot 8H_2O$, forms. Soluble soil salts, mainly chlorides and sulfates of sodium, calcium, and magnesium, when present in quantities over 0.1 to 0.7% cause a condition known as salinity or soil alkali. If much Na_2CO_3 is present, some organic matter is mobilized and together with FeS, colors the soil black, giving rise to the name black alkali.

The most reactive portion of the soil resides in colloidal organic matter, layer silicates, and hydrous oxides of iron, aluminum, and occasionally manganese and titanium. The colloids of soil have a negative electrostatic charge arising through carboxyls of organic compounds and through excess negative charge of oxygen in the silicate structure. The negative charge is neutralized by exchangeable cations, giving systems known as colloidal electrolytes. When these exchangeable ions, i.e., counterions, are hydrogen or aluminum, the colloids act as a moderately strong acid. Different colloids range in the strength of acidity as evidenced by the shapes of the titration curves, which are analogous to the shapes of those of weak and strong soluble acids. The colloids are hydrophilic and subject to flocculation in the presence of dilute salt solutions, owing to repression of the charge developed by dissociated cations. The flocculation is reversible.

Important chemical characteristics of the soil include the total exchange capacity for cations, expressed as total meq of cations per 100 gm of soil, and the base status, which is the percentage saturation of the negative charge with cations such as calcium, magnesium and sodium. The more productive soils are about 80% saturated with calcium and magnesium. Excessive hydrogen and aluminum saturation (much over 15%) is termed soil acidity. Excess sodium saturation (12% or more) leads to dispersiveness of the soil and poor productivity.

There are also positive charges associated with aluminum and iron colloids of soils. These charges give rise to phenomenon known as anion exchange capacity, which is mainly concerned with phosphorus chemistry; the usual soluble anions such as nitrate, chloride, and sulfate are little held. Synthetic organic soil conditioners are long-chain organic molecules with carboxyl charges along the chain which react with the positive charges of the soil particles. These colloidal molecules can bind the soil particles into aggregates. Natural humus of soil acts in a similar way until oxidized by soil organisms.

Analytical methods employed in soil chemistry include the standard quantitative methods for the analysis of gases, solutions, and solids, including colorimetric, titrimetric, gravimetric, and instrumental methods. The flame emission spectrophotometric method is widely employed for potassium, sodium, calcium, and magnesium; barium, copper and other elements are determined in cation exchange studies. Occasionally arc and spark spectrographic methods are employed.

The most commonly made chemical determination is that of soil pH measurement, as an indicator of soil acidity. The glass electrode has proved the most satisfactory method for soil pH measurement because the moistened soil rapidly equilibrates in contact with the glass surface, no reagents are added to the soil, and the soil CO_2 tension is not disturbed by bubbling through of gases. Colorimetric indicators are also employed. Soils of pH 4.3 to 5 are highly acid, of pH of 5 to 6 are moderately acid, of pH 6.3 to 6.6 are very slightly acid, of pH 6.7 to 7.3 are considered neutral; soils of pH 8 to 9 are moderately alkaline, and of pH 9 to 11 are very alkaline. For acid soils, pH measurement serves as a guide to agricultural liming practices. For many crops, such as alfalfa, the soil is adjusted to pH 6.5 to 7 by the addition of ground limestone, the active ingredients of which are $CaCO_3$ in calcic limestone and $CaCO_3$ $MgCO_3$ in dolomitic limestone. A soil colloidal acid may be represented as HX. Then the liming reaction, by which the exchangeable calcium is increased, is

$$CaCO_3 + 2HX \longrightarrow CaX_2 + CO_2 + H_2O$$

The proton donor, X, represents a variety of organic and inorganic donors, including the reaction $Al(OH_2)_6 \longrightarrow Al(OH)(OH_2)_5 + H^+$. The reaction is hastened by fine grinding of the limestone, and liming materials are graded on the basis of fineness and $CaCO_3$ equivalence. Burned lime (CaO), marl ($CaCO_3$), and sugar refinery wastes [$Ca(OH)_2$] are also used in liming. For some crops, owing to disease susceptibility and preferences, soils are kept more acid, as low as pH 5.3. Calcium and magnesium, necessary to plant growth, are furnished to plants from exchangeable form.

Fine grains (finer than 20 μ in diameter) of mica [$KAlSi_3Al_2O_{10}(OH)_2$], and potassium feldspar ($KAlSi_3O_8$) slowly undergo chemical weathering in soils with the release of potassium into exchangeable form. Other ions such as calcium, sodium, and iron are also released by mineral weathering. In subhumid and arid regions the release of potassium is fast enough for crop production but must be supplemented by the addition of potash fertilizer salts in more leached soils of humid regions.

Soil chemists have rapid chemical tests for measurement of the amounts of plant-available K, P, and N, as well as other elements in soils which are essential to plants. When the quantity of an element is too low for efficient crop production, it is added as fertilizer, such as KCl, $Ca(H_2PO_4)_2$, or ammonium or nitrate salts. Large chemical fertilizer industries are required for mining, refining, and preparation of chemical salts for soil application as fertilizers.

Extraction of soils for analysis of the readily available nutrients include replacement of exchangeable cations by salt solutions, dilute acids, and dilute alkalies such as $NaHCO_3$. Fluoride solutions are employed to repress iron, aluminum, and calcium activity during the extraction of phosphorus. Extraction of the soil solution is effected by displacement in a soil column, often through the application of pressure across a pressure membrane. The soil solution is analyzed by conductance and elemental analysis methods. Also, the total elemental analysis of soils is made by Na_2CO_3 fusion of the soil followed by classical geochemical analysis methods.

Organic compounds of great variety have accumulated in soils as residues from plant and animal life of the soil. The more unstable compounds of these residues are rapidly oxidized to CO_2 and H_2O by biochemical processes, while the more stable fractions accumulate. Conjugated ring compounds containing the elements C, H, O, N, P, S, and several other elements in small quantities accumulate in relatively stable organic and organomineral colloidal complexes. Lignin-like, phytin-like, and nucleoprotein-like compounds are included. Sorption of the organic matter on mineral colloid surfaces, particularly on layer silicates, such as montmorillonite, helps to stabilize the organic matter against biochemical oxidation. In tropical soils, high stability of soil organic matter is imparted by coatings of aluminum hydroxide and red ferric oxide. Organic and iron oxide colloids, when fairly abundant, stabilize the soil into porous aggregates through which ample air and water can circulate. Decomposition of soil organic matter, especially when hastened by tillage, gradually releases HNO_3, H_2SO_4, and H_3PO_4 in amounts which are highly significant in nutrition of crops. Much of the nitrogen, sulfur, and phosphorus required by crops is furnished in this way.

The oxidation potential of well-aerated soils is low (−0.5 V) and of reduced soils is high (+0.30 V). These relationships are sometimes expressed by soil scientists as reduction potentials or redox potentials, in which case the algebraic signs are the opposite. The oxidation potential is advantageously measured with a platinum-blackened electrode in the soil in place in the field. Moderately good aeration is a requirment of a productive soil. The oxidation status may also be tested in the field by rapid spot tests for ferric and ferrous iron in soils. Most of the dilute acid-soluble iron is in ferric form in well drained soils. Localized spots of decomposing organic matter are important in reducing small but important quantities of iron to ferrous form and manganese to divalent form so as to be available to plants. Moderately to highly alkaline soils sometimes have inadequate activity of the reduced forms of iron and manganese, particularly in the absence of sufficient organic matter. Small quantities of Cu, Zn, B, and Mo must be present in productive soils in forms which have enough activity to be available to growing plants. See also **Soil**.

SOIL PERMEABILITY. See **Hydrology**.

SOL. A word sometimes used to describe the solar day on the planets and their satellites. A sol or solar day is the interval between two successive transits of the sun past a given meridian. The length of the solar day ranges widely from one planetary body to the next.

SOLANACEAE (Potato Family). A relatively small plant family of some 1,700 species, in about 80 genera. The members include herbs, shrubs, and a few trees, most of the last being found in the tropics. The family has many important food and medicinal plants. All of its members contain poisonous alkaloids, as solanin, capsaicin, nicotine, and atropine.

Members of this family have leaves that are usually alternate and variously shaped, often lobed or dissected or pinnately compound. The variability frequently occurs in the leaves of a single plant. The flowers occur either singly or in cymes, and are regular with an inferior five-lobed calyx, a five-lobed corolla of various shapes. These are often large and conspicuously colored, with five stamens and a pistil composed of two united carpels, a long style, and a single terminal stigma. The ovary contains many ovules. The fruit is either a berry (potato and tomato) or a capsule (tobacco).

The most important member of this family is the Potato, *Solanum tuberosum*, commonly called the Irish potato, common potato, White Potato, or English potato, to distinguish it from the sweet potato. The plant is a branched herb, the branches tending to spread out more or less, and growing 2–4 feet in height. The green stems are annual, but the tubers, which are modified stems, give to the plant a perennial nature. The leaves are pinnately compound and rather irregular. The flowers are $1–1\frac{1}{2}$ inches in diameter, white, often with blue or purple tones or stripes, and with a tubular corolla. The fruit is a globular berry containing many small seeds embedded in a green pulp. Common names given these potato berries are potato balls, potato apples or seed balls. When mature, they are either green or brown; often they contain few seeds, but since they are rarely used in propagating the potato, this is of little consequence. They are used experimentally in the production of new varieties. Once a desirable variety is found, it is perpetuated vegetatively by means of the tubers. These tubers are formed at the tips of modified underground branches, or rhizomes, which radiate outward from the basal portion of the stem and to the casual observer resemble roots. The length of these stems varies from a few inches to a foot or more, depending somewhat on the variety. Rhizome formation and tuber development start soon after the tops appear above ground, and are advanced by darkness and low temperatures. The tubers continue to grow throughout the growing life of the plant. A mature tuber has the structure of a stem, but very much modified. Externally, one may recognize nodes and internodes, the nodes being determined by the eyes, depressions in the surface of the potato, each depression or eye containing a tiny bud. Internally the tuber is largely parenchymatous tissue with the cells filled with starch-grains. Near the surface of the potato, cross sections show a faint dark line which is the vascular tissue, very much reduced. Potato tubers vary greatly in shape, as well as in size; the better varieties are oblong or oval, with smooth skin and rather shallow eyes. In color, tubers range from brown through yellow to red, according to variety. The length of time required to mature a marketable tuber also varies greatly, some early varieties reaching a desirable size in about two months, while late varieties require five or six months.

The tubers are the principal means of propagation. For this purpose a tuber is cut into irregular pieces, each of which contains two or three eyes. To prevent disease the cut pieces are treated with fungicides and allowed to dry slightly, after which they are planted. Sprouting starts at once, indeed frequently occurs while the potato is still in the storage bin. If the bin is dark the sprouts formed will be long, slender and white. Sprouts formed in light are short, stout and dark green.

The potato is a native plant of cool upland regions of South America, where it has been long cultivated by the natives, who use the tubers for food. From America, it was carried to the southern part of Europe, where at first it was grown largely as a curiosity. From Europe the plant was brought back to America and introduced into what is now the United States, thus explaining its name of English or Irish Potato. It is now extensively grown in regions having a cool climate, Maine and Idaho being particularly noted for their potato crops.

In all green parts of the potato a poisonous alkaloid, solanin, occurs. This substance may also occur in the tubers, particularly if the latter are exposed to light long enough to become green in color.

Another important food plant of this family is the tomato, *Lycopersicum esculentum*, and related species. This is a native of South America, in which continent the tomato is still found wild. The tomato is a coarse branching perennial herb which is usually grown as an annual. It is an important food which has become immensely popular. Large quantities are consumed raw or canned. Tomato juice is important in many diets. Greater greenhouse production and improved rapid transportation from southern states makes it possible to enjoy fresh tomatoes in any season.

The tomato was carried to Europe by the early Spanish explorers and became an important food plant in southern European countries. In England, and also in the United States, it was widely grown before 1830 as a garden ornamental known as "Love Apple," which however was not eaten, but was held by many to be rankly poisonous. The Italians seem to be the first to have braved the danger of tasting the delicious fruit of this "poisonous" plant.

A third member of the family providing food to people is the egg plant, *Solanum melongena*, a coarse, somewhat woody, branching herb native to India. The plant has a rough stem, 2 or 3 feet tall, large sinuate-lobed ovate leaves and purplish flowers. See Fig. 1. The fruit is a berry, very large in some varieties. It is eaten either baked or sliced and fried.

Fig. 1. Large-fruited Black Beauty variety eggplant, the most popular of eggplant varieties in the United States. (*USDA photo.*)

Serving rather as a condiment than a food, but still used as a food stuff in some of its varieties, is the pepper, *Capsicum annuum*, another native plant of tropical America. Peppers are either annual or biennial plants, with branching stems 1–3 feet tall, smooth shining leaves and white flowers. There are many varieties, which bear fruits of a variety of sizes and shapes (Fig. 2), as well as degrees of pungency. Some varieties are known as sweet peppers, and are used while yet green in salads or stuffed and baked; others are hot peppers. The pungent taste is due to an acrid compound, capsaicin,

which in hot peppers occurs throughout the fruit, but in sweet peppers is largely restricted to the immediate region of the seeds; since only the fleshy pericarp is eaten, the seed being removed, this pungent substance is lost.

Fig. 2. Comparative sizes and shapes of common peppers: (**a**) bell or bullnose pepper; (**b**) pimiento; (**c**) Cayenne or chili pepper.

Peppers are used in many ways other than as food. Small hot peppers are a frequent component of mixed pickles, and also are used in salads. The whole fruit of some varieties is ground up to a powder, and becomes Cayenne pepper, an extremely pungent condiment. Small smooth fruits of var. *conoides* are preserved whole in brine or vinegar, and known as Tabasco sauce or Tabasco peppers. Red peppers are used medicinally. Many varieties of pepper are grown as ornamental plants, the brilliant fruit offering a startling contrast to the dark green leaves.

More widely grown for its ornamental properties is the *Petunia*, introduced from South America.

Many members of the Potato Family are important drug plants. Here belong *Atropa belladonna*, yielding atropine, and *Datura stramonium*, the Thorn Apple, called also Jimson Weed or Jamestown Weed. The latter is a tall, rather coarse, branching annual having broad leaves with sinuate margins and large trumpet-shaped white flowers, borne singly in the axils of the leaves (a related species, *D. Tatula*, has purple flowers). The fruit is a prickly capsule. In all parts of the plant, but especially in the seed, are found several drugs. The most abundant is hyoscyamine, with small amounts of atropine and scopolamin present. The powdered leaves and seeds are used medicinally, chiefly in treating asthma.

Less important medicinally are several plants such as *Hyoscyamus niger, Solanum dulcamara*, the Bittersweet, and *Solanum niger*, the garden Nightshade, all held to be poisonous plants if eaten in sufficient quantity by man or domestic animals.

Another member of this family, ranking along with the potato in importance, is the tobacco plant, *Nicotiana tabacum*, also a native plant of tropical America. It is an annual plant growing 3–6 feet or more in height, and stout. The leaves are alternate, simple and rather large and, like the stem, covered with sticky hairs. The rather large flowers are borne in terminal racemes and have a funnel-shaped corolla which is yellow, white, pink or purple in different species and varieties. The fruit is a capsule containing many small seeds.

SOLAR CYCLE (The). Solar maximum or "solar max" is the term for the maximum in solar activity that takes place approximately every eleven years; solar minimum is the lowest point of solar activity. The last solar maximum was in 2000, and on March 10, 2006 NASA researchers announced that the next cycle would be the strongest since the historic maximum in 1958 in which northern lights could be seen as far south as Mexico. This projection was based on research done by Mausumi Dikpati of the National Center for Atmospheric Research (NCAR). The current 11-year cycle, the 23rd to have been measured by modern scientists, is called Solar Cycle #23. See Fig.1.

Solar events can interact and interfere with each other, creating a very complex system. Their frequency varies with time. The smaller flares tend to follow the eleven year cycle and peak at several tens of flares per day. The largest flares usually occur only a few times during solar maximum. Sunspots increase with solar maximum, and are relatively rare during solar quiet times. Coronal holes do not last as long during solar maximum. See also **Sun (The)**.

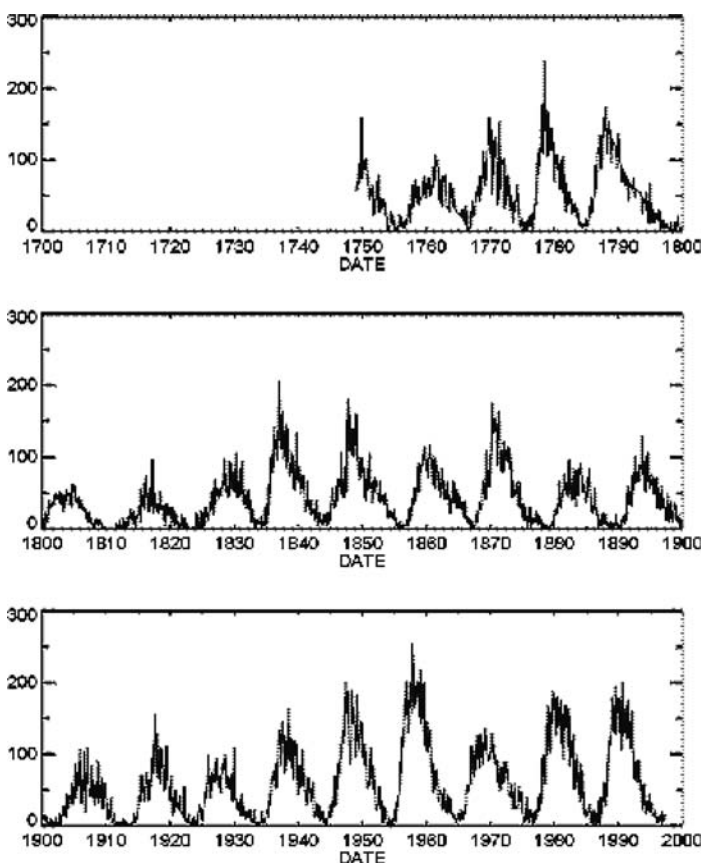

Fig. 1. Monthly averages of the sunspot numbers show that the number of sunspots visible on the Sun waxes, during solar maximum and wanes, solar minimum with an approximate 11-year cycle. (*image courtesy of David Hathaway, NASA MSFC*).

SOLAR ENERGETIC PARTICLES. Solar energetic particles (SEPs) are atoms that are associated with solar flares. SEPs are a type of cosmic ray. They move away from the Sun due to plasma heating, acceleration, and numerous other forces. Flares frequently inject large amounts of energetic nuclei into space, and the composition varies from flare to flare. The mechanisms involved in producing a solar flare can be better understood by studying the composition and charge of these particles. On the scale of cosmic radiation, SEPs have relatively low energies. See also **Cosmic Rays**; **Solar Flares**; and **Space Weather**.

Solar energetic particle (SEP) events are generally classified as either gradual or impulsive. Gradual events are typically large, with average composition similar to that of the corona, and are accelerated by shocks driven by coronal mass ejections. See also **Coronal Mass Ejections**. Impulsive solar energetic particle events are well known for their dramatic over-abundances in ^{3}He and heavy ions. ACE (Advanced Composition Explorer) observations have extended these composition peculiarities to overabundances in the heavy isotopes of Ne and Mg. Possible mechanisms that might explain the observed elemental and isotopic fractionation patterns are still hotly debated, but are thought to be related to the mass-to-charge (M/Q) ratio of the ions during the injection and acceleration process.

SOLAR ENERGY. The vast quantity of energy received by Earth from the sun and the potential for converting that energy into more useful forms for society has intrigued scientists, engineers, and social planners for decades. This interest was sharpened by the oil embargo of the 1970s and, for about a decade after that, tremendous interest was displayed, by the scientific and lay community alike, in alternative energy sources, including a turn to solar energy. Energy from the sun was considered by many people as a relatively low-cost and essentially pollution-free source, particularly in contrast with polluting, nonrenewable, so-called fossil fuels and with nuclear fuels, which many people consider in a negative light. During the 1970s, but tapering off in the 1980s, many, many millions of dollars were invested by governments worldwide and by private institutions, architectural and solar equipment firms, and energy supply firms toward the development of practical, economically competitive solar energy systems.

As a result of that activity, progress in designing passive solar energy systems into office and factory buildings has been impressive, but not nearly so extensive as once estimated. Active solar energy systems, in which solar radiation is converted into another energy form (usually electrical) has also progressed, but the number of outstandingly successful installations is relatively limited, and essentially these are presently regarded as still in an experimental phase. In contrast, considerable research continues to be directed toward solar cells (solid-state devices that convert solar radiation into electric power), but it should be immediately stressed that solar cells for communication and other satellites and space vehicles are vitally needed, because they provide an energy source difficult to obtain in other ways. Cost, in this instance, is not supercritical, but one finds that solar cells for building, etc. heating and power still are essentially noncompetitive. Some relatively low-cost, small solar-powered devices designed mainly for public consumption have appeared in recent years.

To put solar energy into perspective, one should review other energy resources as well. Fortunately, throughout this encyclopedia, such energy information is available. See list of articles at end of this description and also consult alphabetical index.

Availability of Solar Energy

Not to be confused with insulation, the word *insolation* (acronym for "incoming solar radiation") defines the rate at which direct solar radiation is incident upon a unit horizontal surface at any point on or above the surface of the earth. The unit of insolation is the Langley, named after Samuel Pierpoint Langley (1834–1906), an American astronomer, physicist and pioneer in the utilization of solar energy:

$$1 \text{ langley} = 1 \text{ gram calorie per square centimeter}$$

$$= 3.687 \text{ Btu per square foot}$$

Fundamental to the practical application of real-time solar energy systems is the amount of energy received from the sun at any given location at any particular time. The energy received varies with the geometry of the sun-earth system — and thus varies with latitude, season of the year, time of day, as well as with local weather conditions. On a typical day in June, anywhere from 500 to 700 langleys of solar energy can be expected in most parts of the United States, whereas in December, with shorter days and more inclement weather, only from 100 to 300 langleys can be expected. In June, for example, both Saskatoon, Canada and Tampa, Florida receive about 600 langleys of solar energy daily, but in December, the amount of such energy received in Saskatoon drops to 75 langleys per day (only 12% of the June value at that location), whereas, in Tampa, more than 50% of the June amount is received in December. In terms of equipment costs, this translates into needing four times the solar-energy collector surface in Saskatoon as that required in Tampa in order to supply the same amount of power year-round. Maps of the type shown in Fig. 1 can be helpful in this regard.

The solar constant (intensity of solar radiation outside the Earth's atmosphere at the mean distance between the earth and the sun) has been determined by measurements from satellites and high-altitude aircraft and is 1.353 kilowatts per square meter. This extraterrestrial radiation, which corresponds closely to that of a blackbody at 5762 °K, is 7% in the ultraviolet range (wavelength less than 0.39 micrometer) and 47% in the visible range (wavelengths from 0.38 to 0.78 micrometer), with the balance in the near-infrared (largely with wavelengths of less than 3 micrometers). Radiation is depleted as it passes through the atmosphere by a combination of scattering and absorption; the radiation that reaches the ground — the raw material of this energy source — can vary from almost none, under heavy cloud cover, to 85–90% of the solar constant under *very clear* skies.

Solar Energy for Building and Residence Comfort

The application of solar energy for residences and commercial and public buildings tends to fall into three categories of increasing complexity: (1) heating only; (2) cooling only; and (3) combined heating and cooling.

Simple Heating System with Hot Storage. As shown in Fig. 2, the basic elements of this system, exclusive of pumps, valves, and controls, are: (a) a solar collector; (b) an auxiliary heating device; (c) hot storage system; and (d) heater element fan and air duct system. The solar collector absorbs heat energy from the sun and transfers it to a heat-transfer fluid, which conveys the heat to a hot storage system. From the hot storage, heat is withdrawn from storage through a heater coil, where an air-circulating fan carries heat from the coils into an air duct system. When the solar collector cannot provide an adequate amount of heat to maintain the hot storage at a minimum temperature, the auxiliary heating device, such as a fuel burner, electric resistance heating, or an electric driven heat pump, comes on. This auxiliary heat could be added to hot storage as shown in Fig. 2, or used to directly heat the room air. For the case of electric heating, heat addition to storage will provide the opportunity to limit auxiliary heat addition to nonpeak hours.

Solar Cooling System. As shown in Fig. 3, the basic elements of this system are: (a) a solar collector; (b) an auxiliary heating device; (c) a cold storage system; and (d) a heat-actuated refrigeration loop (absorption cycle). The solar collector absorbs heat energy and transfers it to a heat-transfer fluid, which in turn conveys the solar heat to the generator or boiler of the heat-actuated refrigeration loop. This loop can also be driven by auxiliary heating when the solar heat input is not adequate. If the heat-actuated refrigeration loop were of the Rankine-cycle type, rather than

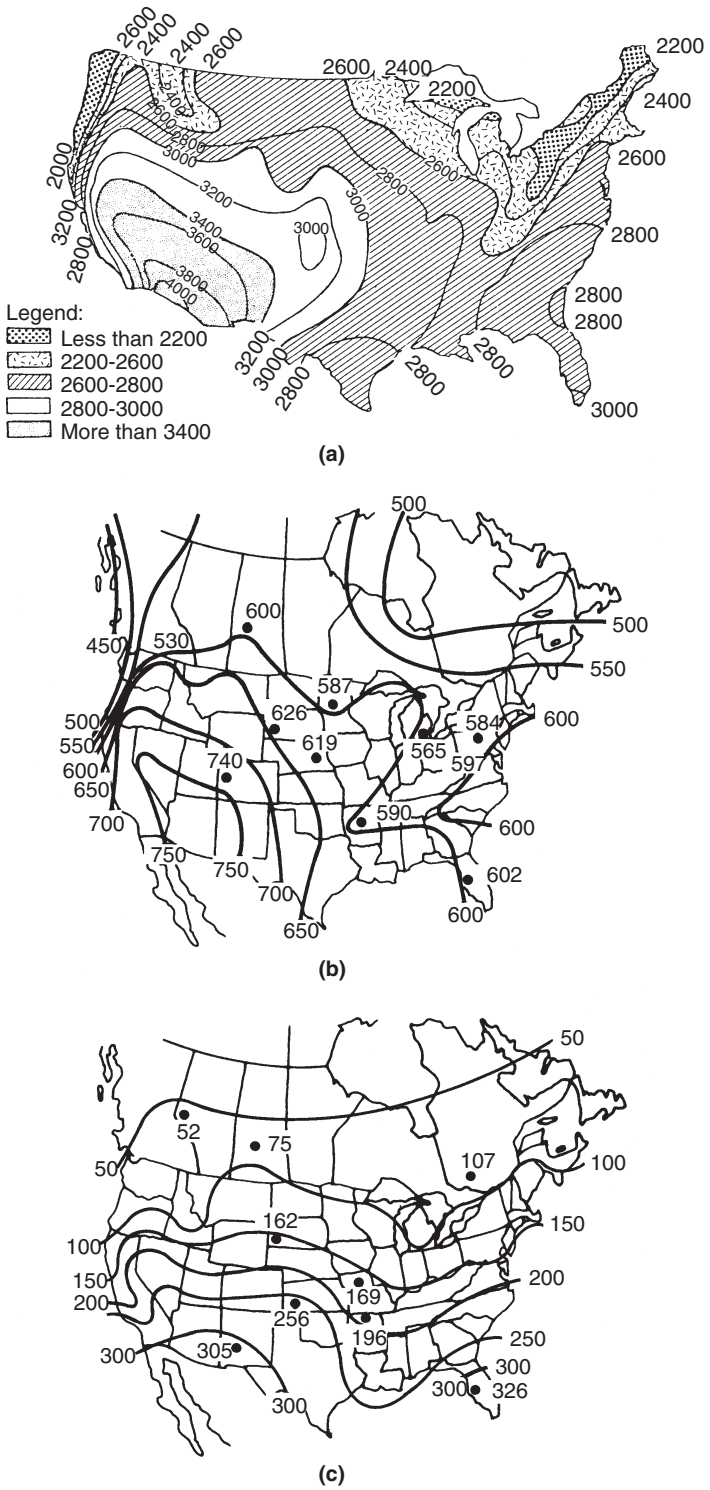

Fig. 1. Availability of solar energy (insolation): (**a**) Average number of hours of sunshine per year (United States); (**b**) median daily insolation in langleys (North America in June); (**c**) in December. (*National Oceanic and Atmospheric Administration*.)

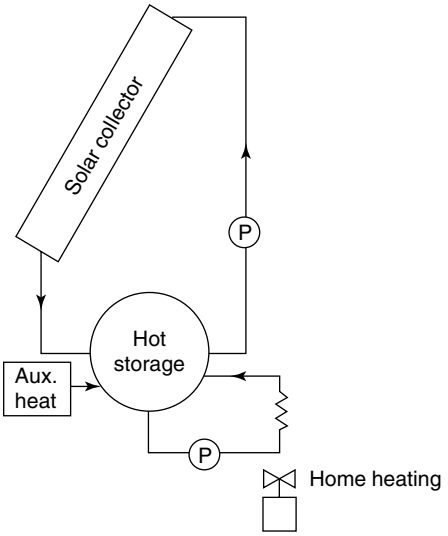

Fig. 2. Basic elements of solar heating system.

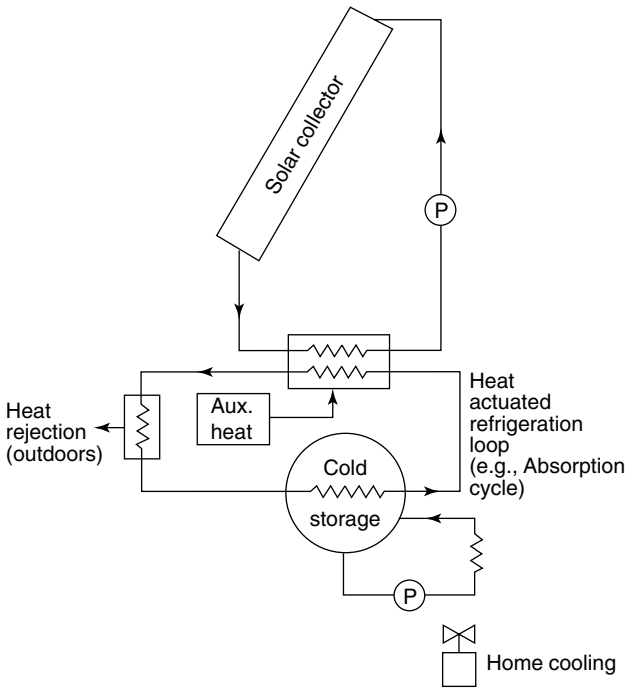

Fig. 3. Basic elements of solar cooling system. Cold storage only.

an absorption cycle, it might also be possible to drive the refrigeration loop with auxiliary power rather than auxiliary heating — a more favorable situation if the auxiliary is electric rather than fuel. The refrigeration loop cools the cold storage reservoir from which home cooling is supplied upon demand.

Combined Solar Heating and Cooling System. A system of this type is shown in Fig. 4. This is only one of a variety of possible systems. The major elements of this system are: (a) a solar collector; (b) an auxiliary furnace with heating coils; (c) a storage system (hot in winter; cold in summer); (d) absorption refrigeration cycle; and (e) necessary valving and controls. The system is designed to provide both heating and cooling upon demand. The heat energy generated by the solar collector is directed to either the hot storage tank or the refrigeration cycle generator, according to the seasonal mode of operation. When solar energy (either direct or stored) cannot supply the required heating or cooling load, auxiliary heating or cooling can be used.

In the winter mode of operation, solar energy is gathered at the collector and is pumped directly to the storage system. From the storage system, heat is extracted according to household needs through the heating/cooling coil in the main air duct. This coil is controlled by 3-way valves which are open to heating and shut to cooling. Heat is then extracted from the coil by air fans and carried into the house. At certain times, the solar collector and storage system will not be able to provide enough heat to maintain the heat needs of the household. In these cases, the auxiliary furnace will assume the heating load until the solar system is able to provide heating. This furnace will also provide auxiliary heat for domestic hot water when solar energy cannot provide this function. At times, while on winter mode

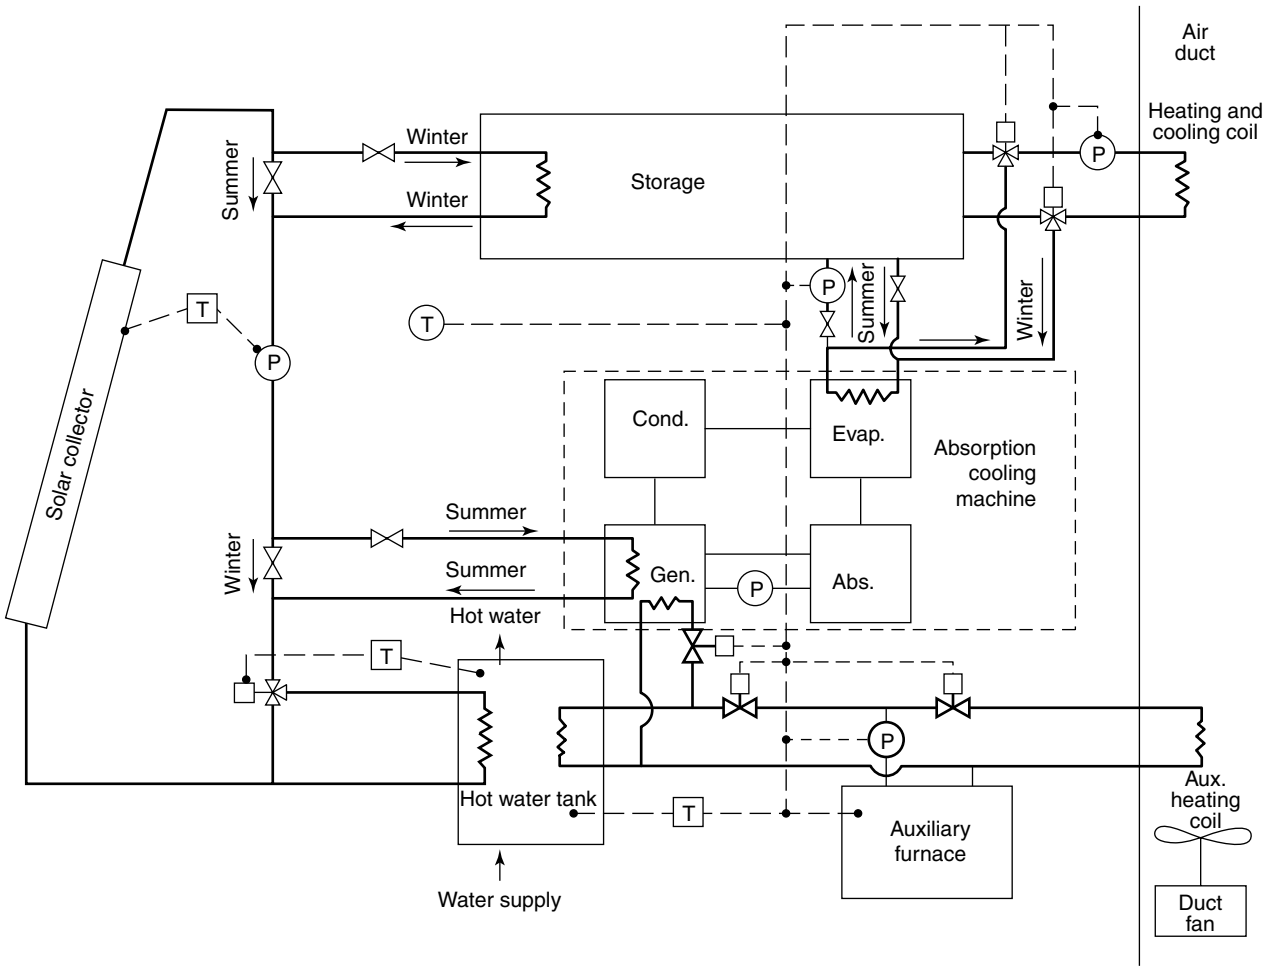

Fig. 4. Combined solar climate heating and cooling system.

operation, there will be days when cooling may be required. When this condition exists, the auxiliary furnace will drive the absorption cycle. The two 3-way valves on the heating/cooling coil will be actuated to permit chilled water from the absorption machine to circulate through this coil.

In the summer mode of operation, solar energy is gathered at the collector and pumped in the form of heat directly to the absorption refrigeration machine and to the domestic hot water heater. The collected energy serves as the main driving force for the cooling system. When the collector is unable to provide the necessary energy for the cooling system, the auxiliary furnace is activated to supplement the energy load. Once the cooling cycle is activated, the cooling produced is directed to the same storage system used for storing heat in the winter. Cooling is extracted per household needs from the storage system through the heating/cooling coil. In this mode, the 3-way valves of the coil are open to storage system and shut to direct cooling from the cooling cycle. Should the storage system not be able to provide the cooling, these valves would be closed to the storage system and open to direct cooling. While on the summer mode, the auxiliary furnace can be used to heat the house on occasional cold nights.

The foregoing systems are representative of general concepts and not necessarily of final designs or optimum arrangements. The final detail system design will, in particular, be dependent upon whether fuel or electricity is used for auxiliary heating. For the near term, natural gas or fuel oil may be preferable to electric heating. However, in the longer term, as developments in solar collection and heat storage reduce the amount of auxiliary heat required, and as heat pump technology is improved, electricity may become more attractive.

Architectural and Building Factors. Solar climate control systems will have to be integrated with different building designs. New buildings can be designed to fit the requirement of a solar climate control system while applications to existing buildings will have to be determined individually. Collectors can be installed on flat roofs of buildings, or designed to fit the sloping roofs of a wide variety of buildings. Collectors could serve a single building or a cluster of buildings. As previously pointed out, the geometry of the collector installation varies with location latitude. Economics to a large degree will be determined by availability of reasonably sustained sunshine.

Flat-Plate Collectors. Essentially since the outset of solar energy technology for environmental heating and cooling of living and working enclosures, the flat-plate collector has dominated the field. Within recent years, however, some of the initial needs for collectors of this nature have been obviated by more attention being given to the design of passive solar collectors, described a bit later. Also, for very large commercial installations, there has been a trend toward the use of nonfocusing or trough or line-focusing concentrators, also described later.

The essential features of a flat-plate solar collector are shown in Fig. 5. A blackened receiver surface covered by one or more special glass plates is used. Since the glass is transparent to the incident solar radiation, but opaque to the reradiated energy, the solar collector, like a greenhouse, serves to trap solar energy. The working fluid used to remove the heat from the collector can be either air flowing between the blackened surface and the glass plate or water (or some other liquid) flowing in tubes attached to the blackened plate. Solar collection efficiency is defined as the ratio of usable energy collected per unit time to the incident solar flux. Efficiency, η, may be calculated as:

$$\eta = \alpha\tau - \frac{q_L}{q_{in}}$$

where: α is the absorptivity for sunlight; τ is the transmittance of the glass plate; q_L is the heat loss from the collector; and q_{in} is the incident solar flux. The heat loss q_L is, in turn, dependent upon the emissivity, ε, for low-temperature radiation. Typical performance characteristics for a solar energy collector are shown in Fig. 6, which is a plot of collector efficiency versus temperature of the absorber plate for an incident radiation

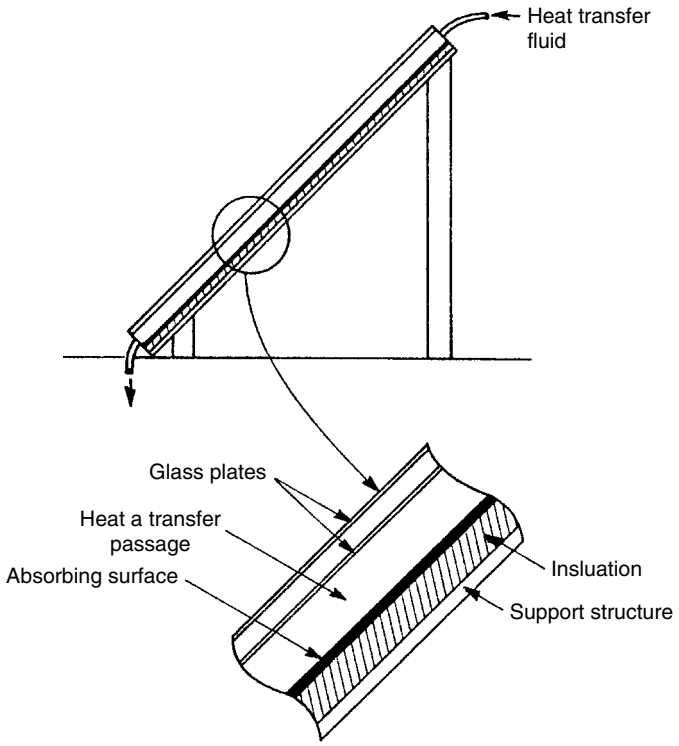

Fig. 5. Basic elements of a flat-plate solar collector.

of 300 Btu/(hour) (square feet); 814 kcal/(hour) (square meter). Note that the efficiency falls off as absorber temperature rises. Efficiency, of course, also drops off rapidly as the incident radiation is reduced, since the heat loss term is a function of absorber temperature only.

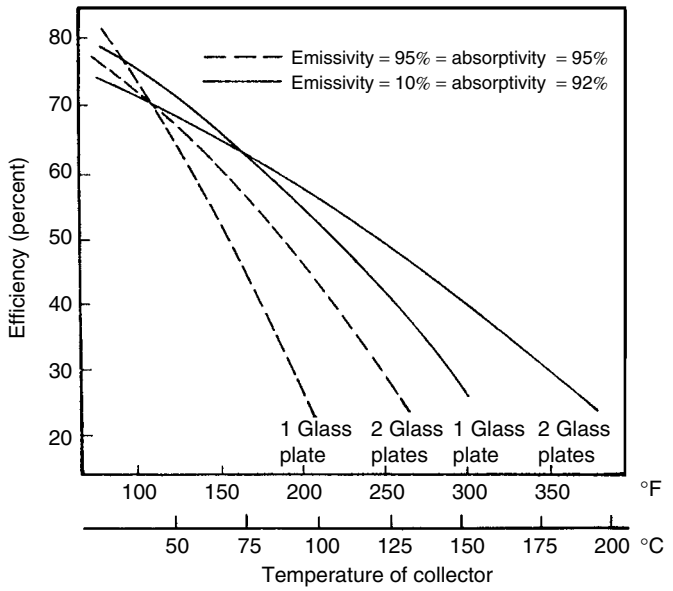

Fig. 6. Relative solar collection efficiency of plate-type solar collectors with different emissivities.

A problem that must be faced by architects and engineers is the need to integrate collectors into building and residence design in a way to maximize thermal performance and, at the same time, provide an esthetically satisfactory structure. A major variable, depending upon energy requirements and the average solar insolation over a year, is the amount of collector area needed. Obviously, the larger the energy requirements and the less favorable the insolation, the greater the problem. Because collectors must be oriented within rather narrow limits if they are to maximize their capture of solar radiation, the problem of retrofitting many existing structures sometimes renders a project impractical. Thus, the general pattern has been one of concentrating on new construction, particularly for low-rise, flat-roofed buildings, such as schools and shopping centers, where cooling may be more important than heating. Where surrounding area is available, as, for example, an adjacent parking area or facility, the collectors can be installed apart from the structure to be heated and/or cooled. Also, by turning to advanced collector designs, which provide greater efficiency, even at greater initial cost, architects and builders can better cope with the problem of collector area required. Passive heating of buildings is also a possibility in many cases.

Evacuated-Tube Collectors. In this type of collector, an inner glass cylinder, blackened to absorb solar radiation, is enclosed within an outer protective cylinder. The space between the two cylinders is evacuated. The inner cylinder is usually coated with material that reduces energy loss through reradiation. Transfer of heat is accomplished by a fluid (air or liquid) that flows through the inner cylinder. These collectors are similar to flat-plate collectors in that they can use both direct and diffuse light. However, the evacuated-tube collectors operate better during the early and late parts of the day. The vacuum provides such excellent insulation that they are less affected by high winds and cold weather than the flat-plate collectors. The output of the evacuated-tube collectors is essentially independent of ambient temperature and their efficiency is generally 40–50%. Ordinarily these collectors operate at about 180 °F (82 °C) for space-heating applications and certain process heating uses. Equipped with reflectors, they can operate up to 240 °F (116 °C), which is sufficient to drive absorption air conditioners. Cylindrical evacuated tube collectors can absorb radiation coming from any direction (360° aperture). Usually, they are mounted in arrays with a spacing of about one cylinder diameter between tubes and with a reflective material behind them.

Large-scale collectors, with or without focusing (radiation concentrators) are described a bit later.

Heat Storage. A comparison of heat-storage capacity on a volumetric basis between various storage media shows that water can store 62.5 Btu per cubic foot per degree Fahrenheit (311.5 kcal per cubic meter per degree Celsius. Rocks, bricks and gravel can store about 36 Btu/cu. ft/degree F (179.4 kcal/cu. meter/degree C). In addition to fluid media and solid media, advantage can be taken of the latent heat of a phase transition. Some salts, which melt in the desired temperature range, can store about 60 Btu/cu. ft/degree F (299 kcal/cu. meter/degree C) as sensible heat, and 9500 Btu/cu. ft./degree F (47,348 kcal/cu. meter/degree C) at the melting point as heat of fusion. However, these salts tend to undercool rather than crystallize during the cooling cycle. While undercooling can be prevented by use of nucleating agents, the fixed rate of crystal growth is very slow in most salt hydrates. Heat cannot be withdrawn more rapidly than it can be supplied by the growth of crystals. This is a serious problem, which can only be partially overcome by the design of the storage container to provide a large heat-transfer area. Based upon these alternatives, an insulated tank of water to store heat is one of the most efficient solutions. Early work concentrated on $Na_2SO_4 \cdot 10H_2O$ which undergoes a phase transition when heated at 32 °C (89.6 °F). Because phase separation of this hydrate occurs on cycling, other chemical systems are being sought which can undergo thousands of cycles without loss of storage capacity.

Typically optimum storage capacity varies from 1 to 3 typical winter days' solar energy supply, depending upon the site, and for a medium-size residence or small commercial building would be in the range of 1000–2000 gallons (38–76 hectoliters). A section of a comparatively small solar-heated building is shown in Fig. 7.

Collectors also can be used as energy dissipaters by designing them to lose heat by convection and radiation to the clear night sky. The role of the collector is thus fully reversed for the cooling cycle. This requires a system for moving insulation, unless design compromises in collector design are made for both the heating and cooling cycles.

Solar collectors also can be combined with heat pumps. The latter can serve as an independent (auxiliary) source of heating energy, or the collector-storage system can serve as the energy source for the evaporator of the heat pump. The latter system has apparent advantages of lowering mean collector temperature and raising the mean evaporator temperature of the heat pump, thus improving the performance of each. See Fig. 8; see also the entry on **Heat Pump**.

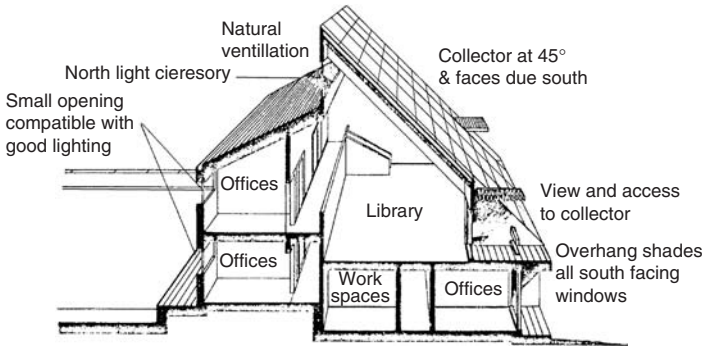

Fig. 7. Section of solar-heated building. Solar collector has an area of 3500 square feet (325 square meters) facing south at an angle of 45 degrees. There are about 8000 square feet (743 square meters) of working space. Estimates of heat loss indicate heat demand is in range of 40,000–70,000 Btu (10,080–17,640 kcal) per day. Located in the northeastern United States, the building was designed to furnish between 65 and 75% of total seasonal heating load.

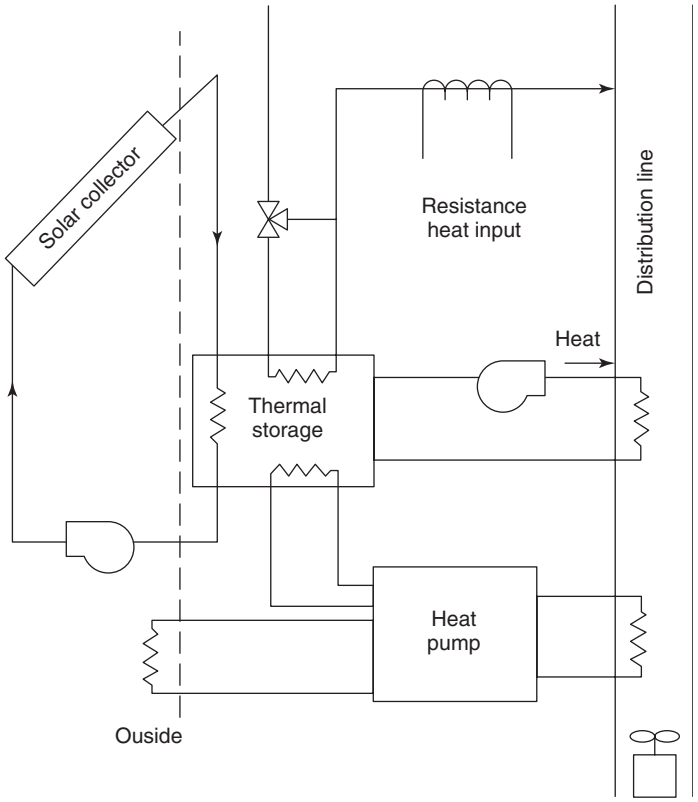

Fig. 8. Solar heating system with heat pump auxiliary.

In addition to close cycle absorption cooling, open cycles are of potential interest. Desiccants can be used to absorb water vapor from room air, which then can be evaporatively cooled. The desiccant is regenerated and recycled. Löf has suggested the use of triethylene glycol as a desiccant, with solar-heated air for regeneration. Lithium chloride also has been proposed as a desiccant.

Heat-Actuated Refrigeration. A variety of heat-actuated refrigeration cycles has been proposed for solar air conditioning. These can be divided into heat engine types, such as the Rankine and Stirling cycles, and the absorption machines. Most successful to date have been the lithium bromide-water and the ammonia-water absorption cycles. Regardless of type, operating temperature is a tradeoff when coupling a solar collector to a heat-actuated refrigeration machine. The efficiency of solar collectors decreases with temperature. On the other hand, the coefficient of heat-actuated refrigerators increases with generator temperature. Figure 9 shows Carnot coefficient of performance as a function of generator temperature for an evaporator temperature of 45 °F (7 °C) and for heat rejection temperatures of 120 °F (49 °C) (typical of air cooling) and 100 °F (38 °C) (warm water cooling, such as might be achieved with well water). For the case of absorption machines, it is assumed that absorber and condenser operate at a common heat-rejection temperature. Using these plots, the collection efficiency–Carnot coefficiency of performance product for the simple single-pane black collector reaches a maximum rate at about 175 °F (80 °C) and falls off rapidly at higher temperatures. For a more refined collector, such as a single pane with selective surface collector, the efficiency coefficient of performance-product is maximum and nearly constant in the range of 200 to 300 °F (93 to 149 °C).

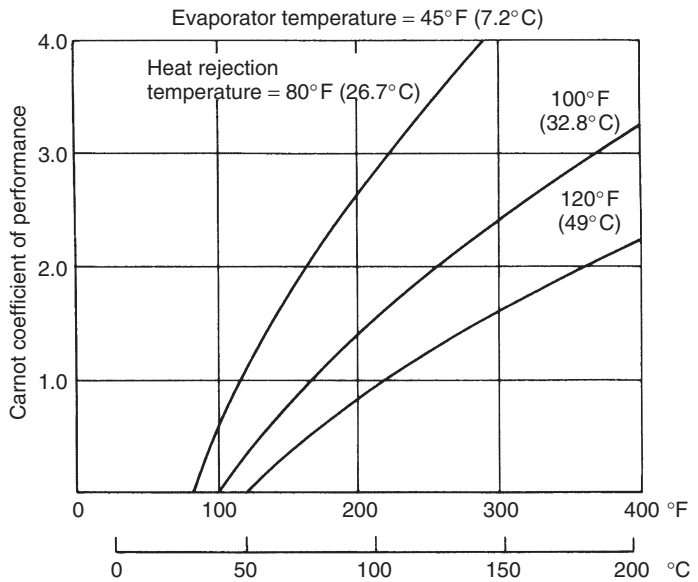

Fig. 9. Carnot coefficient of performance of heat-actuated refrigerators.

To achieve temperatures above the boiling point of water, concentrators are required as well as collectors. One of the largest high-temperature solar energy systems for building heating and cooling commenced operation in late 1978, at an eight-story office building (Minneapolis), which houses about 500 employees, and has over 100,000 square feet (929 square meters) of working space. During an average year, the system was designed to generate about 50% of heating needs, 80% of cooling energy needs, and 100% of heat for hot water needs. On the roof of a parking ramp adjacent to the building, 252 trough-like collectors track the sun to focus its rays on liquid-filled pipes. The liquid, which may reach 177 °C (350 °F), is pumped to an isolation heat exchanger that allows different fluids, pressures, and flow rates to be used in the two-loop system, dictated because of the cold winter temperatures. Excess heat is stored underground in two 18,000-gallon (681 hectoliters) tanks until required. Each row of solar collectors is under the control of a local system that uses a photosensitive sun tracker and bidirectional electric drive A.C. motor. Wind, solar isolation and other safety control circuits are continuously monitored to protect the collector field from damage by weather excesses.

Passive Solar Heating and Cooling. Although not always the practical solution, one of the most sensible approaches to the utilization of solar energy does not require pumps, fans, etc., but utilizes the building or residence structure per se as the solar radiation absorber (or insulator). An example of the modern approach to passive approaches is, ironically, incorporated in Montezuma's Castle, built around 700 A.D. by the cliffd-welling Indians of Arizona. The basic philosophy is to design the structure to capture and retain heat during winter and to remain cool during summer. For example, the windows that face north are made small or largely eliminated. These windows do not contribute much to heat collection during summer or winter and thus, if small, diminish heat leakage in either direction during all seasons. South-facing windows are made large because they are required as radiation collectors during winter. However, they are protected during the summer season by an overhanging roof. These features

alone, of course, are common-sense ideas that have been used by some designers for many years. Passive systems also take advantage of heavy masonry walls (or other sources of thermal mass) which can absorb solar radiation during the day and reradiate some of it at night. Such an arrangement could be called a "concrete collector." The designer can improve the effectiveness of extensive south-facing windows by constructing an interior masonry wall adjacent to the windows (lighting becomes a problem for special design). In an experimental building (Wallasey School, Liverpool, England), the south wall of the two-story concrete structure is made up essentially of double-glass windows with a heat-storage (or insulating) wall. The only supplementary heat required is derived from body heat of the students and heat radiated by electric lights. A structure of this type, of course, is subject to wider interior temperature variations than those to which much of society has become accustomed. Temperature swings can be reduced by partially decoupling thermal storage from the living and working space. In this concept, solar radiation entering the south-facing windows is absorbed by a masonry wall (sometimes called a Trombe wall) or by a water wall in which water-filled drums are placed. This wall insulates the building from high temperatures during daytime and transmits stored energy to the structure for warming during nighttime. There is an office building and warehouse in northern New Mexico which incorporates a water wall passive system and which provides 95% of the energy required for heating.

Some designers use a "roof pond," in which plastic bags filled with liquid are exposed to the sun during the day. They are covered with an insulating panel at night so that they can radiate stored heat downward to the structure. The cycle can be reversed to provide cooling during summer.

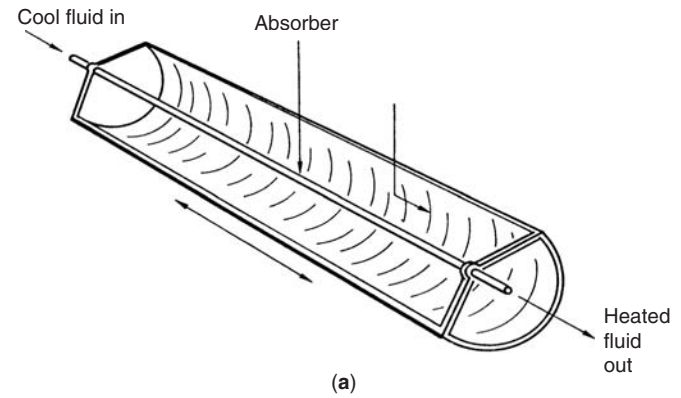
Investigations indicate that the optimum thickness for concrete thermal storage walls is about 30–40 centimeters (1–1.3 feet). Innovations in passive systems are appearing at a rapid rate. Some of these include movable insulation for shielding glass areas at night, and more compact thermal storage systems, such as ceiling tiles which have been developed by the Massachusetts Institute of Technology. These tiles contain a material that undergoes a phase change at 75 °F (24 °C), storing heat as the material melts and later releasing the heat to the room as the material solidifies. It is expected that, as passive systems improve, there will be a considerable impact on the traditional flat-plate collector.

Large-Scale, High-Temperature Solar Energy Systems

Systems in this category require concentration of solar radiation prior to its collection and utilization. Concentrators fall into three categories:

(1) *Nonfocusing concentrators* have the advantage that they do not have to continuously track the sun and thus do not require optical precision. Also, they can utilize both diffuse and direct radiation and thus are partially operable on cloudy days. They do not, however, operate as efficiently as focusing types, particularly during the early and late periods of the day. A simply designed nonfocusing concentrator essentially will consist of a stationary mirror or reflector located next to a flat-plate collector. In another approach, placing reflectors behind evacuated-tube collectors also accomplishes a modest degree of concentration. An advanced nonfocusing concentrator, known as the *compound parabolic concentrator* (CPC) was developed by the Argonne National Laboratory as the result of experience gained from designing light-concentrating devices for use in high-energy physics experiments. The device incorporates a parabolic surface designed to provide the maximum amount of radiation to an absorber for a given concentration ratio. In one configuration, the radiation is concentrated 1.8 times and, when operated in conjunction with a stationary collector, will reach temperatures as high as 250 °F (121 °C). Units with even higher concentration ratios (3× up to 6×) have been developed for use with evacuated-tube collectors and can achieve temperatures between 300 and 450 °F (150 and 232 °C). At a concentration ratio of 6, it is necessary to reorient the collector once each month. Currently, manufacturing costs are relatively high, but the CPC holds promise for a number of future applications.

(2) *Trough or line-focusing concentrators* track the sun by focusing in one direction only. Concentrations in this category of device range from 10× to 100× and they are capable of achieving temperatures between 200 and 600 °F (93 and 316 °C). On average, these devices deliver a minimum of 50% of the solar energy available to the heat-transfer medium in the absorber. In one configuration, mirrors form a parabolic trough that focuses radiation onto a linear absorber. Usually the mirrors are constructed of polished metal or coated plastic; the absorbers are blackened metallic pipe or evacuated-glass tubes. See Fig. 10. The entire assembly or array tracks the sun. Although normally considered in terms of relatively large thermal capacities, versions have been offered for residence and small building applications. Other, more sophisticated versions, operating at the high-temperature range, are used to drive Rankine-cycle heat engines for pumping irrigation water in a number of locations in the southwestern United States. Other installations include water heating for industrial processes. In another type of line-focusing concentrator, the optics are altered to utilize plastic Fresnel lenses for focusing the radiation onto the absorbers. Apparently a similar thermal result can be accomplished, as compared with the parabolic mirror approach, with a smaller optical surface.



(**a**)

(**b**)

Fig. 10. (**a**) One configuration of an optical-type concentrator with axial absorber; (**b**) parabolic troughs under test for various uses, including irrigation pumping for croplands.

(3) In another one-axis tracking concentrator, a fixed trough is made up of flat mirrors and tracking is accomplished by moving the absorber. Known as the *Russell collector*, this unit apparently can reach temperatures up to 900 °F (482 °C).

Two-axis focusing systems will be described a bit later.

High-Temperature Solar Energy

Prior to the serious consideration of high-temperature solar energy as a source of electric power, much was learned from the design of solar furnaces, the objective of which was the production of extremely high temperatures for materials testing, a very useful research function that continues. Much knowledge was and is continuing to be learned from the operation of solar furnaces — knowledge that is helpful in the design of solar power plants. It is fitting here, as a backdrop to describing the solar power tower concept, to present information on solar furnaces. Historically,

solar furnaces have been selected for high-temperature research and development activities where a highly concentrated source of nonpolluting radiant energy is required. Generally such activities can be categorized as: (1) high-temperature chemistry involving the formation of very pure or otherwise unique materials; (2) high-temperature processing by which a material is fused, purified or otherwise improved; (3) high temperature property measurements involving the determination of the behavior of a material under conditions which require a noncontaminating environment; (4) determination of the thermal shock resistance or other behavior of materials in a high-temperature, high-heat flux radiant energy environment; and (5) study of high temperature solar-thermal conversion systems. Certain of these applications may be refined further by conducting the operation in an optically transparent vessel or one containing a transparent window such as fused quartz through which the radiant energy may pass and in which the composition and pressure of the atmosphere can be controlled.

A few examples of the types of high temperature studies which have been conducted in the previously described categories are: (1) gas phase reactions to form pyrolytic graphite; (2) production of very high purity fused aluminum oxide and fused silica, the production of stabilized zirconia and the purification of reactive metals in a controlled atmosphere; (3) determination of microwave transmission characteristics of dielectric materials at very high temperatures; (4) study of the thermal shock resistance of materials under high heat flux thermal radiation conditions simulating exposure to the thermal radiation pulse provided by a nuclear explosion; and (5) study of heat exchangers, such as boilers and superheaters for the production of steam for electric power generation.

Although the motivation for the design of such furnaces may be for high-temperature research, much can be learned from them that is applicable to the design of solar energy facilities for power generation. Up to the point of conversion, the problems are essentially parallel.

Solar Furnaces in France. In 1948, under the leadership of Professor F. Trombe, the Centre National de la Recherche Scientifique (CNRS) in Paris undertook the design, construction, and development of the world's first large solar furnace at Montlouis in the French Pyrenees mountains. This furnace was completed in 1952, and provided 50 kilowatts of thermal energy. The Montlouis solar furnace became the prototype design for other large high-temperature solar furnaces. Basically, this design utilized a single large heliostat (array of numerous flat mirror elements) which continuously tracked the sun to direct the sun's rays onto a concentrating reflector (parabolic or spherical) consisting of many smaller mirror elements each of which was contoured to concentrate the incident radiation at a common focal point. In the case of the Montlouis furnace, the heliostat was 43 feet (13.1 meters) wide and 34 feet (10.4 meters) tall and contained 540 flat mirrors each 50×50 centimeters. The concentrating reflector was made up of 3,500 mirrors 16×16 centimeters arranged in a parabolic configuration 36 feet (11 meters) wide and 30 feet (9.1 meters) high with a focal length of 6 meters. Each of the 3,500 flat mirror elements in the parabolic concentrator was mechanically contoured and aligned to focus the radiation received from the heliostat onto the focal point of the parabola.

The successful performance of Montlouis solar furnace led to the use of its design as the prototype for the next three large single heliostat-concentrator solar furnaces which were to be built during the next twenty years. All three of these furnaces were similar to the Montlouis furnace in size, operation and thermal power level and were constructed by: (1) U.S. Army Quartermaster Corps, Natick, Massachusetts; (2) Tohoku University, Sendai, Japan; and (3) the French Army's Laboratoire, Central de L'Armement, Odeillo, Font-Romeu, France. In 1973 the U.S. Army's solar furnace was moved to the Nuclear Weapon Effects Laboratory, White Sands Missile Range, New Mexico, where it became operational in 1974.

Although the Montlouis solar furnace played a major role in developing applications for high-temperature solar energy, and in providing design information for the three other large solar furnaces, its most valuable contribution to the field of high-temperature solar energy was the experience and background it provided the CNRS Solar Energy Laboratory. This led them to design and construct the CNRS 1,000-kilowatt solar furnace.

The CNRS 1,000 kilowatt solar furnace is located at Odeillo, Font-Romeu, altitude of 5,900 feet (1798 meters) about 25 miles (40 kilometers) east of Andorra and 5 miles (8 kilometers) west of Montlouis. At this location, the sun shines as many as 180 days a year and solar intensities as high as 1,000 watts per square meter are common. The solar furnace was completed on October 1, 1970, after more than 10 years of construction.

Figure 11 is a schematic of the CNRS 1,000-kilowatt solar furnace. This furnace utilizes 63 heliostats to direct the sun's rays onto the surface of the giant parabolic concentrator.

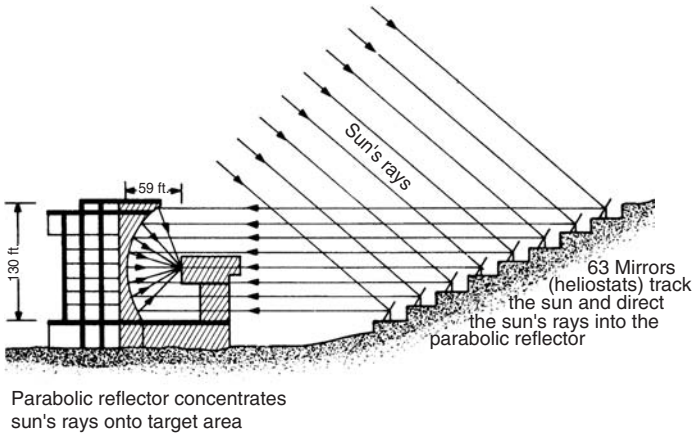


Fig. 11. Schematic representation of the 1000-kilowatt solar furnace at Odeillo, Font-Romeau, France. (*Centre National de la Recherche Scientifique*.)

The 63 heliostats are each 7.5 meters wide by 6 meters high and contain 180 single flat mirror elements 50×50 centimeters. The total area of mirror surface in the 63 heliostats is 2,835 square meters or over one-half the playing area of a football field.

The heliostats are located directly north of the parabola and are arranged on eight terraces. Each terrace corresponds in elevation to one of the floors of the building supporting the concentrating parabola. A solar beam of constant energy is thus directed horizontally and southward from the heliostats to the mirrors that make up the concentrating parabola.

Each heliostat is designed to illuminate a specific area on the parabola and is equipped with a dual optical control system, which maintains the proper orientation for each heliostat by means of a dual hydraulic system. This dual system permits each heliostat to be operated in either a "search" or "track" mode. In both cases, the optical guidance system uses an optical tube, which contains four photodiodes that control the heliostat motion in east-west and up-down direction.

When operating in the "search" mode a short (10-centimeter) optical tube with a 40 degree acceptance angle is used to activate the "fast" hydraulic system, which operates in an on-off mode to quickly bring the heliostat to within the operating range of the "track" system. In the "track" mode a 100-centimeter optical tube is used to control a slower acting hydraulic system which operates in a proportional control mode. The size of the sun's image at the base of the 100-centimeter tube is $\frac{1}{2}$-inch (13 mm) in diameter and the accuracy of the control is one minute of arc.

The concentrating parabola has a focal length of 18 meters, is 40 meters high and 54 meters wide, and the focal axis is 13 meters above the first floor. The parabola consists of 9,500 initially flat glass mirrors that were mechanically curved and adjusted to provide a solar image of minimum diameter at the focal point. Almost two years were required to accomplish these two precise adjustments which were completed on 1 October 1970. Figure 12 shows the parabola and the focal building into which the concentrated solar energy is directed. See also Fig. 13.

The solar energy incident on an area of about 2,000 square meters is concentrated by the parabolic reflector onto an area of less than 0.3 square meters. Sixty percent of the total thermal energy (about 600 kilowatts) is concentrated in an area of less than 0.08 square meter at the center of the focal plane of the parabola.

The diameter of the image of the sun at the focal point is 17 centimeters and 27% of the thermal energy (about 270 kilowatts) is concentrated in

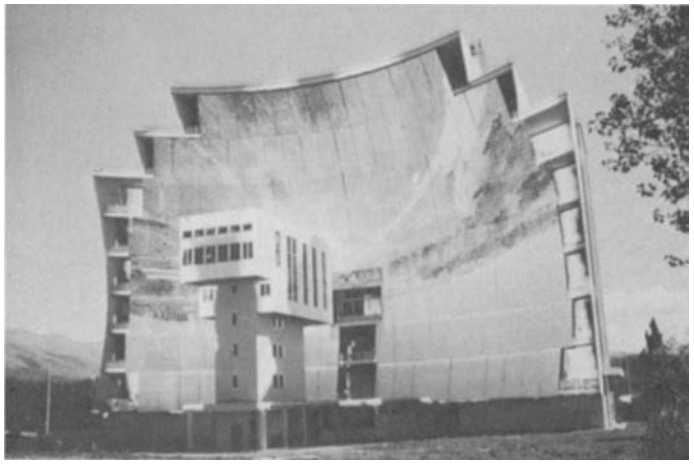

Fig. 12. Large parabolic reflector and focal building in foreground. Concentrated energy is directed at the solar furnace located within the focal building. Installation is at Odeillo, Font Romeu, France. (*Photo by Glenn D. Considine*.)

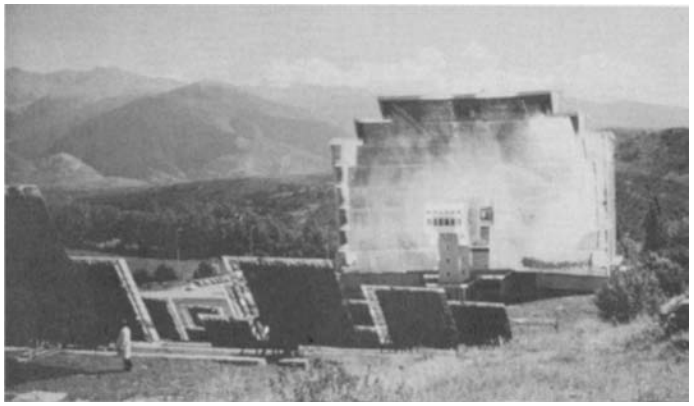

Fig. 13. Field of heliostat-controlled collector-reflector mirrors, which direct their energy to the parabolic reflector at the solar furnace installation at Odeillo, Font-Romeu, France. (*Photo by Glenn D. Considine*.)

this area. Heat flux data in watts per square centimeter in the focal area are presented graphically in Fig. 14. Curve 0 represents the heat flux at the focal plane. Curve d/2 shows the heat flux and temperature at a plane removed one-half the diameter of the solar image (8.5 centimeters) behind the focal plane. Curve d presents the same data on a vertical plane removed one diameter of the solar image (17 centimeters) behind the focal plane.

Solar Tower Energy Collector

Authorities have observed that solar energy can be usefully collected optically from one square mile (2.6 square kilometers) of surface area, or even larger, and concentrated onto a central receiver by an array of heliostats, i.e., independently steered mirrors. By judiciously spacing mirrors over 35% of the area, such a system in the desert southwest of the United States, for example, could collect 2800 megawatt-hours thermal per day in midwinter and almost twice that amount of energy in midsummer. In order that the reflected radiation from this field be efficiently intercepted, the central receiver would have to be several hundred meters high.

Unlike the Odeillo installation, previously described, where a field of heliostats finally focus their energy to a small aperture by way of a huge parabolic reflector, in the solar tower approach, the energy from each mirror is directed to a central receiving tower, located high above the field, as shown schematically in Fig. 15. Shown is a large array of heliostats by which essentially flat mirrors are automatically steered to reflect or redirect the incident solar radiation to a high tower. It is assumed that the terrain of the heliostat field is flat. However, a gentle slope southward would be advantageous. After reflection from the mirrors, the redirected solar energy can be absorbed and converted to heat by a black body receiver placed in the focal region. The heat can be transported down the supporting tower by way of liquid metal and/or steam lines and can be stored or used to operate a conventional turbine generating station. Alternate uses would be direct conversion to electricity by way of high-power-density solar cells placed in the focal region, or use of the heat to produce a fuel thermodynamically. Two-axis control can be obtained by either hydraulically or electrically operated servo-mechanisms that derive a signal from a simple position-sensing element.

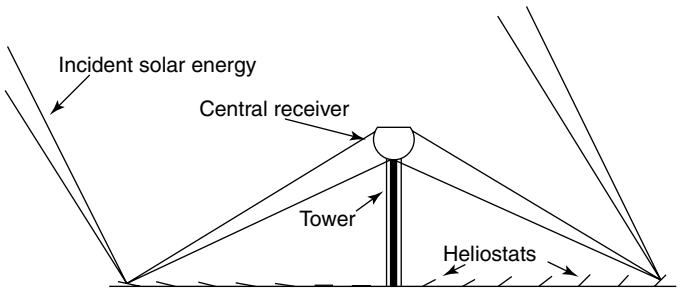

Fig. 15. Schematic diagram of solar tower energy concept.

It requires energy collected from an area like a square mile to be of interest to power utilities. Energy collection from hundreds of such installations would be required to make a significant impact on the energy supply. If one replaces the 300-meter tower with geometrically identical systems using 100-meter towers, it is found that 9 such towers would be required. Although the cost of nine smaller towers would compare with the cost of a single, large tower, additional costs and losses would be incurred in connecting heat-transfer lines to a central generator to handle 9 collectors. Also, heliostats smaller than about 20 square meters are not economical because the cost per heliostat of the support, actuator, and steering systems have a substantial fixed component.

The first choice of heat-transfer fluid would be steam because it would appear not to require any new technology. However, because the flux density that must be absorbed and transferred to the fluid can be appreciably higher than in conventional steam plants, efficient operation may require some new technology. Also, because of the large daily and seasonal heat flux variations, the design of the receiver is not trivial and may ultimately be best accomplished by utilization of liquid metal, such as sodium, for heat transfer from the receiver surface to a steam line. Liquid sodium technology has been developed for nuclear reactors and operating temperatures of 550 to 650 °C appear reasonable. Sodium also presents a promising high-temperature thermal storage medium. In general, the thermal cycling due to the intermittent nature of solar energy of this high-temperature system will have to be considered in any detailed design. The black body boiler surface should not deteriorate at high temperature in the presence of air. If deterioration is a problem and if convective losses are appreciable an

inverted cavity design can be used in order to avoid the use of vacuum jacketing.

Solar energy may best be utilized at first by a steam generator operating in a solar-only mode with short-term storage of an hour or less to provide operational stability. Because utilities require very high reliability, little new plant capacity credit would be given such a plant because of possible cloudiness. New plant credit could be given if there were possibilities of using liquid fuels, such as liquid petroleum gas or oil for backup. This could be accomplished by adding a simple low-cost, but possibly inefficient burner to add heat. Although liquid fuels may be in short supply, they are easily stored and afford an ideal way of giving a solar plant high reliability as an intermediate plant. Depending on actual operating conditions, it may be that very little liquid fuel is burned. The comparison of such a hybrid plant should be made with a solar plant that has a gas turbine as a backup. An alternate approach might be to store solar energy as sensible heat, perhaps in underground cavities, or as latent heat.

Some authorities believe that close ties between solar power and conventional electric power plants — so-called solar thermal electric designs — represent an ideal approach to the large-scale use of solar energy. In this concept, instead of a solar-powered facility being linked to traditional power-generating facilities by way of the electric grid, a fossil fuel backup for a solar system would be located at the same site as the solar electric plant. Savings could be realized through the common usage of certain equipment items. In one design, the oil-fired backup would use the same turbine as a power tower system. Some designers have estimated that this additional capability would add only about 0.26% of the total cost of the solar electric facility.

There are other authorities who believe that adapting solar energy to electric utilities will limit the economic potential of solar energy. The basic problem, is that both technologies are very capital intensive and that the electric utility, because of the high fixed costs of generation, transmission, and distribution capacity, represents a poor backup for solar energy systems. On the other hand, the solar collection system, because it represents pure, high-cost capital and because of its outage problems, cannot be considered as a part-load source of auxiliary energy for the electric utility system.

Solar Energy Plant at Electric Utility Level

Construction commenced in 1975 on an experimental 10 MWe central receiver pilot plant in a combined effort by two electric utilities in the southwestern United States, Southern California Edison and the Los Angeles Department of Water & Power, who worked in cooperation with the U.S. Department of Energy and the California Energy Commission. The start of continuous electric power production commenced in August 1984 and the plant is now up to its design capacity of 10 MWe. The plant, known as *Solar One*, is located in Daggett, California just off Highway 40 and east of Barstow. A panoramic view of the facility, clearly showing nearly 2000 heliostat-controlled mirrors focusing their collected energy on a boiler atop a 300-foot (91-meter) tower, is given in Fig. 16.

Although large and very impressive, *Solar One* is regarded as an experimental pilot plant for proving and testing technological improvements that can be incorporated in future commercial-size plants. The Daggett plant is a scale model of a 100 MWe generating plant. On its own, *Solar One* is currently furnishing the electricity requirements for a community of about

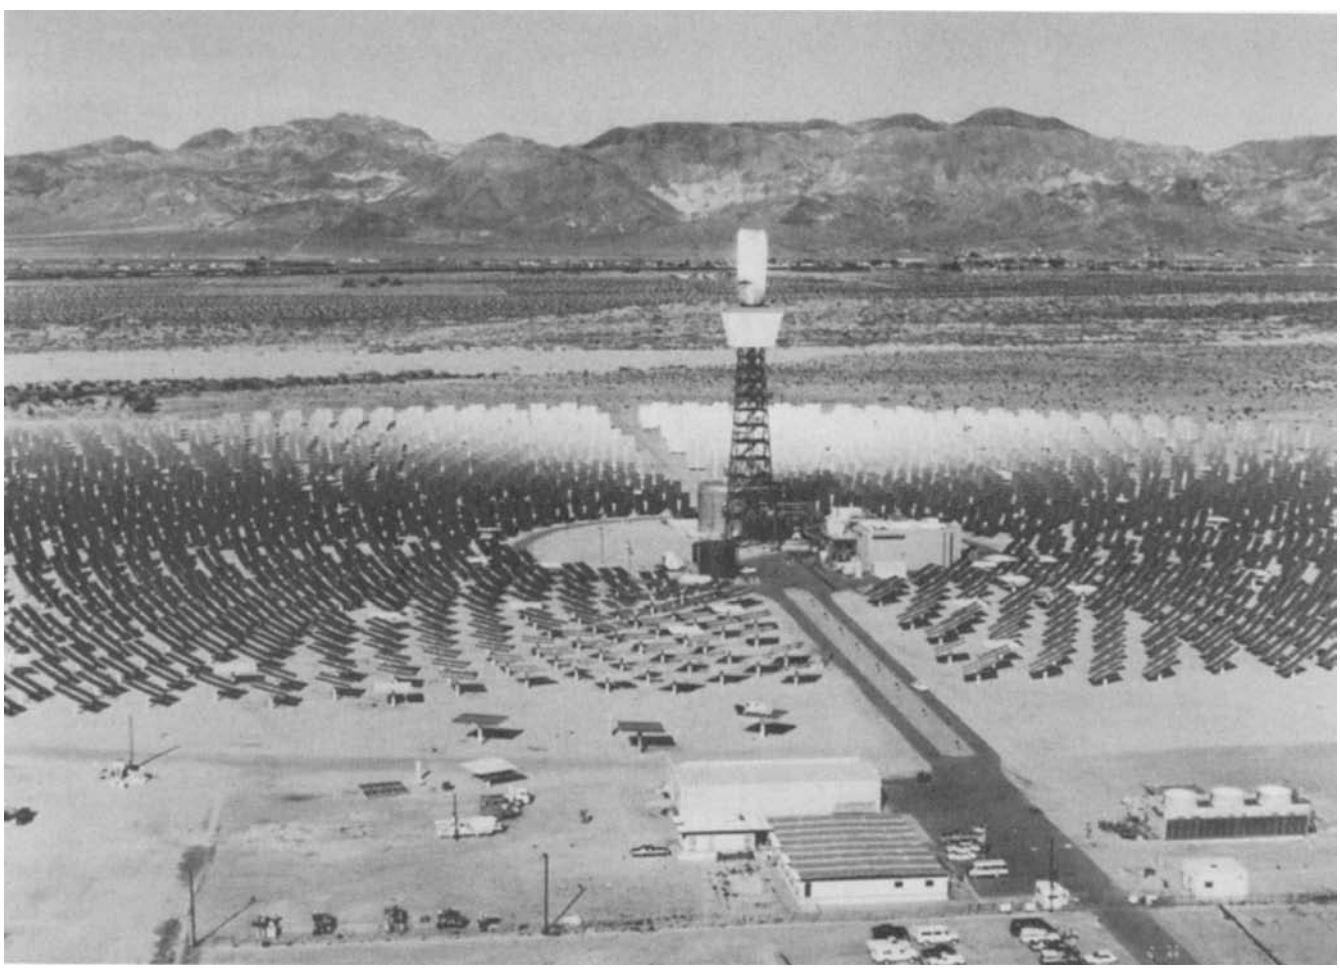

Fig. 16. Panoramic view of the world's largest solar thermal electric power plant, located on the Mojave Desert, near Daggett, California. The 10 megawatt (electric) facility commenced operation in 1982 and achieved design capacity in 1984. The collector tower (receiver upon which solar energy is reflected) is located atop a 300-foot (91-meter) tower. The north field of heliostats (mirrors kept in synchronism with the movement of the sun), 1240 in number, is shown in background; the south field (578 heliostats) is shown in foreground. Operating facilities, turbine generators, and storage tank are shown in circular middle section under the tower. The facility is operated by Southern California Edison and the Los Angeles Department of Water and Power, in conjunction with the U.S. Department of Energy and the California Energy Commission.

6000 people. *Solar One* relies on a combination of both old and new solar technology. Certain features not found in typical commercial generating plants allow great flexibility in plant operation. Several different types of solar central receiver plants can be simulated within this one project.

The Basic Concept of *Solar One*. Computer-controlled mirrors (heliostats) totaling 1818 in number form a circular array around a central tower. Within the receiver, the solar energy is transformed into high-temperature thermal energy in a water-steam heat transport fluid. The thermal energy can be converted to electric power immediately or stored to extend plant operation. See Fig. 17. The collected solar energy is most efficiently put to work as receiver steam to power a turbine-generator (Path A). If the energy is to be stored, receiver steam follows path B and heats oil that is routed to and from the thermal storage tank. Energy is discharged from storage by using hot oil from the tank (path C) to generate steam, which is then sent to the turbine along path D.

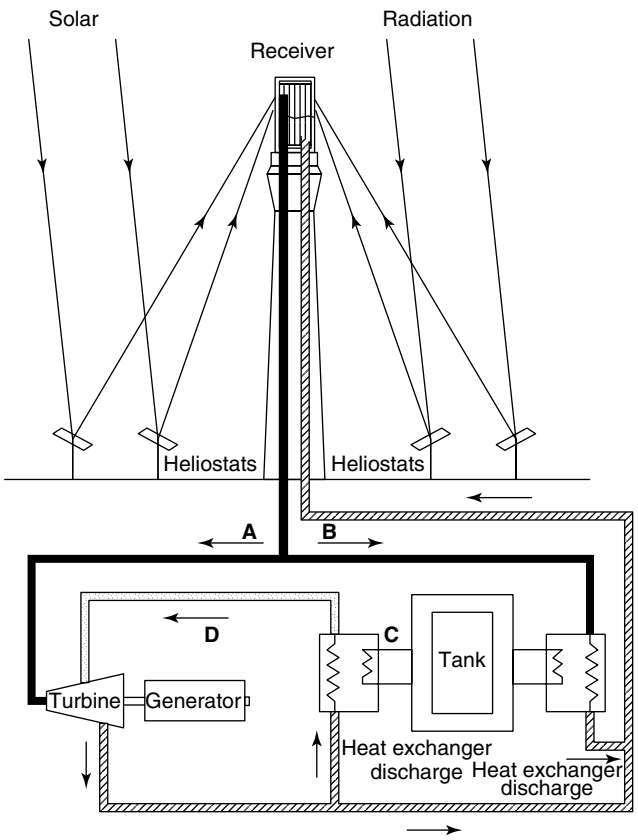

Fig. 17. General concept of *Solar One*. Within the receiver, the solar energy is transformed into high-temperature thermal energy in a water-steam heat transport fluid. The thermal energy can be converted to electric power immediately or stored to extend plant operation. The collected solar energy is most efficiently used as *receiver steam* to power a turbine-generator (Path A). If the energy is to be stored, receiver steam follows Path B and heats oil that is routed to and from the thermal storage tank (Path C) to generate steam, which is then sent to the turbine along Path D. The thermal storage system uses oil as both a thermal storage medium and as a heat-transport fluid.

The thermal storage system uses oil as both a thermal storage medium and a heat transport fluid. The maximum operating temperature of the storage system is 575 °F (300 °C). As a result, electricity is generated less efficiently than when 960 °F (515 °C) receiver-supplied steam is used directly in the turbine.

The operating temperature of the storage system simulates steam generation conditions in industrial plants and the chemical processing industry. Furthermore, because storage-supplied heat can supplement solar-supplied energy, *Solar One* can simulate a plant that uses both conventional fuels and solar energy.

Heliostats. The facility receives 3600 to 4000 hours of sunlight/year (9.8 to 10.9 hours/day). Construction of the 1818 heliostats for the pilot plant demonstrated that prototype designs can be successfully produced in volume quantities with conventional manufacturing techniques. Each heliostat has a reflective area of 430 square feet (39.3 square meters). The heliostat glass is specially formulated to contain a minimum amount of impurities. As a result, 91% of the incident sunlight can be reflected when the mirror surface is clean. A close-up of a set of mirrors (in a vertical position for demonstration purposes) is given in Fig. 18.

The vertical and horizontal movement of the heliostats is directed by a control system — a microprocessor in each heliostat, a controller to regulate groups of up to 32 heliostats, and a central computer. Over 97% of the heliostats are available more than 98% of the time. Operation of the heliostats has suggested areas for further research and development; for example, rain water may be sufficient to maintain the cleanliness of the mirrors, and mechanical rinsing may be required only in dry months.

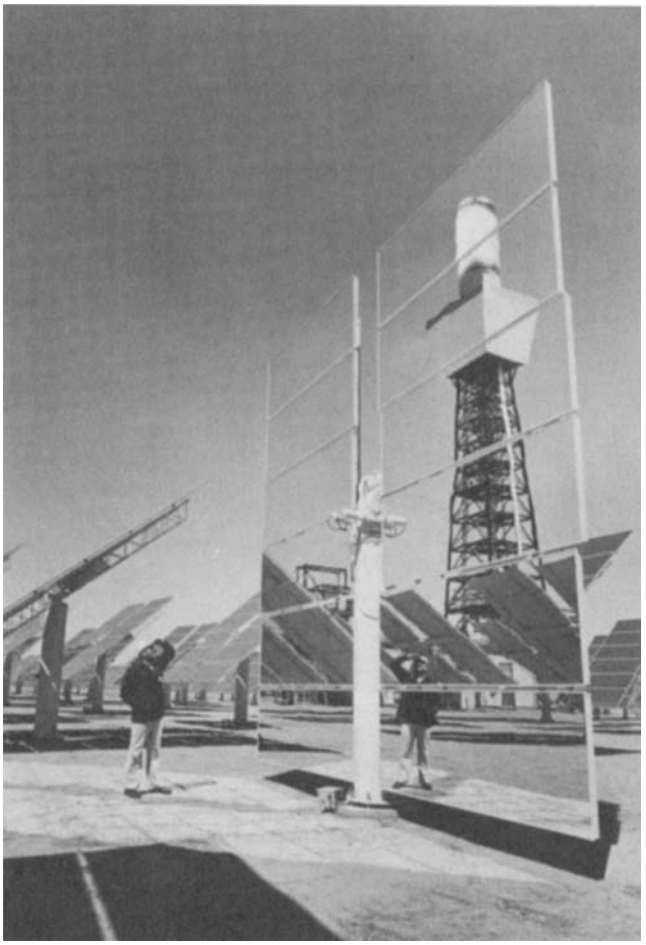

Fig. 18. Close-up of a heliostat rack assembly shown in vertical position for demonstration purposes. Note reflection of tower in mirrors. *Solar One* has a total of 1818 heliostats.

The heliostats, as shown in Fig. 19, are distributed in a south field (578) and a north field (1240). The mirrors are slightly concave (approximately 1000 foot focal length with $\frac{1}{6}$-inch curvature in a 10-foot length). The total weight of a heliostat, as previously shown in Fig. 18, is 4312 pounds (1956 kg). The heliostats are normally stowed in a vertical position except when high wind conditions exist. During daylight hours, of course, the mirrors are rotated by a drive mechanism to follow the direct solar rays as closely as possible. It is interesting to note that the sun's position is calculated rather than sensed — so that even when clouds briefly cover the sun, maximum energy is reflected.

Receiver. On top of the steel tower rests the cylindrical receiver, a superheated steam boiler that is 14 meters (46 feet) tall and 7 meters (23 feet) in diameter. The receiver weighs almost 50 tons and is positioned over 20 stories above the ground. Feedwater is pumped to the bottom of

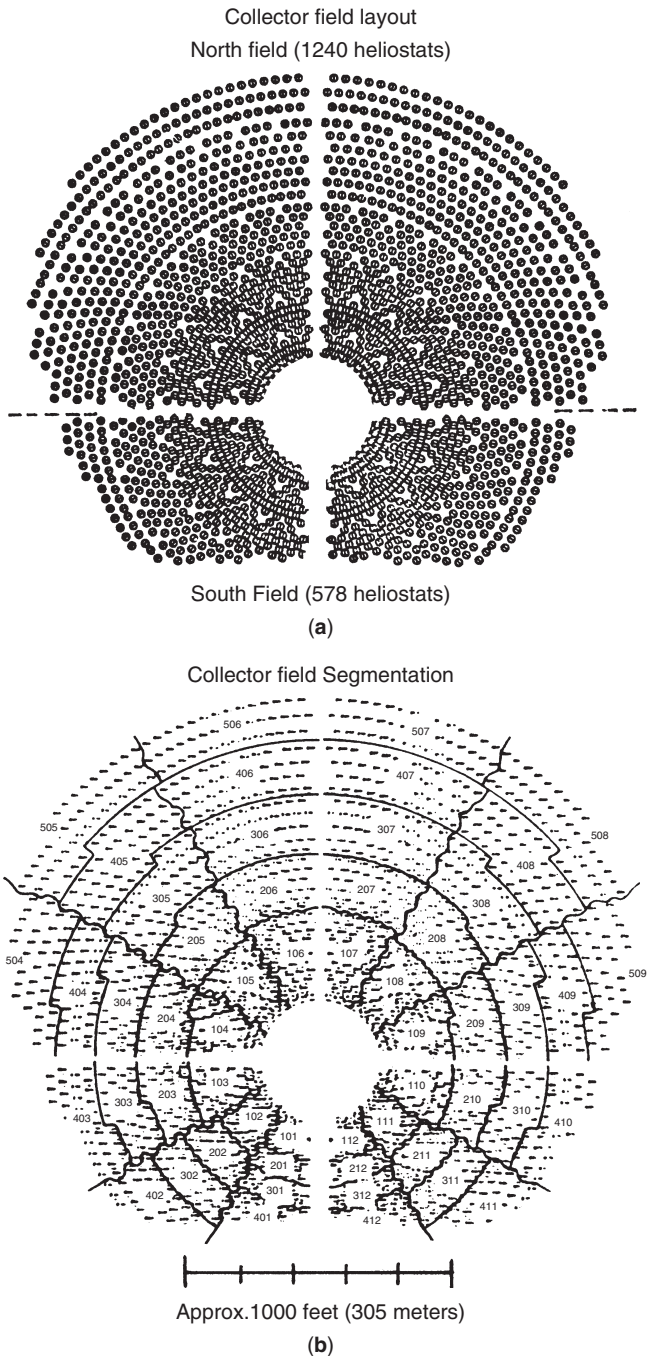

Fig. 19. (**a**) The heliostats are distributed in two fields — North and South; (**b**) for control purposes, the heliostats are segmented.

the receiver, where it is vaporized to superheated steam in a single pass to the receiver's top. The steam is then piped to the turbine-generator at the foot of the tower. This steam can also provide heat to the thermal storage system.

Thermal Storage System. On a clear day, the receiver can generate sufficient steam to simultaneously operate the turbine and also deliver heat to the storage system. The thermal storage can generate power in the evening or during periods of cloud cover. It also provides steam for start-up in the morning and for keeping selected portions of the plant warm when the plant is not operating. The steel-walled insulated storage tank has a capacity of 3.5 million liters and sits on lightweight insulating concrete. The tank is filled with sand, rocks, and a high-temperature thermal oil. Steam from the receiver is routed through heat exchangers to heat the thermal oil, which is then pumped into the tank to heat the rock and sand. This stored thermal energy can then be transferred to the turbine generator for electrical power production.

Power Generation Station. The turbine-generator is rated at 12.5 megawatts and is sized to handle the full plant system output plus all internal plantloads. The dual-admission turbine has a high-pressure steam inlet for steam produced by the receiver and a low-pressure inlet for steam produced from thermal storage. The rated turbine thermal-to-electric efficiency from receiver to steam is 35%. The efficiency is 25% from the lower quality thermal storage system.

Master Control System. In the morning the operator, through keyboard commands, positions the heliostats at standby operating points, begins water circulation in the receiver, and then issues a command to the system to start up the plant. At this point, a computer takes over and automatically directs heliostats to track the receiver. When receiver steam conditions are correct, steam is routed to the turbine. The operator then synchronizes the turbine to the electric grid, after which the minimal manual attention is needed. If conditions change, such as a cloud passing over, the control system automatically makes adjustments to keep the plant in the best operating state. If some abnormal event occurs, alarm messages tell the operator which parameters are out of normal operating range. The operator can, at any time, make changes in any plant operating condition. While the pilot plant control system was designed for controlling a water-steam central receiver solar plant, the basic functions and operating philosophy are readily adaptable to other power plants.

Performance. The requirement for production of 10 MWe was exceeded by a peak production of 12.1 MWe. Similarly, the required 7 MWe net generation from storage was exceeded by an output of 7.3 MWe. The plant also has successfully operated down to 0.5 MWe, which is considerably lower than the designed minimum operating production level of 2 MWe. The minimum sunlight threshold for operation was designed as 450 W per square meter, yet the plant has operated in direct solar radiation levels as low as 300 W per square meter. In an endurance test, the receiver and storage system kept the turbine continuously on-line for 33.6 hours and generated 127 MWe net.

Solar One was designed to have 95% of the heliostats available at any one time. Between April 1982 and April 1983, 98% of the heliostats were available for operation. This percentage later increased to 99%. The establishment of the sharp thermal gradient (thermocline) needed for the storage system has been verified. Gradients of 49 °C/meter have been measured. Equally important is the very low rate of heat loss from the storage tank. The tank heat loss has been measured at 1.3% day.

Central Receiver Test Facility

The largest facility specifically designed for testing central receiver components and subsystems was built in Albuquerque, New Mexico in the late 1970s. At this facility, a 15-meter (49-foot) diameter concrete-and-steel receiver tower rises some 60 meters (197 feet) above the ground. Within the tower, three test bays at different levels are used for experiments. A huge elevator can transport equipment weighing as much as 100 tons to these test bays. There is a total of 222 heliostats; when all of them are focused on a receiver in one of the test bays, temperatures in excess of 2000 °C (3632 °F) can be generated. In practice, lower temperatures are used for receiver testing. The test facility has been used to try out innovative receivers that use gas, liquid sodium, or molten nitrate salts for thermal transport. In one system, molten salt has been used as the heat transport fluid and storage medium in an integrated central receiver system to produce an electrical power output of 750 kWe.

Solid-Particle Central Receiver. A new type of receiver has been under investigation. A novel concept for a central receiver uses sandsize refractory particles that free-fall in a cavity receiver. A conceptual design is shown in Fig. 20. Scientists observe that the advantages of a solid particle receiver over traditional fluid in-tube receivers are: (1) the particles can directly absorb solar radiation, and (2) the particles maintain their integrity at high temperatures. These advantages, coupled with the possibility that the particles can serve as the storage medium, could provide a cost-effective means of high-temperature solar energy utilization. High temperatures are attractive for fuels and chemical production, industrial process heat applications, or Brayton cycle electricity generation. The concept is in an early experimental stage.

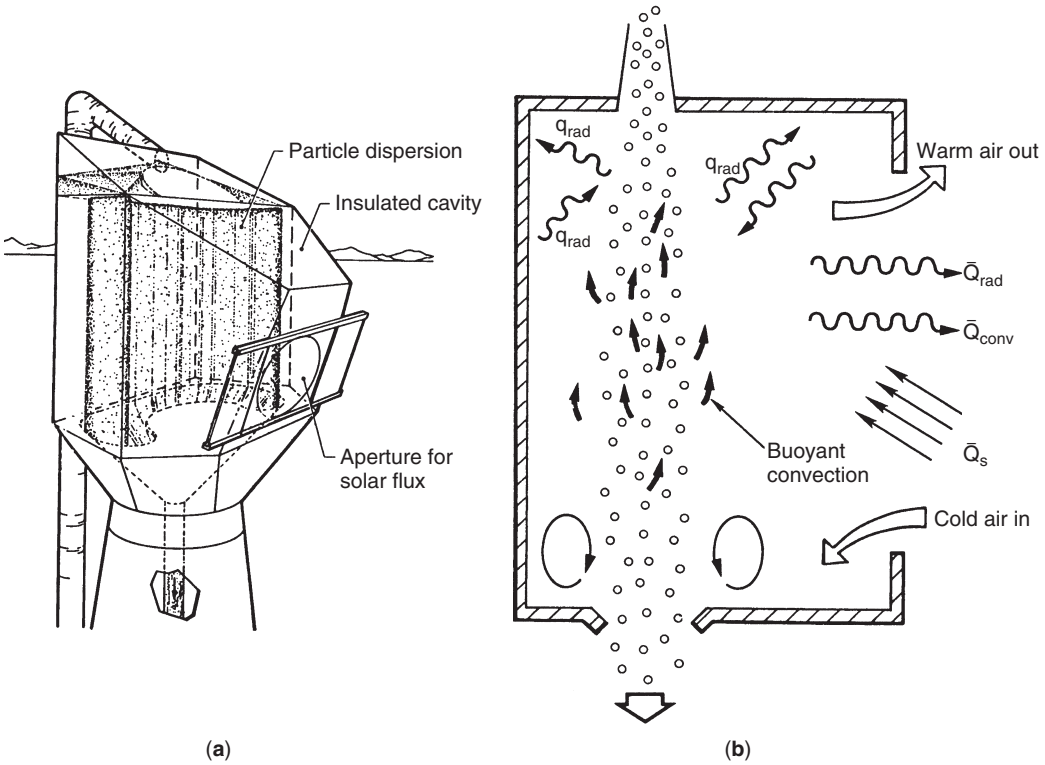

Fig. 20. Solid-particle central solar energy receiver: (**a**) conceptual design; (**b**) thermal phenomena in a solid particle receiver. (*Sandia National Laboratories*.)

Heat Engine Cycles for Solar Power

Heat engines for conversion of solar energy to electric power ideally should have the following attributes: (1) low cost per kilowatt output capacity; (2) long life and reliable operation with minimal maintenance; (3) safe and environmentally acceptable operation; (4) characteristics compatible with cycle top temperatures up to 1,000 K; and (5) efficiency approaching Carnot values.

Heat engines that are potential candidates for coupling a solar heat source include thermoelectric, thermionic, thermochemical, magnetohydrodynamic, Rankine, Brayton (simple or recuperated), and cascaded cycles.

Rankine Cycle. The steam-Rankine cycle employing steam turbines has been the mainstay of utility thermal electric power generation for many years. The cycle, as developed over the years, is sophisticated and efficient. The equipment is dependable and readily available. A typical cycle (Fig. 21) uses superheat, reheat, and regeneration. Heat exchange between flue gas and inlet air adds several percentage points to boiler efficiency in fossil-fueled plants. Modern steam Rankine systems operate at a cycle top temperature of about 800 K with efficiencies of about 40%. All characteristics of this cycle are well suited to use in solar plants.

Brayton Cycle. In recent years, attention has been drawn to the Brayton cycle as a potential and practical alternative to the steam Rankine cycle for solar power and for high-temperature gas-cooled nuclear reactors. The Brayton cycle is most familiar in its open form as used in aircraft gas turbines. The open Brayton cycle cannot compete with steam-Rankine in efficiency. In a power-generation application, cycle efficiencies on the order of 20% would be expected. However, the Brayton cycle can achieve higher efficiency through recuperation, sometimes called regeneration. A representative cycle diagram is given in Fig. 22. The working fluid is an inert gas, typically helium. Inert gas mixtures, such as helium-xenon, have been studied and have potential advantages.

The recuperated Brayton cycle approaches Carnot efficiency in the ideal limit. As compressor and turbine work are reduced, the average temperatures for heat addition and rejection approach the cycle limit temperature. The limit is reached as compressor and turbine work (and cycle pressure ratio) approach zero and fluid mass flow per unit power output approaches infinity. It can be expected from this that practical recuperated Brayton cycles would operate at relatively low pressure ratios, but be very sensitive to pressure drop. With the assumption of constant gas specific heat over the cycle temperature range, a good assumption for helium, the cycle efficiency of a recuperated Brayton cycle may be expressed:

$$\eta e = 1 - \left[\frac{\dfrac{r_{pc}\zeta - 1}{\eta_b} + \dfrac{\Delta T_r}{T_0}}{\dfrac{T_3}{T_0}\eta_T \left[1 - \left(\dfrac{G}{r_{pc}} \right)^{\zeta} \right] + \dfrac{\Delta T_r}{T_0}} \right]$$

where r_{pc} is compressor pressure ratio (>1)
η_b is compressor efficiency
ΔT_r is temperature difference across recuperator ($T_4 - T_2$ in Fig. 21)
T_0 is cycle lower limit temperature
T_3 is cycle top temperature
η_T is turbine efficiency
ζ is specific heat factor, $(\gamma - 1)/\gamma = 0.4$ for $\gamma = 1.67$ as for helium
G is the product of the four pressure drop factors,

$$\left(\frac{P_1}{P_2}\right) \quad \left(\frac{P_2}{P_3}\right) \quad \left(\frac{P_4}{P_5}\right) \quad \left(\frac{P_5}{P_0}\right)$$

Solar Energy for Industrial/Metallurgical Processes

It is interesting to note that experiments on melting large masses of metals were conducted at the French Odeillo solar furnace as early as the mid-1970s. Since the mid-1980s, solar furnaces in other locations have researched what promises to be an important technology in the near future — namely, Solar Induced Surface Transformation of Materials (SISTM). In the past, numerous heat-treating methodologies have been practiced widely. Less traditional methods have been developed in recent years, including cladding/coating, self-propagating high-temperature synthesis, thin-film deposition, and ion-, laser-, and electron-beam processes.

Researchers have found that, for delivering large fluxes on target, the solar furnace is less capital intensive than competing methods that require an intermediate energy-conversion step. For example, a 1-square-meter

(11 ft^2) solar dish can deliver about 1 kW of optical power to a target. To deliver the same amount of radiant energy, an arc lamp would have to be powered by the electrical output of an 11-square-meter (120 ft^2) dish, and a carbon dioxide laser would require the energy supplied by 26-square-meter (280 ft^2) disk.

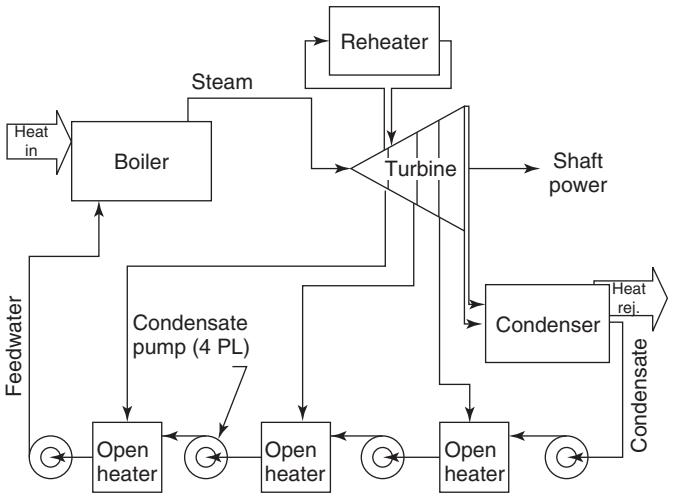

Fig. 21. Schematic diagram of regenerative-reheat steam Rankine cycle.

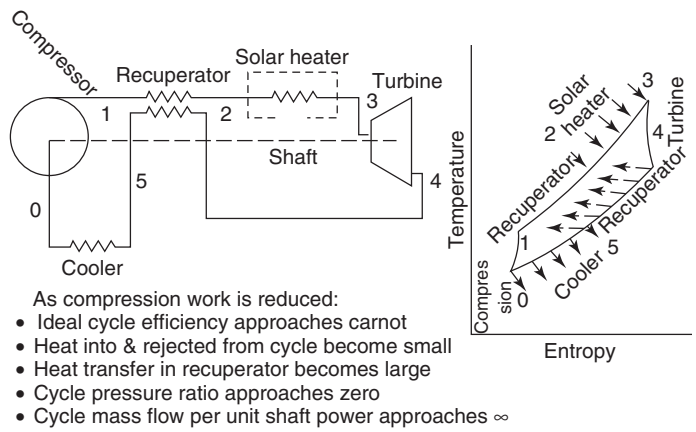

Fig. 22. Recuperated Brayton cycle diagram.

The automotive industry, which turned to laser transformation hardening of engine and other drivetrain components, is now seriously investigating the "solar hardening" process.

Solar Furnaces No Longer Uncommon. The past decade has brought increased interest in using solar energy for industrial processes, not just to conserve energy or avoid the use of fossil fuels. Some of the important installations, as of the early 1990s, are listed in Table 1.

The time required to bring a part to treating temperature also is an important consideration. Solar furnaces have no competition on this point. See Table 2.

Chemicals Directly from Solar Energy. Whereas the early solar furnace located in Odeillo, France, was constructed for solar energy studies in general and later used for melting huge masses of metals and materials and the solar plant in the Mojave Desert in California is being used directly to generate electric power, scientists in the early 1990s were taking a somewhat different approach.

Researchers have recognized that the regions where ample sunshine is available for harvesting seldom coincide with the population and industrial centers of the world. Further, solar energy is of an intermittent nature because it depends upon clear skies with no cloud cover. I. Dostrovsky (Weizmann Institute of Science) observes that most of the limited amount of research on solar energy focuses on converting sunlight to electricity, mainly by photovoltaic and thermal methods, or, in the case of the Daggett, California, utility installation, to furnish heat to supply steam turbines.

An alternative approach is that of using solar energy to produce chemicals that can be stored and transported much as present fossil fuels. One installation along these lines is now undergoing demonstration operation in Saudi Arabia. This project, known as *HYSOLAR*, is a joint venture of Saudi Arabia and Germany. In essence, the facility consists of a plant that produces hydrogen. See also **Hydrogen (Fuel)**.

One process involves the high-temperature decomposition of sulfuric acid, using recoverable iodine as an intermediate reactant. In a first stage,

TABLE 1. COMPARISON OF HIGH-FLUX SOLAR FACILITIES

Location	Total Power kW	Peak Flux MW/m^2
Albuquerque, New Mexico		
Central receiver test facility	5000	2.4

sulfuric acid yields water and sulfur dioxide. In a second stage, the sulfur dioxide plus water and iodine yield hydrogen iodide and sulfuric acid. In the third stage, the hydrogen iodide yields hydrogen (the desired product) and recoverable iodine.

In an electrolytic process, hydrogen is produced by electrolyzing a mixture of sulfur dioxide and water to produce sulfuric acid and hydrogen. In still another electrolytic process, bromine, sulfur dioxide, and water react to form hydrogen bromide and sulfuric acid. By applying 0.62 V to the hydrogen bromide molecules, hydrogen is yielded and the original bromine is recovered.

This type of approach is somewhat reminiscent of the chemistry of coal gasification. More detail is given in the Dostrovsky reference listed.

Solar Energy for Detoxifying Hazardous Chemicals. The Solar Energy Research Institute, Golden, Colorado, has developed a system for detoxifying hazardous chemicals in polluted groundwater. In essence, a photocatalyst is added to the polluted water and then pumped through long, narrow glass tubes that are exposed to sunlight. High- energy photons activate the catalyst, which in turn breaks the pollutants down into nontoxic components. The tubes are mounted in reflecting glass troughs to improve the efficiency of the process. The system has proved particularly effective against trichloroethylene, once a common industrial cleaner. In this application, the polluted water is mixed with titanium dioxide catalyst. Hydroxyl radicals are created that break the offending solvent into water, carbon dioxide, and very dilute hydrochloric acid. The next step is that of determining how effective the process may be in removing other chlorinated hydrocarbons, as well as such substances as benzene, various pesticides, and textile dyes.

Photovoltaic Conversion (Solar Cells)

Photovoltaic devices made of selenium have been known since the 19th Century. Pioneering research in semiconductors, which led to the invention of the transistor in 1947, formed the basis of the modern theory of photovoltaic performance. From this research, the silicon solar cell was the first known photovoltaic device that could convert a sufficient amount of the sun's energy to power complex electronic circuits. The conventional silicon cell is a solid-state device in which a junction is formed between single crystals of silicon separately doped with impurity atoms in order to create *n* (negative) regions and *p* (positive) regions which respectively are receptors to electrons and to "holes" (absence of electrons). The first solar cell to be demonstrated occurred at Bell Laboratories (now AT&T Bell Laboratories) in Murray Hill, New Jersey in 1954.

In a photovoltaic device, the energy in light is transferred to electrons in the semiconductor when a photon collides with an atom in the material with enough energy to dislodge an electron from a fixed position in the material. A common technique for producing a voltage is by creating an abrupt discontinuity in the conductivity of the cell material (typically silicon) through the addition of dopants. A basic limit on the performance of these devices stems from the fact that light photons lacking the energy needed to lift electrons from the valence to the conduction bands ("band gap" energy) cannot contribute to photovoltaic current, and from the fact that the energy given to electrons which exceeds the minimum excitation threshold cannot be recovered as useful electric current. Most of the photon energy not recovered as electricity is converted to thermal energy in the cell.

Photon energies in the visible light spectrum vary from 1.8 eV (deep red) to 3 eV (violet). In silicon, about 1.1 eV is needed to produce a photovoltaic electron; in gallium arsenide (GaAs), this is about 1.4 eV. Silicon is a comparatively poor absorber of light and consequently silicon cells must be from 100 to 200 micrometers thick to capture an acceptable fraction of the incident light. This places limitations on crystal grain size and thus, with present technology, single crystals must be used. Polycrystalline materials may alter this problem favorably and much research is being directed toward developing polycrystalline materials and, in general, for finding methods to minimize the impact of grain boundaries.

Thin films of gallium arsenide (GaAs) and cadmium sulfide/copper sulfide (CdS/Cu_2S) show potential because they are better absorbers of light and can be made thinner than crystalline silicon. Smaller crystal grains can be tolerated better than with crystalline silicon. See also **Thin Films**. These can be spray- or vapor-deposited, thus simplifying manufacturing. One possible drawback of the CdS and GaAs materials is their toxicity, particularly hazardous during manufacturing operations.

Where solar cells are used in *concentrated* sunlight, efficiency becomes of particular importance because of its effect upon total collector area needed, this being a major cost component of a solar energy system. A number of ingenious collector configurations have been developed. Further, there is the concept of the *thermophotovoltaic cell*, which may be able to achieve efficiencies as high as 30–50% through shifting the spectrum of light reaching the cell to a range where most of the photons are close to the minimum excitation threshold for silicon cells. High efficiencies in intense radiation can be achieved, for example, with GaAs cells by covering them with a layer of $Ga_xA1_{1-x}As$, a material that reduces surface and contact losses. Clearly the interface between cell and solar radiation is of as great importance as development of new cell materials per se.

So-called *wet solar cells* show promise, particularly because of their relative ease of fabrication. In this type of photovoltaic cell, the junction is formed between a semiconductor and a liquid electrolyte. No doping is required because a junction forms spontaneously when a suitable semiconductor, such as GaAs, is contacted with a suitable electrolyte. Three knotty problems (accelerated oxidation of surface of semiconductor; exchange of ions between semiconductor and electrolyte forming a blocking layer; and deposition of ions of impurities on the surface of the semiconductor) all have been solved and thus the concept now appears technically viable.

Over a number of years, the photovoltaic cell developers received large financial incentives from the U.S. government. For example, the National Photovoltaics Act of 1978 was passed by the U.S. Congress, which authorized an expenditure of $1.5 billion for research, development, and demonstration of solar cell systems for converting sunlight into electric power. Also, in connection with the Federal Non-Nuclear Energy Research and Development Act of 1974, which established the concept of "net energy" — that is, the effect of new devices and systems on the overall energy balance. Projects were evaluated on the basis of their "potential for production of net energy." Although there have been some breakthroughs of particular significance to scientists and a gradually expanding market for photovoltaics in addition to use in space, particularly in various consumer products, the long awaited and ultimate application (generation of electric power in impressive amounts at competitive prices) has remained elusive. Scores of analyses have been made and forecasts range from very pessimistic to quite optimistic. The era of practically achieving this goal on the part of the photovoltaic cell community tends to be progressively shifted outward into the future. Forecasts usually are based upon numerous assumptions that are subject to periodic change and their reporting is best left to the periodicals and thus are not detailed here.

It is in order, however, to sum up the observations of the Electric Power Research Institute (EPRI): Photovoltaics need significant additional research to reduce cost and increase efficiency of the cells as well as their support systems (tracking and D.C.-to-A.C. power conversion) before they can be competitive with conventional electricity supply technologies. Current manufacturing costs for flat-panel arrays of interconnected, encapsulated cells are approximately $5000 per peak kW, and balance-of-plant costs double the effective system cost to $10,000 per peak kW. This compares roughly with $300 per kW for combustion turbines; $1400/kW for pulverized coal plants; and $2500/kW for nuclear plants. Two classes of photovoltaic converters that appear to show the most promise for producing large amounts of power are (1) the inexpensive, flat-plate, thin-film devices with target prices of less than $1500 per peak kW and efficiencies of 15%, compared with their current costs of $5000 per peak kW and efficiencies of about 10%; and (2) very high-efficiency, high-concentration devices with target prices less than $1500 per peak kW and efficiencies of 25%, compared with their current costs of $7000 per peak kW and efficiencies to utilities (largely subsidized or experimental programs).

Some authorities estimate that photovoltaic utility capacity could range from 0.6 to 16 GW by the year 2010, provided that needed technical performance is achieved. See also **Photovoltaic Cells**.

Satellite Energy Collectors

Having proven their value in connection with relatively small space satellites, probes, etc., a huge satellite energy collector was first proposed in the late 1960s and, largely on the basis of national concerns with

energy supplies precipitated by the oil embargo of the 1970s, considerable attention was given at the design level and in the literature to a solar power satellite (SPS). One proposal called for a space-based array requiring about 90 square kilometers (55 square miles)! That is about the size of Manhattan Island. The satellite would be in a geosynchronous orbit some 36,000 kilometers (22,000 miles) above Earth. Because nearly all authorities now consider such a project very "futuristic," no further details are reported here.

NOTE: To construct a perspective on the energy situation for the 1990s, some readers may wish to refer to the following articles in this encyclopedia: **Energy; Coal; Coal Conversion Processes; Electric Power Production and Distribution; Fuel Cells; Geothermal Energy; Hydroelectric Power; Hydrogen (Fuel); Natural Gas; Nuclear Power; Petroleum; Semiconductors; Tar Sands**; and **Tidal Energy**. SOLAR FLARES. A solar flare occurs when magnetic energy that has built up in the solar atmospheres is suddenly released. Radiation is emitted across virtually the entire electromagnetic spectrum, from radio waves at the long wavelength end, through optical emission to X-rays and gamma rays at the short wavelength end. Solar flares are tremendous explosions on the surface of the Sun. In a matter of just a few minutes they heat material to many millions of degrees and release as much energy as a billion megatons of TNT. They occur near sunspots, usually along the dividing line (neutral line) between areas of oppositely directed magnetic fields. The first solar flare recorded in astronomical literature was on September 1, 1859. Two scientists, Richard C. Carrington and Richard Hodgson, were independently observing sunspots at the time, when they viewed a large flare in white light.

Flares are characterized by their brightness in X-rays (X-Ray flux). The biggest flares are X-Class flares. M-Class flares have a tenth the energy and C-Class flares have a tenth of the X-ray flux seen in M-Class flares. The National Oceanic and Atmospheric Administration (NOAA) monitors the X-Ray flux from the Sun with detectors on some of its satellites. See also **Geostationary Operational Environmental Satellite (GOES)**.

As the magnetic energy is being released, particles, including electrons, protons, and heavy nuclei, are heated and accelerated in the solar atmosphere. The energy released during a flare is typically on the order of 10^{27} ergs[1] per second. Large flares can emit up to 10^{32} ergs of energy. This energy is ten million times greater than the energy released from a volcanic explosion. On the other hand, it is less than one-tenth of the total energy emitted by the Sun every second.

There are typically three stages to a solar flare. First is the *precursor* stage, where the release of magnetic energy is triggered. Soft x-ray emission is detected in this stage. In the second or *impulsive* stage, protons and electrons are accelerated to energies exceeding 1 MeV[2]. During the impulsive stage, radio waves, hard x-rays, and gamma rays are emitted. The gradual build up and decay of soft x-rays can be detected in the third, *decay* stage. The duration of these stages can be as short as a few seconds or as long as an hour.

Solar flares extend out to the layer of the Sun called the corona. The corona is the outermost atmosphere of the Sun, consisting of highly rarefied gas. This gas normally has a temperature of a few million degrees Kelvin. Inside a flare, the temperature typically reaches 10 or 20 million degrees Kelvin, and can be as high as 100 million degrees Kelvin. The corona is visible in soft x-rays, as in the above image. Notice that the corona is not uniformly bright, but is concentrated around the solar equator in loop-shaped features. These bright loops are located within and connect areas of strong magnetic field called *active regions*. Sunspots are located within these active regions. Solar flares occur in active regions.

The frequency of flares coincides with the Sun's eleven year cycle. When the solar cycle is at a minimum, active regions are small and rare and few solar flares are detected. These increase in number as the Sun approaches the maximum part of its cycle. The Sun will reach its next maximum in the year 2000 or 2001.

A person cannot view a solar flare by simply staring at the Sun. (NEVER LOOK DIRECTLY AT THE SUN! EYE DAMAGE CAN RESULT.) Flares are in fact difficult to see against the bright emission from the photosphere. Instead, specialized scientific instruments are used to detect the radiation signatures emitted during a flare. The radio and optical emissions from flares can be observed with telescopes on the Earth. Energetic emissions such as x-rays and gamma rays require telescopes located in space, since these emissions do not penetrate the Earth's atmosphere.

SOLAR PARALLAX. The angle subtended by the equatorial radius of the earth at the distance of the sun is called the solar parallax. It is related

[1] A cgs unit of energy equal to work done by a force of 1 dyne acting over a distance of 1 cm. 10^7 (ten million) erg s^{-1} (ergs per second) = 1 watt. Also, 1 Calorie = 4.2×10^{10} (42 billion) ergs.

[2] One million electron volts.

directly to the astronomical unit which scales the solar system and is the baseline for the determination of stellar parallax.

One method for obtaining the solar parallax is to determine accurately the distance between the earth and another planet. Since their orbits are extremely well observed (on unit scale), knowing the separation at any given moment allows one to place an absolute value to the scale. The minor planet Eros has been used because of its close approach to Earth of only 26,000,000 kilometers and its point-like appearance on the photographic plate. Such observations have yielded a value for the solar parallax of

$$\pi = 8''.7984 \pm 0.0004$$

Radar observations of Venus accomplish the same purpose and yield a value for the astronomical unit of

$$\text{A.U.} = 149{,}598{,}640 \pm 250 \text{ kilometers}$$

which results in a solar parallax of

$$\pi = 8''.79414 \pm 0''.00002$$

and a lunar parallactic term in longitude of

$$P = 124''.987 \pm 0''.001$$

The radar observations are believed to be the better values by an order of magnitude. It is interesting to note that the results from lunar occultations lead to the value of

$$\pi = 8''.793 \pm 0''.003$$

$$P = 124''.97 \pm 0''.04$$

SOLAR TIME. Time based upon the rotation of the Earth relative to the Sun. Solar time may be designated as mean or astronomical if the mean Sun is the reference, or apparent if the apparent Sun is the reference. The difference between mean and apparent time is called equation of time. Solar time may be further designated according to the reference meridian, either the local or Greenwich meridian or additionally in the case of mean time, a designated zone meridian. Standard or daylight-saving are variations of zone time. Time may also be designated according to the timepiece, as chronometer time or watch time, the time indicated by these instruments. See also **Time**.

SOLAR WIND. A solar wind is a stream of charged particles (i.e., plasma) which are ejected into interplanetary space from the sun's corona. When originating from stars other than the Earth's Sun, it is sometimes called a stellar wind. The solar wind is present continuously in interplanetary space. After escaping from the gravitational field of the sun, this gas flows outward at a typical speed of 400 km per second (249 miles per second) to distances known to be beyond the orbit of Pluto. Besides affecting Earth's weather, solar activity gives rise to a dramatic visual phenomenon in our atmosphere. The streams of charged particles from the Sun interact with the Earth's magnetic field like a generator to create current systems with electric potentials of as much as 100,000 volts. Charged electrons are energized by this process, sent along the magnetic field lines towards Earth's upper atmosphere, excite the gases present in the upper atmosphere and cause them to emit light which we call the auroras. The auroras are the northern (aurora borealis) and southern (aurora Australis) lights. Many phenomena can be explained by the solar wind, including: geomagnetic storms that knock out power grids on Earth, auroras, why the tail of a comet always points away from the Sun, and the formation of distant stars.

While early models of the solar wind used primarily thermal energy to accelerate the material, by the 1960s it was clear that thermal acceleration alone cannot account for the high speed solar wind. Some additional acceleration mechanism is required, but is not currently known.

History

In 1913, Norwegian researcher Birkeland may have been the first to predict that plasma was ubiquitous in space. He wrote: "It seems to be a natural consequence of our points of view to assume that the whole of space is filled with electrons and flying electric ions of all kinds. We have assumed that each stellar system in evolutions throws off electric corpuscles into space. It does not seem unreasonable therefore to think that the greater part of the material masses in the universe is found, not in the solar systems or nebulae, but in "empty" space. In 1916, Birkeland was probably the first person to successful predict that the solar wind behaves as do all charged particles in an electric field, "From a physical point of view it is most probable that solar rays are neither exclusively negative nor positive rays, but of both kinds"; in other words, the Solar Wind consists of both negative electrons and positive ions.

In 1919, Lindemann was one of the first people to suggest that in the Solar Wind particles of both polarities, protons as well as electrons, come from the Sun. He was probably not aware that Kristian Birkeland had made the same prediction three years earlier in 1916.

Around the 1930s, scientists had determined that the temperature of the solar corona must be a million degrees Celsius because of the way it stood out into space (as seen during total eclipses). Some very clever spectroscopic detective work confirmed this extraordinary temperature. In the mid-1950s the British astronomer and geophysicist Sydney Chapman calculated the properties of a gas at such a temperature and determined it was such a superb conductor of heat that it must extend way out into space, beyond the orbit of Earth. Also in the 1950s, a German astronomer named Ludwig Franz Benedict Biermann became interested in the fact that no matter whether a comet is headed towards or away from the Sun, its tail always points away from the Sun. Biermann postulated that this happens because the Sun emits a steady stream of particles that pushes the comet's tail away. He made important contributions to astrophysics and plasma physics, and predicted the existence of the solar wind.

Eugene Parker a solar astrophysicist who received his BS degree in physics from Michigan State University in 1948 and Ph.D., from Caltech in 1951, realised that the heat flowing from the Sun in Chapman's model and the comet tail blowing away from the Sun in Biermann's hypothesis had to be the result of the same phenomenon. Parker showed that even though the Sun's corona is strongly attracted by solar gravity, it is such a good conductor of heat that it is still very hot at large distances. Since gravity weakens as distance from the Sun increases, the outer coronal atmosphere escapes into interstellar space. Furthermore, Parker was the first person to notice that the weakening effect of the gravity has the same effect on hydrodynamic flow as a de Laval nozzle: it incites a transition from subsonic to supersonic flow. He is most famous for developing, in the mid 1950s, the theory of the supersonic solar wind, and for predicting the Parker spiral shape of the solar magnetic field in the outer solar system. In 1987, Parker proposed that the solar corona might be heated by myriad tiny "micro-flares", miniature solar flares that occur all over the surface of the Sun.

In January 1959, the first ever direct observations and measurements of strength of the solar wind were made by the Soviet satellite Luna 1.

On October 6, 1990 the Ulysses spacecraft a joint mission of the United States National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA) was launched http://helio.estec.esa.nl/ulysses/. The Ulysses scientific investigations encompass studies of the heliospheric magnetic field, heliospheric radio and plasma waves, the solar wind plasma including its minor heavy ion constituents, solar and interplanetary energetic particles, galactic cosmic rays and the anomalous cosmic ray component. Other investigations are directed towards studies of cosmic dust and interstellar neutral gas, as well as solar x-rays and cosmic gamma-ray bursts. Radio science experiments to probe the solar corona and to conduct a search for gravitational waves have also been carried out. See also ***Ulysses*** **Mission**.

In the late 1990s the Ultraviolet Coronal Spectrometer (UVCS) instrument on board the SOHO spacecraft http://sohowww.nascom.nasa.gov/,

observed the acceleration region of the fast solar wind emanating from the poles of the Sun, and found that the wind accelerates much faster than can be accounted for by thermodynamic expansion alone. Parker's model predicted that the wind should make the transition to supersonic flow at an altitude of about 4 solar radii from the photosphere; but the transition (or "sonic point") now appears to be much lower, perhaps only 1 solar radius above the photosphere, suggesting that some additional mechanism accelerates the solar wind away from the Sun.

Properties

In the solar system, the composition of the solar wind is identical to the Sun's corona: 73% ionized hydrogen and 25% ionized helium with the remainder as trace impurities. These components are present as a plasma, consisting of about 95% singly ionized hydrogen, 4% doubly ionized helium, and less than 0.5% other ions (often called minor ions). The exact composition has been difficult to measure due to large fluctuations. A sample return mission, Genesis http://genesismission.jpl.nasa.gov/, returned to Earth in 2004 and is undergoing analysis, but it was damaged by crash-landing when its parachute failed to deploy on re-entry to Earth's atmosphere, possibly contaminating the solar samples.

Near Earth, the velocity of the solar wind varies from 200 to 889 km/s (124 to 552 mi/s). The average is 450 km/s (280 mi/s). Approximately 1×10^9 kg/s of material is lost by the Sun as ejected solar wind, about one-fifth that lost due to fusion, which is equivalent to about 4.5 Tg (4.5×10^9 kg) of mass converted to energy every second. The total mass loss is equivalent to a lump of Earth-density rock about 125 m (410 ft) across every second, and at that rate the Sun would last for 10 million million (1×10^{13}) years. However, our current understanding of star formation implies that the Sun's solar wind may have been about 1000 times more massive in the distant past, which would seriously affect the history of planetary atmospheres and that of the Martian atmosphere in particular.

Since the solar wind is a plasma, it has the characteristics of a plasma, rather than a simple gas. For example, it is highly electrically conductive so that magnetic field lines from the Sun are carried along with the wind. The dynamic pressure of the wind dominates over the magnetic pressure through most of the solar system (or heliosphere), so that the magnetic field is pulled into an Archimedean spiral pattern (the Parker spiral) by the combination of the outward motion and the Sun's rotation. Depending on the hemisphere and phase of the solar cycle, the magnetic field spirals inward or outward; the magnetic field follows the same shape of spiral in the northern and southern parts of the heliosphere, but with opposite field direction. These two magnetic domains are separated by a two current sheet (an electric current that is confined to a curved plane). This heliospheric current sheet Fig. 1, has a similar shape to a twirled ballerina skirt, and changes in shape through the solar cycle as the Sun's magnetic field reverses about every 11 years.

The plasma in the interplanetary medium is also responsible for the strength of the Sun's magnetic field at the orbit of the Earth being over 100 times greater than originally anticipated. If space were a vacuum, then the Sun's 10^{-4} tesla magnetic dipole field would reduce with the cube of the distance to about 10^{-11} tesla. But satellite observations show that it is about 100 times greater at around 10^{-9} tesla. Magnetohydrodynamic (MHD) theory predicts that the motion of a conducting fluid (e.g. the interplanetary medium) in a magnetic field, induces electric currents which in turn generates magnetic fields, and in this respect it behaves like a MHD dynamo. See also **Interplanetary Medium**.

Solar Wind Event Categories

Changes in solar wind characteristics, so called **solar wind events**, can be categorized in several groups.

The categories used in this catalog are:

- BzN = Strong northward Bz for extended period
- BzS = Strong southward Bz for extended period
- EyC = Change in Ey = VxBz
- HSS = Very high speed stream for extended period
- IMC = Interplanetary magnetic cloud
- IR = Interaction Region

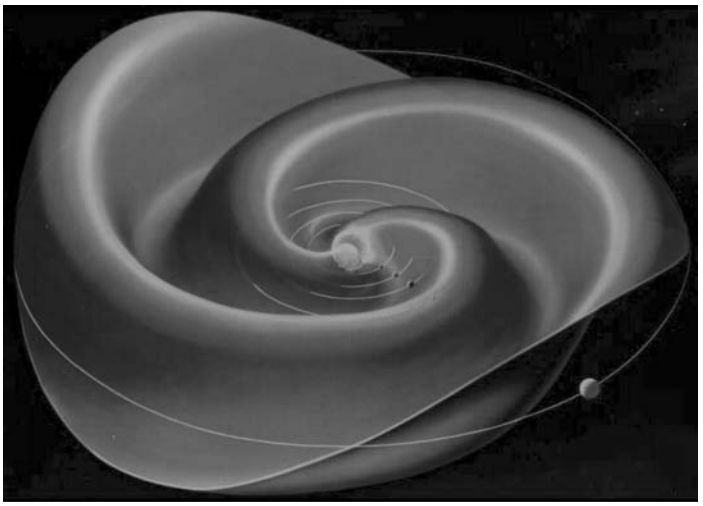

Fig. 1. Heliospheric current sheet, the largest structure in the Solar System, resulting from the influence of the Sun's rotating magnetic field on the plasma in the interplanetary medium (Solar Wind). The wavy spiral shape has been likened to a ballerina's skirt. (*Image courtesy of NASA artist Werner Heil*).

- IS = Interplanetary shock
- LSS = Very low speed stream for extended period
- MISC = Miscelaneous, which may include a very broad range of features
- PC = Pressure change
- SBC = Interplanetary sector boundary crossings (usually in a set)

Variability and Space Weather

The solar wind is responsible for the overall shape of Earth's magnetosphere, and fluctuations in its speed, density, direction, and entrained magnetic field strongly affect Earth's local space environment. For example, the levels of ionizing radiation and radio interference can vary by factors of hundreds to thousands; and the shape and location of the geopause (Earth's bow shock wave in the solar wind) can change by several Earth radii, exposing geosynchronous satellites to the direct solar wind. These phenomena are collectively called space weather. See also **Bow Shock**; and **Space Weather**.

Both the fast and slow solar wind can be interrupted by large, fast-moving bursts of plasma called interplanetary coronal mass ejections, or ICMEs. ICMEs are the interplanetary manifestation of solar coronal mass ejections, which are caused by release of magnetic energy at the Sun. ICMEs are often called "solar storms" or "space storms" in the popular media. They are sometimes, but not always, associated with solar flares, which are another manifestation of magnetic energy release at the Sun. ICMEs cause shock waves in the thin plasma of the heliosphere, launching electromagnetic waves and accelerating particles (mostly protons and electrons) to form showers of ionizing radiation) that precede the ICME.

When an ICME impacts the Earth's magnetosphere, it temporarily deforms the Earth's magnetic field, changing the direction of compass needles and inducing large electrical ground currents in Earth itself; this is called a geomagnetic storm and it is a global phenomenon. ICME impacts can induce magnetic reconnection in Earth's magnetotail (the midnight side of the magnetosphere); this launches protons and electrons downward toward Earth's atmosphere, where they form the aurora.

ICMES are not the only cause of space weather. Different patches on the Sun are known to give rise to slightly different speeds and densities of wind depending on local conditions. In isolation, each of these different wind streams would form a spiral with a slightly different angle, with fast-moving streams moving out more directly and slow-moving streams wrapping more around the Sun. Faster-moving streams tend to overtake slower streams that originate westward of them on the Sun, forming turbulent corotating interaction regions that give rise to wave motions and accelerated particles, and that affect Earth's magnetosphere in the same way as, but more gently than, ICMEs.

SOLENOIDAL. Applied to vector field having zero divergence, hence, one that may be expressed as the curl of another vector:

$$\mathbf{a} = \nabla \times \mathbf{b}$$

where **a** is the solenoidal vector and **b** is a vector field (sometimes called the vector potential of **a**), which can be determined from the differential equation. An equivalent definition of a solenoidal vector is one of which the integral over every reducible surface in its field is zero.

See also **Divergence (Mathematics)**.

SOLENOID (Electrical). An electrically energized coil that may consist of one or more layers of windings. It is the basis of all forms of the electromagnet and is thus part of the operating mechanism of many electrically operated devices. One of the simplest forms and at the same time a widely used one is the plunger type solenoid. This is a coil wound on a non-magnetic form in which a magnetic plunger may move. Energizing the coil pulls the plunger up into the coil and thus operates the associated mechanism. The iron-clad solenoid is similar except for an iron case surrounding the coil. This increases the magnetic pull on the plunger. Other types use a fixed core and various types of external armatures. Solenoids are widely used for operating circuit breakers, track switches, valves, and many other electromechanical devices.

SOLFATARA. A type of fumarole (volcanic), the gases of which are characteristically sulfurous. The *solfateric stage* is a late or decadent type of volcanic activity, characterized by sulfurous gases emitted from the vent. Also may refer to Etymol, the Solfatara volcano in Italy.

SOLID. Matter in its most highly concentrated form, i.e., the atoms or molecules are much more closely packed than in gases or liquids and thus more resistant to deformation. The normal condition of the solid state is crystalline structure — the orderly arrangement of the constituent atoms of a substance in a frame work called a lattice. See also **Crystal**. Crystals are of many types and normally have defects and impurities that profoundly affect their applications, as in semiconductors. The geometric structure of solids is determined by X-rays that are reflected at characteristic angles from the crystalline lattices, which act as diffraction gratings.

Some materials that are physically rigid, such as glass, are regarded as highly viscous liquids because they lack crystalline structure. All solids can be melted (i.e., the attractive forces acting between the crystals are disrupted) by heat and are thus converted to liquids. For ice, this occurs at 0 °C (32 °F); for some metals the melting point may be as high as 3300C. Some solids convert by sublimation directly to a gas.

SOLID ANGLE. Consider a small cone with a base of area dS and a vertex at a fixed point P. This cone will cut out an area $d\sigma$ on a sphere of radius r with center at P. The solid angle subtended by dS at P is defined as $d\omega = d\sigma/r^2$. It is numerically equal to the area cut out by the same cone on a sphere of unit radius at the same point P. The unit used for measuring a solid angle is the steradian.

See also **Angle (Mathematics)**.

SOLID (Geometry). A solid is a limited portion of space, bounded by a surface. A distinction should be made between the surface and the solid, thus a conical surface and a cone are not identical. A surface of revolution is a solid generated by the revolution of a plane area about a line, the axis of revolution. The study of solid properties is the main concern of solid geometry.

Among the figures considered are: anchor ring, cone, cylinder, ellipsoid, hyperboloid, paraboloid, parallelepiped, polyhedron, prism, prismatoid, pyramid, sphere.

See also **Conic Section**; and **Geometry**.

SOLID ROCKETS. See **Rocket Propellants**.

SOLID-STATE CHEMISTRY. Study of the exact arrangement of atoms in solids, especially crystals, with particular emphasis on imperfections and irregularities in the electronic and atomic patterns in a crystal and the effects of these on electrical and chemical properties. It therefore has a strong overlap with solid-state physics, mineralogy, crystallography, ceramics, metallurgy, thermodynamics, materials science and electronics with a focus on the synthesis of novel materials.

See also **Ceramics**; **Crystal**; **Mineralogy**; **Semiconductors: Silicon-Based Semiconductors**; and **Solid-State Physics**.

SOLID-STATE PHYSICS. The study of the physical properties (crystallographic, electrical and electronic, magnetic, acoustic, optical, thermal, mechanical, etc.) of substances in the solid phase.

In years past, much emphasis has been given to crystalline solids and this continues, but there has been a growing shift of interest to polymeric and amorphous substances as well. Much attention in the past has been given to metals and this also continues apace, but other substances are now under very serious investigation, including the ceramics, glasses, and organics. Interest in the solid state, of course, was given a tremendous boost by the discovery of semiconductors in the 1940s. During the intervening years, this interest has been spurred by other electronic and electrical materials, including dielectrics, piezoelectrics, ferroelectrics, conductors and superconductors, electrodes, insulators, contacts, and polymers and macromolecular materials, notably those that are electroactive. Interest outside the electronics field, notably in the science of ceramics, glasses, and entirely new materials, such as composites, also has been adding to the body of knowledge of the solid state. However, because of the great need for solid materials with special properties for a host of applications, solid-state theory has tended to lag practice.

Nevertheless, solid-state theory has made excellent progress during the past decade. Just a few examples would include:

Excitonic Matter. The interaction of light with solid matter is a phenomenon of fundamental importance for exploring the quantum mechanics of materials. This field dates back to Einstein's finding that light energy is carried by quantized packets of radiation (photons). More recently, it has been found that a conduction electron can combine with a positively charged "hole" in a semiconductor to create an *exciton*, which, in turn, can form molecules and liquids. Some authorities consider the exciton as a new phase of matter. It was learned several years ago that the energy of incident photons can be converted inside a crystal into what might be termed short-lived neutral entities, i.e., excitons. As reported in an excellent paper by Wolfe and Mysyrowicz (1984), the exciton resembles the hydrogen atom. It consists of two oppositely charged carriers bound together by electrostatic attraction. In the hydrogen atom, the positive charge is a proton, which is surrounded by the negatively charged electron. In the exciton, the positive charge has a mass of an estimated $\frac{1}{1000}$th that of the proton. In the Wolfe/Mysyrowicz paper (details far beyond the scope of this encyclopedia), the investigators address several interesting questions.

Can the exciton propagate freely through the crystal like a free hydrogen atom in a gas? Can two or more excitons combine to form a molecule? Can the excitonic "atoms" or the molecules made up of them form liquid or solid phases? Can more exotic phases of condensed excitonic matter come into being? How are excitons created by light in a crystal? Why does a crystal absorb light at all?

Electron Transport in Solids. It is well established (elucidated in several articles in this encyclopedia) that the production of integrated circuits (ICs) requires manufacturing techniques of extreme precision and sophistication. The purity of materials used is also far higher than experienced by most other materials-processing industries. It has been observed by Howard, Jackel, Mankiewich, and Skocpol (AT&T Bell Laboratories), in a 1986 paper, that a single-crystal silicon wafer 15 cm or more in diameter can be obtained with concentrations of undesired dopants at less than 1 part in 10 billion and with only about one defect per square centimeter. Accuracy in recent years is in terms of a few nanometers, and feature sizes in commercial circuits are down to 1 micrometer (micron) and getting smaller. Thus, it is no surprise that the silicon transistor can serve as a model for investigating numerous areas of the solid state. Using new patterning techniques, devices almost $\frac{1}{100}$th the size of commercial ICs can be made, making it possible to study transport physics in microstructures only a few hundred atoms across.

In 1985, two research institutions (IBM and AT&T Bell Laboratories) reported that electrons can travel through a semiconductor without being slowed by collisions (*ballistically*). The report was based upon experimental data showing a ballistic peak in the electron energy spectra of gallium arsenide (GaAs) test devices. This is reported in more detail in article on **Arsenic**.

Electroactive Polymers and Macromolecular Electronics. Electroactive polymers are of particular interest in connection with their use in fabricating improved electronic microstructures. Scientists at AT&T Bell Laboratories have been active in the investigation and development of electroactive polymers notably for electrodes. As reported by Chidsey and Murray (1986), electrodes can be coated with electrochemically reactive polymers in several microstructural formats called sandwich, array, bilayer, micro-, and ion-gate electrodes. These microstructures can be used to study the transport of electrons and ions through the polymers as a function of the polymer oxidation state, which is essential for understanding the conductivity properties of these new chemical materials. The microstructures also exhibit potentially useful electrical and optical responses, including current rectification, charge storage and amplification, electron-hole pair separation, and gates for ion flow. In their well-illustrated paper, the investigators explore the three broad categories of electroactive polymers: (1) pi-conjugated, electronically conducting polymers; (2) polymers with covalently linked redox groups (redox polymers); and (3) ion-exchange polymers. In summary, the authors observe that although macromolecular electronics is still at a rudimentary level, the concepts involved are quite novel and with continued development may lead to practical applications. See also entry in this encyclopedia, **Molecular and Supermolecular Electronics**.

Quantized Hall Effect. In 1980, at the Max Planck Institute, Klaus von Klitzing discovered the quantized Hall effect, a phenomenon that occurs in certain semiconductor devices at low temperatures in very strong magnetic fields. As pointed out by Halperin (1986), the quantized Hall effect is observed in artificial structures known as two-dimensional electron systems. The conduction electrons in these systems are trapped in a very thin layer, such that the electronic motion perpendicular to the layer is frozen into its lowest quantum mechanical stage and thus plays no role in the conductivity of the device. In his experiment, Klitzing worked with a silicon field effect transistor (MOSFET). Electrons are trapped in what is called an inversion layer near the surface of a silicon crystal that is covered with a film of insulating silicon oxide, on top of which is deposited a metal gate electrode, used to control the density of conduction electrons in the inversion layer. This effect had been predicted as early as 1975 by Japanese investigators. Considerable detail pertaining to von Klitzing's experimental apparatus is given in the Halperin paper.

Surface Physics. Closely allied with solid state physics is the discipline of surface science. Investigations in this area have been quite intense during the past decade, notably in connection with catalysts. A catalyst is a species that changes the rate of a reaction and yet is regenerated by that reaction so that it seems to be unchanged in the net reaction. Although there are enzyme catalysts, for example, the majority of industrially interesting catalysts are found among the metals, the surfaces of which serve to catalyze reactions. The first catalytic phenomena were observed as early as 1835 by Berzelius and later better quantified by Ostwald in 1894. Aided by the great volume of catalysts used industrially ($ billions/year), the incentive for research is large. See articles on **Catalysis; Scanning Tunneling Microscope**; and **Silicon**.

Extremely High-Pressure Research. The invention and refinement of the modern diamond anvil cell (Carnegie Institution) occurred in the mid-1980s. This is a tool par excellence for optical, infrared and Raman spectroscopy and enables the researcher to study the changes in the electronic structure and chemical binding caused by the application of high pressure. Phase transitions, which involve changes in the atomic architecture can be determined with the diamond cell using the x-ray diffraction technique. Studies with the diamond anvil cell have been particularly valuable for obtaining geophysical information — for example, the state of silicate minerals and oxides in the mantle region right up to the core-mantle boundary to provide a view of the earth's interior, where high pressure and high temperature conditions exist. In solid-state physics, there is the fascinating challenge of making metallic hydrogen under ultrahigh pressure. This extraordinary change from a very good insulating to a metallic state in hydrogen is predicted to occur near 3 to 4 million atmospheres. See article on **Diamond Anvil High Pressure Cell**.

The foregoing examples are but a few to indicate the continuing vigorous research into the nature of the solid state. See also **Superconductivity**.

Concepts of Solids Simplified

The atoms that comprise a solid can be considered for many purposes to be hard balls which rest against each other in a regular repetitive pattern called the crystal structure. Most elements have relatively simple crystal structures of high symmetry, but many compounds have complex crystal structures of low symmetry. The determination of crystal structures, of atom location in the crystal, and of the dependence of many physical properties upon the inherent characteristics of the perfect solid is an absorbing study, one that has occupied the lives of numerous geologists, mineralogists, physicists, and other scientists for many years.

The rigid, hard-ball model is not adequate to explain many properties of solids. To begin with, solids can be deformed by finite forces, thus solids must not be completely rigid. Furthermore, atoms in a solid possess vibrational energy, so the atoms must not be precisely fixed to mathematically defined lattice points. This deformability of solids is built into the model by the assignment of deformable bonds (springs) between nearest atom neighbors. This ball-and-spring model has many successes; one important early use was that of Einstein to devise a reasonably successful theory of specific heats. Later incorporation by Debye of coupled motion of groups of atoms led to an even more successful theory.

Several measures exist of the strength of these bonds. One is the size of the elastic constants — for most solids, Young's modulus is about 10^{11} newtons per square meter. The other is the frequency of vibration of the atoms — values around 10^{13} to 10^{14} Hz are found.

The lack of perfection occasioned by elastic deformation of solids is but one of many kinds of crystalline imperfections. Defects are frequently found in crystals, produced in nature and in the laboratory. These defects may be characterized by three principal parameters — their geometry, size, and energy of formation.

All real crystals have atoms which occupy external surface sites and which do not possess the correct number of nearest neighbors as a consequence. Thus, a surface is a seat of energy and is characterized by surface tension. Furthermore, internal surfaces exist, grain boundaries and twin boundaries across which atoms are incorrectly positioned. In a crystal of reasonable size — say 1 cubic centimeter, these two-dimensional defects, called *surface defects*, contain only about 1 atom in 106, a rather small fraction. Even so, surfaces are important attributes of solids.

Some defects have extent in only one dimension — *line defects*. The most prominent of these, the dislocation, is a line in the crystal along which atoms have either an incorrect number of neighbors or neighbors which have not the correct distance or angle. In 1 cubic centimeter of

a real crystal, one might find a wide variation of length of dislocations present — from near zero to perhaps 10^{11} centimeters.

Defects which have extent of only about an atomic diameter also exist in crystals — the *point defects*. Vacant lattice sites may occur — *vacancies*. Extra atoms — *interstitials* — may be inserted between regular crystal atoms. Atoms of the wrong chemical species — *impurities* — also may be present.

The properties of defects are intimately related to their energy of formation. A standard against which this energy can be compared is provided by the energy of sublimation — the energy necessary to separate the ions of a solid into neutral, noninteracting atoms. This energy is about 81,000 calories per mole for a typical metal, copper, at room temperature, about 3.5 eV per atom. Energies of surfaces, both free surfaces and grain boundaries, are about 1000 ergs per square centimeter, about 1 eV per surface atom. Dislocation energies are of similar size per atom length of dislocation, about 1 to 5 eV, so the energy of a dislocation is about 10^{-4} erg per centimeter of length. Point defects, too, possess an inherent energy of about 1 eV each. Vacancies in copper have an energy of about 1 eV; self-interstitials, 2 or 3 eV.

The energies per atom of these various defects, surface, line, and point, are all much larger than the average thermal energy per atom in a solid at reasonable temperatures. This thermal energy kT is only about $\frac{1}{40}$ eV at room temperature. Thus, defects can be produced only by conditions which exist during manufacturing (artificial and natural) by external means, such as plastic deformation or particle bombardment; or by large local fluctuations in thermal energy away from the average.

The total amount of energy bound up in ordinary concentrations of these defects is not large as compared to the total thermal energy of a solid at normal temperatures. All the vacancies in equilibrium in copper, even at the melting point, comprise less than 10 calories of energy per mole, much less than the enthalpy at 1357 K (the melting point) of more than 7000 calories per mole. In a material with very heavy dislocation density, 10^{12} centimeters per cubic centimeter, the total dislocation energy is only a few calories per mole. And the total energy of a free surface of a compact block of 1 mole of copper is even less: about 10^{-3} calorie. Thus, the inherent energy of these defects is not large; even so they are immensely important in controlling many phenomena in crystals — as in the case of semiconductor devices.

Crystallographic defects need not remain stationary in the crystal; they may move about with time. Some of these movements may reduce the overall free energy of the solid; others (these are chiefly movement of the point defects) may simply be the wandering of random walk. Since these movements require larger than kT, the motion of defects depends upon rather large local fluctuations in energy. Consequently, their rate of motion depends upon temperature through a Boltzmann factor $\exp(-\Delta H/RT)$, where ΔH is the enthalpy increase necessary to move the defect from the lowest-energy site to the top of the barrier.

A convenient description of the crystalline structure of solids is thus seen to consist of successive stages of approximation. First, the mathematically perfect geometrical model is described; then departures from this perfect regularity are permitted. The deformability of solids is allowed for by letting the force constants between adjacent atoms be finite, not infinite. Then, misplacement of atoms is permitted and a variety of crystalline irregularities, called defects, is described. Some of these defects have intrinsic features which affect properties of the crystal; other affect the properties by their motion from site to site in the crystal. In spite of their relatively small number, defects are of immense importance.

Electronic Structure of Solids. In principle, the electronic structure of solids is determined by the electronic structure of the *free atoms* of which the solid is composed. Since the free atom structure is known rather well, especially for atoms of lower atomic number, the electronic structure of solids should be subject to determination by calculation. This is not the case. A wide variety of interactions occur between the electrons on adjacent atoms as they approach the equilibrium distance characteristic of solids. These interactions are of such complex nature that they tend to defy concise definition and involve such a host of charged particles, electrons, and ion cores, that only approximate calculations can usually be made. Nevertheless, the use of approximate models allows many general features of the electronic structure to be deduced, especially when close interplay between theory and experiment is established. As for the crystalline structure of solids, two stages are useful in understanding the electronic structure. First, the perfect electronic structure is defined. Then, irregularities in this structure, again termed defects, are described. Although both the geometry and energy of crystalline defects are defined, description of the geometry of the charge distribution of many of the electron defects is difficult, and one must generally be content with description of the formation energy of the defect.

The nuclei of the atoms in a solid and the inner electrons form ion cores with energy levels little different from corresponding levels in free atoms. The characteristics of the valence electrons are modified greatly, however. The state functions of these outer electrons greatly overlap those of neighboring atoms. Restrictions of the Pauli Exclusion Principle and the Uncertainty Principle force modification of the state functions, and the development of a set of split energy levels becomes a quasi-continuous band of levels of width, which are several electron volts for most solids. Importantly, unoccupied levels of the atoms are also split into bands. The electronic characteristics of solids are determined by the relative position in energy of the occupied and unoccupied levels as well as by the characteristics of the electrons within a band.

Metals. The solid is called a *metal* if excitation of electrons from the highest filled levels to the lowest unoccupied levels can occur with infinitesimal expenditure of energy. Thus, excitation can occur by means of many external forces, such as electric fields, heat, light, radio waves. Metals are, therefore, good conductors of electricity and of heat; they are opaque to light and they reflect radio waves.

Insulators. Some solids have wide spacing between the occupied and the unoccupied energy states — 2 eV or more. Such solids are called *insulators* since normal electric fields cannot cause extensive motion of the electrons. Examples are diamond, sodium chloride, sulfur, quartz, mica. They are poor conductors of electricity and heat and are usually transparent to light (when not filled with impurities or defects).

Semiconductors. Solids with conductivity properties intermediate between those of metals and insulators are called *semiconductors*. For them, the excitation energy lies in the range 0.1 to about 2 eV. Thermal fluctuations are sufficient to excite a small, but significant, fraction of electrons from the occupied levels (the valence band) into the unoccupied levels (the conductance band). Both the excited electrons and the empty states in the valence band (aptly called *holes*) may move under the influence of an electric field, providing a means for conduction of current. Such electron-hole pairs may be produced not only by thermal energy, but also by incident light, providing photo-effects. The inverse process, emission of light by annihilation of electrons and holes in suitably prepared materials, provides a highly efficient light source (example, light-emitting diodes).

Crystallographic defects, in general, are also electronic defects. In metals, they provide scattering centers for electrons, increasing the resistance to charge flow. The resistance wire in many electric heaters consists of an ordinary metal, such as iron with additional alloying elements such as nickel or chromium providing scattering centers for electrons. In semiconductors and insulators, however, alloying elements and defects provide an even greater variety of effects, since they can change the electron-hole concentrations drastically in addition to providing scattering centers. This is the basis of semiconductor technology. See also **Semiconductors**.

Interactions of Solids with Light. Solids are useful because of their interaction with external forces or stimuli, such as electric and magnetic fields, heat, and mechanical forces. Yet among these interactions, probably the most important is the interrelation between matter and light. This interaction, important to all photosynthetic phenomena and the production of food; to the artificial generation of light; to the use of phosphors in cathode-ray tubes — is also the basis of spectroscopy and its use in the study of solids. In this field, first came investigation of emission and absorption of radiation from free atoms. Later investigations included emission and absorption of radiation by atoms in solids — giving rise to maser and laser phenomena, Mossbauer spectroscopy, nuclear magnetic resonance, X-ray diffraction, infrared spectroscopy, fluorescence, the Raman effect, microwave emission and absorption, among many other useful effects.

Band Theory of Solids

The success of the simple free electron theory of metals was so striking that it was natural to ask how the same ideas could be applied to other types of solids, such as semiconductors and insulators. The basic assumption of the free electron theory is that the atoms may be stripped of their outer electrons, the resulting ions arranged in the crystalline lattice, and the electrons then poured into the space between.

The free electron model results from the neglect of the interaction of the various atoms and of the periodic variation of the potential in which the electrons move, i.e., as their distance from the nearest metallic ion changes. When the former is taken into account, it is found that each energy eigenstate of an isolated atom is split into N non-degenerate states, where N is the number of atoms in the crystal. The group of levels that result from a single atomic state form an *allowed band*. If we start from the free electron picture and consider the effect of the periodic variations of potential, the Bloch theorem leads to the conclusion that there will be discontinuities in the plot of energy vs. momentum whenever the wave vector $\mathbf{k}$ has magnitude and direction such that it satisfies the Bragg law for reflection, in which λ may be set equal to $1/\mathbf{k}$ to give $\mathbf{k} \cdot \mathbf{d} = n$. Here $\mathbf{k}$ is the wave vector, $\mathbf{d}$ is the vector separation of two atomic planes in the crystal, and n is an integer equal to the scalar product. As with the atomic interaction model, the number of eigenstates between two energy breaks is equal to the number of atoms in the crystal. Thus, either approach leads to the existence of a manifold of energy levels occurring in groups of N closely spaced levels, the groups being separated by energies that are often very large compared with the spacing of levels within a group, somewhat as shown in Fig. 1. Each group of levels is known as an *allowed band*; the energies between groups are said to be in a *forbidden band*. Because these levels depend on the properties of the body as a whole, the entire

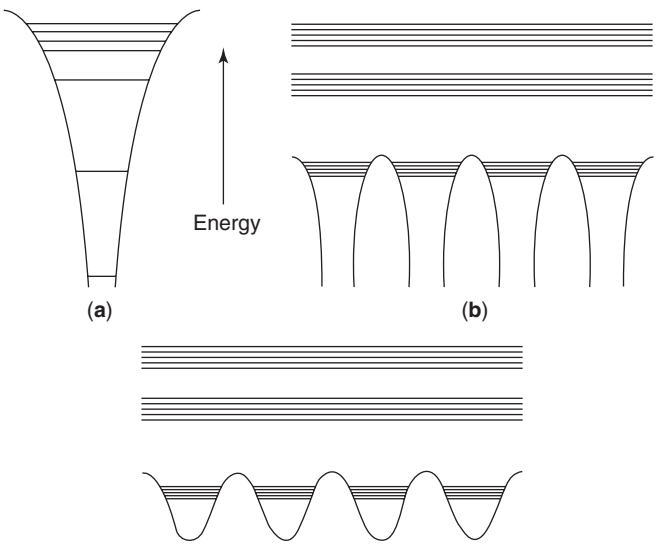

Fig. 1. Origin of the energy levels in a crystalline solid. The curves represent potential energy versus distance. At (**a**), the potential energy is that of an isolated ion; the energy levels, represented by the horizontal lines, are sharp. At (**b**), the overlap of the fields of the ions lowers the potential energy curve between the atomic positions and results in a splitting of each atomic level into a band of allowed levels. At (**c**), the model is derived from one in which the electrons are free, subject only to a periodic potential resulting from the ionic fields.

macroscopic crystal may be considered to be a single giant molecule. The electrical, mechanical, and thermal properties of the crystal are then largely determined by the electrons in the energy levels within the highest occupied bands.

Because electrons obey the Pauli Exclusion Principle, not more than two of them (with oppositely directed spin) can exist in any single energy level. In thermal equilibrium at the zero of absolute temperature, than, all of the levels up to some particular energy, determined by the number of electrons present, will be occupied and all above this energy will be vacant. This highest level is known as the *Fermi level*. At higher temperatures there will not be a sharp discontinuity in occupancy — some of the levels below the Fermi level will be vacant and some above it will be occupied. The *Fermi level* is then defined as the energy of the state that has a 50% chance of being occupied.

The Fermi level is determined by the number of electrons present, and the properties of the material are therefore dependent on whether this energy falls near the bottom, top, or middle of an allowed band. If the number of electrons is such as to exactly fill certain bands, with a wide gap above them, the material will be an insulator (m). If the gap is very narrow, or if there are impurities present to create extra levels, the substance may be semiconducting (o). See Fig. 2. In these cases, it is difficult to supply sufficient thermal energy to an electron to promote it into the conduction band above the gap, where alone it is free to carry an electric current. In a metal (n), however, there is always a partially filled band, in which the electrons behave in many respects as if they were free. The existence of the partially filled band may be due either to the fact that each atom contains an odd number of electrons or to the overlapping of two allowed bands, each of which will be partly filled. Direct evidence for the existence of bands is provided by the soft X-ray emission spectra, but the importance of the theory is not so much its correctness in detail as the simplicity of the band scheme by which the energy relations between various phenomena may be shown on a single diagram.

SOLIDUS CURVE. A curve representing the equilibrium between the solid phase and the liquid phase in a condensed system of two components. The relationship is reduced to a two-dimensional curve by disregarding the influence of the vapor phase. The points on the solidus curve are obtained by plotting the temperature at which the last of the liquid phase solidifies, against the composition, usually in terms of the percentage composition of one of the two components.

SOLION. A small electrochemical oxidation-reduction cell consisting of a small cylinder containing a solution and divided into sections by platinum gauze, porous ceramics, or other materials. A type of solion for detecting sound waves consists of a potassium iodide-iodine solution in which the iodide ions are oxidized to triiodide ions at the anode, and the reverse process occurs at the cathode. The cell is constructed so that the sound waves cause agitation of the solution between the electrodes, and thus change the current. In addition to detection of sound, solions can be designed to detect changes in other conditions, such as temperature, pressure, and acceleration.

SOLSTICE. Either of the two points on the sun's apparent annual path, where it is displaced farthest, north or south, from the earth's equator, i.e., a point of greatest deviation of the ecliptic from the celestial equator.

The point north of the celestial equator is termed the summer solstice, and the point south of the equator is called the winter solstice, inasmuch as the sun is at these respective points at the commencement of summer and winter in the Northern Hemisphere.

SOLUBILITY. A property of a substance by virtue of which it forms mixtures with other substances which are chemically and physically homogeneous throughout. The degree of solubility is the concentration of a solute in a saturated solution at any given temperature. The degree of solubility of most substances increases with a rise in temperature, but there are cases (notably the organic salts of calcium) where a substance is more soluble in cold than in hot solvents.

SOLUBILITY CURVE. The graph showing the variation with temperature of the concentration by a substance in its saturated solution in a solvent.

SOLUBILITY PRODUCT. A numerical quantity dependent upon the temperature and the solvent, characteristic of electrolytes. It is the product of the concentrations of ions in a saturated solution and defines the degree of solubility of the substance. When the product of the ion concentrations exceeds the solubility product, precipitation commonly results. Strictly speaking, the product of the activities of the ions should be used to determine the solubility product, but in many cases the results obtained using concentrations, as suggested by Nernst, are correct.

SOLUBILIZATION. Defined loosely, solubilization is the enhancement of the solubility of one substance, the solubilizate, by another substance, the solubilizing agent or solubilizer. See also **Solubility**; and **Solubility Product**. More strictly, it is a process occurring in the presence of a solvent, whereby one species, the solubilizing agent, diminishes the activity coefficient of another species, the solubilizate, and both species are soluble thereafter, J. W. McBain, who coined this term, used it to denote the dissolution of an otherwise insoluble material brought about by interaction with micelles, a type of colloid, present in the solvent. See also **Solvent**. The definition given here, however, is more inclusive than his original concept, and could be extended logically to systems whose characteristics are remote or completely apart from colloidal behavior. Practice nevertheless limits the term to usage in which there is either a close or a marginal relationship to micelles, and the literature of solubilization refers chiefly to systems in which the solubilizers are micelle formers. For example, potassium laurate solubilizes hydrocarbons in water, and calcium xenylstearate solubilizes water in hydrocarbons because of the micelle-forming nature of the respective solubilizing agents. However, the striking similarity among interactions between various agents and both soluble and insoluble species makes it undesirably arbitrary to restrict the term solubilization rigidly to its original usage.

Because absolute insolubility does not exist in nature, insolubility must be considered a matter of degree. Consequently, if an *apparently* insoluble species, in unlimited excess, is in contact with a solvent it must have a finite concentration and activity in the solvent at equilibrium. A solubilizing agent added to the system may interact with this species by coordination, hydrogen bonding, dipole interaction, complex formation, or in some other manner. In any case, the interaction results in a decrease of the effective concentration, or activity, of this species. Accordingly, more of the solubilizate progressively dissolves until its activity returns to the initial equilibrium value in the pure solvent, whereupon the activity coefficient is correspondingly less. If a species is freely soluble, or even infinitely miscible with a solvent, an interaction causes no *apparent* increase in the solubility of the species, but its activity, as evidenced by its osmotic behavior, nevertheless similarly decreases. The activity represents the tendency of the species to escape from the solution. Since solubility depends upon a balance between the opposing tendencies to enter and to leave the solution, the decreased activity is in effect equivalent to increased solubility. Solubilization is said to occur then, regardless of the independent solubility or insolubility in the pure solvent.

The salts of high-molecular weight organic acids are particularly important solubilizing agents. In nonpolar solvents such as hydrocarbons, they form colloidal aggregates known as association micelles. Most frequently such a micelle constitutes a limited number of salt monomers associated into a spheroidal cluster, with the polar ends of the salt monomers oriented toward the interior, and the nonpolar hydrocarbon ends at the periphery. Other polar species such as water, alcohol, acids, and dyes can be solubilized by these micelles in a variety of ways. In benzene solution, for example, zinc dinonylnaphthalene sulfonate can solubilize at least six moles of water for each equivalent weight of the salt present. The solution remains transparent, and no phase separation is observed. During the progressive addition of six moles of water per gram-equivalent of salt, the micelles expand to aggregations containing ten acid residues per unit, whereas the water-free micelles contain only seven. The water molecules are believed to be held in the polar core of the micelle where the environment is favorable to their retention.

Methanol, on the other hand, decreases the size of magnesium phenylstearate micelles. As methanol is solubilized by this salt in toluene solution, the micelle size decreases progressively from 23 salt monomers per aggregate to as little as 2 at a methanol concentration of 2% by weight. Each of these dimers is then associated with ten molecules of the alcohol. The partial pressure of methanol over the solution is demonstrably less than that over the salt-free methanol-toluene solution of equal methanol concentration. Rhodamine B dissolves very sparingly in pure benzene as the colorless and nonfluorescent base form. It is converted to the brilliantly fluorescent colored form by the addition of any of numerous micelle-forming solubilizers. No major changes in micelle size are believed to result from this solubilization, and it is postulated that a dye molecule replaces a monomer of the solubilizing agent in the matrix of the micelle.

In aqueous solutions, salts of high-molecular weight acids from micelles whose orientations are the reverse of those in nonpolar solvents. The

hydrocarbon portions of the monomers, being insoluble in water, are oriented inward, whereas the ionic, or polar ends are oriented outward. Solubilization by these agents is complicated by dissociation of cations from surfaces of the aggregates and by the resulting surface charges developed. Both polar and nonpolar species such as hydrocarbons, dyes, alcohols, fats, organic acids, and a wide variety of soluble and insoluble species are solubilized in aqueous micellar solutions. Micelle enlargement is frequently said to follow from solubilization by these salts in aqueous solution, although the possibility of reduction of micelle size should not be excluded from consideration.

A nonpolar solubilizate such as hexane penetrates deeply into such a micelle, and is held in the nonpolar interior hydrocarbon environment, while a solubilizate such as an alcohol, which has both polar and nonpolar ends, usually penetrates less, with its polar end at or near the polar surface of the micelle. The vapor pressure of hexane in aqueous solution is diminished by the presence of sodium oleate in a manner analogous to that cited above for systems in nonpolar solvents. A 5% aqueous solution of potassium oleate dissolves more than twice the volume of propylene at a given pressure than does pure water. Dimethylaminoazobenzene, a water-insoluble dye, is solubilized to the extent of 125 mg per liter by a 0.05 *M* aqueous solution of potassium myristate. Bile salts solubilize fatty acids, and this fact is considered important physiologically. Cetyl pyridinium chloride, a cationic salt, is also a solubilizing agent, and 100 mL of its *N*/10 solution solubilizes about 1 g of methyl ethyl-butyl ether in aqueous solution.

Among other species that are good solubilizing agents are the nonionic compounds such as the polyethylene oxide-fatty acid condensates and the fatty esters of polyalcohols. A wide variety of nonionic solubilizing agents is possible, but most of those available are of variable composition. They can be effective in both aqueous and nonaqueous solutions.

The colloidal nature of some systems can disappear completely as solubilization proceeds. For instance, when methanol is solubilized by magnesium and sodium dinonylnaphthalene sulfonates, the aggregates decrease in size to a degree beyond which they can be considered micelles. In toluene solutions, micelles of these salts dissociate progressively on the addition of methanol increments until each of the particles in these solutions contains only one salt monomer when the methanol concentration reaches about 2% by weight. Probably the properties of some species which cause them to aggregate are those which make them good solubilizing agents, but it is evident that micelles are not a necessary condition for solubilization.

Accordingly, it is logical for solubilization to occur in systems which show no colloidal behavior, although frequently the effect in these cases is described by other proper terminology. Usually the term "solubilization" is applied in cases where the solubilizing agent is effective in small quantities, but arbitrary limitations of quantity might confuse the basic concept of solubilization. The terms cosolvency, hydrotropy, and "salting in" are used sometimes to describe effects which may be considered within the broad general scope of solubilization.

Applications of solubilization, although not always completely understood, range widely. A solubilizing agent can be used to bring an otherwise insoluble substance into solution where it is needed for a specific use, or it can be incorporated in a formulation to suppress the activity of an unwanted species which otherwise cannot be eliminated or prevented from occurring. In the pharmaceutical industry, drugs which are insoluble in pure water are solubilized by suitable agents to form homogeneous solutions. Dyes are solubilized for more efficient penetration and uniform coloring of fabrics. Soaps and detergents in aqueous solution are effective cleansing agents because they solubilize oily and greasy residues which may be flushed away from contaminated surfaces, although other effects may be equally important in the process. Removal of silver halides from photographic papers and films by aqueous fixing solutions may be considered solubilization by noncolloidal solubilizers. Certain oil-soluble salts dissolved in dry cleaning fluids can solubilize water. The water, which is solubilized in the micelles can in turn solubilize inorganic salts. The salts are then retained in the polar cores of the micelles where the water is held. This effect is referred to as secondary solubilization. In automotive fuels and lubricating oils, nonaqueous detergents are used to maintain engine cleanliness by solubilizing products of oxidation and combustion which tend to form sludges and gums, and to suppress the destructive effects of acids and other species generated in operation. Other solubilizing agents are used in these fluids to incorporate otherwise insoluble additives for oxidation and corrosion inhibition.

SAMUEL KAUFMAN, Naval Research Laboratory, Washington, District of Columbia

SOLUTIONS. The equilibrium of a saturated solution represents a balance between the potentials and entropies of the molecules present in the two phases. These depend upon pressure, temperature, and the kind and strength of the attractions between the molecules. The attractions may be classified as interactions between ions, dipoles, metallic atoms, and the "electron clouds" of nonpolar molecules, differing among themselves in kind, in range, and in strength. The potential energy of the molecules of a nonpolar liquid is measured appropriately for the purpose of solubility relations by its energy of vaporization per cc, called its "cohesive energy density." The square root of this quantity will be used below as a "solubility parameter" δ.

We consider, first, the mutual solubility of two nonpolar liquids, whose molecules have practically equal sizes, and equal attractive and repulsive forces. When they are brought into contact, thermal agitation will cause mutual diffusion until the two species are uniformly distributed. The mixing process has produced maximum molecular disorder, and therefore entropy, which is given by the expression, for 1 mole of solution,

$$\Delta S^M = -R(x \ln x_1 + x_2 \ln x_2) \tag{1}$$

where R is the gas constant and x_1 and x_2 the respective mole fractions. The partial molal entropies of transfer of 1 mole from pure liquid to solution are

$$\overline{s}_1 - \overline{s}_1^0 = -R \ln x_1 \tag{2}$$

for component 1, and with subscript 2, for the other component.

The partial molal free energies of transfer are related to the *fugacities* in pure liquid, f^0 (vapor pressure corrected for deviation from the perfect gas law), and in solution, by the equations,

$$\overline{F}_1 - \overline{F}_1^0 = -R \ln(f_1/f_1^0) \tag{3}$$

and its counterpart.

Liquids such as are here postulated mix with no heat effect; therefore $F_1 - F_1^0 = -T(s_1 - s^0)$, etc.; therefore

$$f_1/f_1^0 = x_1 \text{ and } f_1/f_1^0 = x_2 \tag{4}$$

which is Raoult's law, and defines the *ideal* solution.

If one of the components of an ideal solution, e.g., component 2, is a solid, its fugacity, f_2^s, is less than the fugacity of the pure, supercooled liquid, and limits the amount that can dissolve to $x_2 = f_2^s/f_1^0$. The ratio f_2^s/f_2^0, can be calculated from its melting point and heat of fusion.

Most solutions deviate from Raoult's law. The curved lines in Fig. 1 represent positive deviations, with $f_1/f_1^0 > x$. The ratio f_1/f_1^0 is called *activity*, and

$$f_1/f_1^0 = a, \text{ and } a_1/x_1 = \gamma, \tag{5}$$

the *activity coefficient*.

Regular Solutions

The internal forces of a pair of liquids are seldom so nearly alike as to permit their mixture to obey Raoult's law very closely throughout the whole range of composition. In the absence of chemical interaction, the attraction between two different molecular species, provided their dipole moments are zero or small, is approximately the geometric mean of the attractions between the like molecules. Since a geometric mean is less than an arithmetic mean, the mixing is accompanied by expansion and absorption of heat. The partial molal heat of transfer per mole from pure liquid to solution is given with fair accuracy for many systems by the equation 6 and its cognate.

$$H_2 - H_2^0 = v_2 \phi_1^2 (\delta_2 - \delta_1)^2 \tag{6}$$

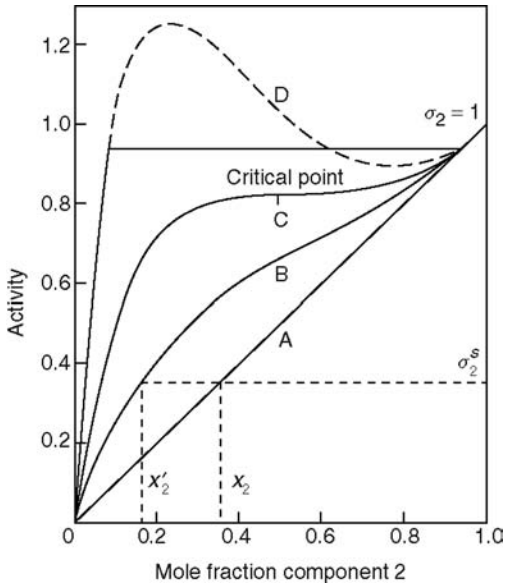

Fig. 1. Activity versus mole fraction for varying deviations from Raoult's law.

where $v \equiv$ molal volume, δ is a *solubility parameter*, the square root of the energy of vaporization per cm^3, and ϕ_2 is volume fraction.

Thermal agitation, except in the liquid–liquid critical region, suffices to give essentially maximum randomness of mixing, especially when one component is dilute, so that the entropy of mixing may be practically ideal, although the heat of mixing is not, and the partial molal free energy can be computed by combining the entropy and the heat terms, Eqs. 2, 5, and 6,

$$RT \ln a_2^s/x_2 = v_2\phi_1^2(\delta_1 - \delta_2)^2 \qquad (7)$$

This equation neglects the effects of expansion upon both the heat and the entropy, but the errors largely cancel when combined in Eq. (7) .

A plot of a_2 vs. x_2 for symmetrical systems (i.e., $v_1 \approx v_2$) is shown in Fig. 1 for a series of values of the heat term. It shows how the partial vapor pressure of a component of a binary solution deviates positively from Raoult's law more and more as the components become more unlike in their molecular attractive forces. Second, the place of T in the equation shows that the deviation is less the higher the temperature. Third, when the heat term becomes sufficiently large, there are three values of x_2 for the same value of a_2. This is like the three roots of the van der Waals equation, and corresponds to two liquid phases in equilibrium with each other. The criterion is that at the critical point the first and second partial differentials of a_2 and a_1 are all zero.

The presence of a dipole in one component adds a temperature-dependent component to its self-attraction and also induces a dipole in the other component. The effect can often by allowed for, for practical purposes, by an empirical adjustment of its solubility parameter.

If the dipole is hydrogen bonding, then this component is "associated," and it mixes less readily with a nonpolar second component.

If the components are, respectively, electron-donor and acceptor, or basic and acidic in the generalized sense of Gilbert Lewis, negative deviations from Raoult's law occur, with enhancement of solubility.

The effects of these various factors are well illustrated by solutions of iodine, I_2. In Fig. 2 are plotted the saturation values of log x_2 for iodine against log T. The slopes of the lines, when multiplied by R, give the entropy of transfer of iodine from solid to saturated solution. The solid lines are for violet solutions, from which chemical equilibria are absent. The positions of the lines are determined by the solubility parameters: how well is seen in Table 1, where δ-values are given for iodine in a spread of solvents calculated by means of Eq. (7) from the measured values of x_2. The broken lines indicate nonviolet solutions.

TABLE 1. δ-VALUES FOR I_2, 25 °C

Solvent	Molal Vol. CC.	δ_1	100_{x_2}
n-C_7F_{16}	227.0	5.7	.0185
$SiCl_4$	115.3	7.6	.499
Cyclo-C_6H_{12}	109.	8.2	.918
CCl_4	97.1	8.6	1.147
$TiCl_4$	110.5	9.0	2.15
CS_2	60.6	9.9	5.46
$CHBr_3$	87.8	10.5	6.16

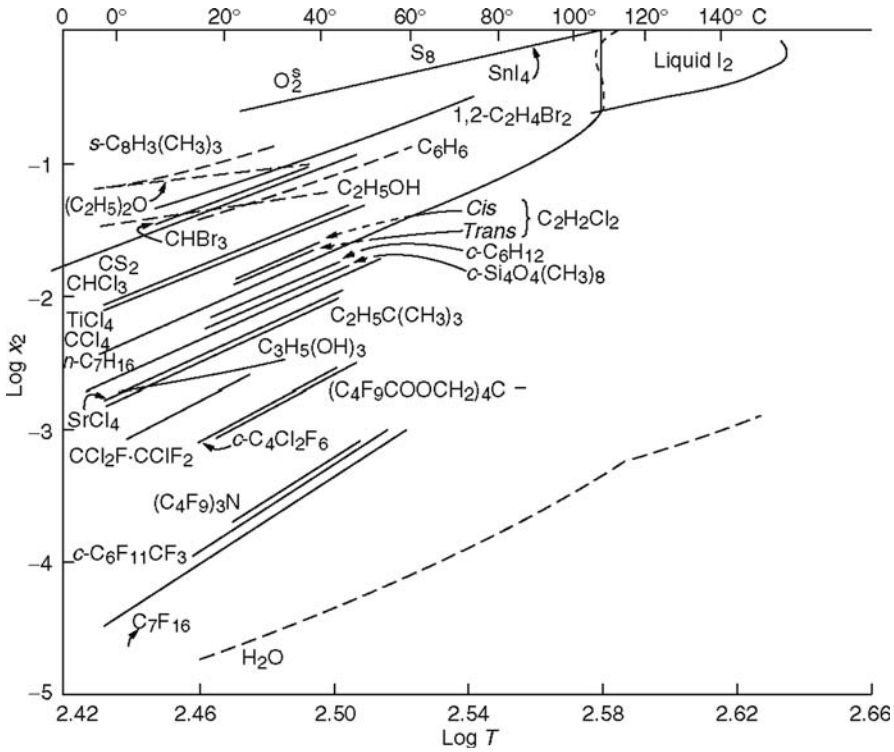

Fig. 2. Solubility of iodine.

The factors that cause solutions of iodine to deviate from the behavior of regular solutions are illustrated in Fig. 3 , in which values of the left hand member of Eq. (7) are plotted against those of the right for iodine solutions at 25 °C; a_2^s is the activity of solid iodine; x_2 denotes measured solubility; v_2 is the extrapolated molal volume of liquid iodine, 59 cm^3;ϕ_1 is the volume fraction of the solvent, ~1.0; $\delta_2 = 14.1$; δ_1 is the solubility parameter of the solvent. Illustrative values of x_2 and δ_1 are given in Table 1.

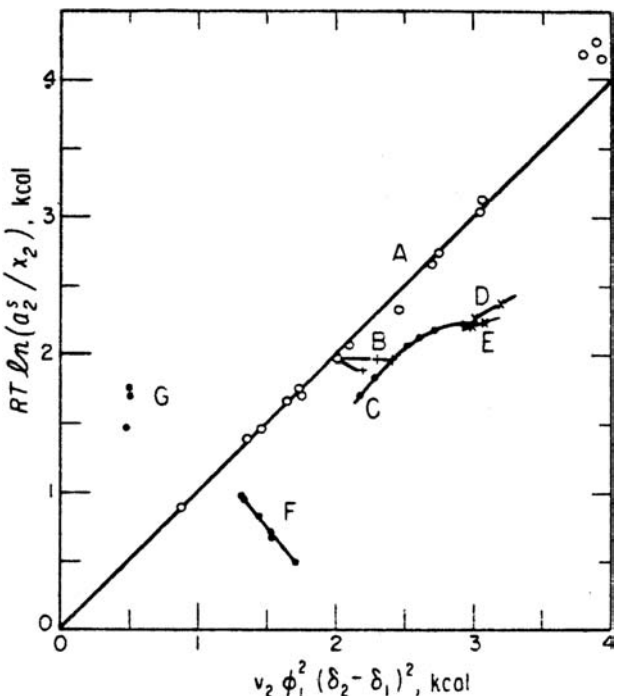

Fig. 3. Relation between energy of solution of iodine derived from measured solubility, x_2, and that calculated from solubility parameters.
Line A (beginning at lower left)
CS_2, $CHCl_3$, $TiCl_4$, *cis*-$C_{10}H_{18}$, *trans*-$C_{10}H_{18}$, CCl_4*c*-C_6H_{12}, *c*-C_5H_{10}, $SiCl_4$, CCl_3CF_3, $CCl_2F{\cdot}CClF_2$, $C_4Cl_3F_7$, *c*-$C_4Cl_2F_6$, C_7F_{16}.
Line B (left to right)
c-C_6H_{12} (on line A), *c*-$C_6H_{11}C_2H_5$ (below), *c*-$C_6H_{11}CH_3$, *c*-$C_6H_{10}(CH_3)_2$.
Line C (left to right, normal paraffins)
$C_{16}H_{34}$, $C_{12}H_{26}$, C_8H_{18}, C_7H_{16}, C_6H_{14}, C_5H_{12}.
Line D (left to right)
2,3-$(CH_3)_2C_4H_8$, 2,2-$(CH_3)_2C_4H_8$.
Line E (left to right)
2,2,3-$(CH_3)_3C_4H_7$, 2,2,4-$(CH_3)_3C_5H_9$.
Line F (top to bottom)
C_6H_6, $C_6H_5CH_3$, *p*-$C_6H_4(CH_3)_2$, *m*-$C_6H_4(CH_3)_2$, 1,3,5-$C_6H_3(CH_3)_3$.
Group G (from top)
1,2-$C_2H_4Cl_2$, CH_2Cl_2, 1,1-$C_2H_4Cl_2$.

The points on line A are all for regular solutions, conforming to Eq. (7) over large ranges of x_2. Line B starts with a point for iodine in cycyohexane, next a point for methylcyclohexane, followed by one for dimethylcyclohexane. The point below is for ethylcyclohexane. Line C is for normal alkanes, from $C_{16}H_{34}$toC_5H_{12}; groups D and E are for branched alkanes. Displacements from line A increase with increasing ratios of $-CH_3$ to $-CH_2$. The reason for this is not clear.

Line F contains points for aromatics, from benzene at the top to mesitylene at the bottom. All complex with iodine, altering its color. Group G consists of CH_2Cl_2 and 1,1- and 1,2-$C_2H_4Cl_2$, with strong dipoles, which enhance energy of vaporization without increasing solvent power for iodine.

Gases

Gas solubilities may be expressed as (1) volume of gas dissolved in unit volume of solvent, known as the *Ostwald coefficient*, designated by γ; (2) the volume of gas reduced to 0 °C (32 °F) and 1 atmosphere dissolved in unit volume of solvent, known as the Bunsen coefficient, designated α; (3) the mole fraction, x; or (4) the moles per liter, c, dissolved at 1 atmosphere partial pressure. Henry's law, that the amount of gas dissolved is proportional to its partial pressure, holds rather well at moderate pressures in the basence of a chemical equilibrium. The fact that a substance is a gas at 1 atmosphere and ordinary temperatures indicates that its attractive forces are low and that consequently its solubility will be greater in solvents with low δ-values; also that solubility of different gases in the same solvent will be higher the higher the critical temperature of the gas.

The solubility of a number of gases at 1 atmosphere partial pressure and 25 °C (77 °F) expressed as $RT \ln x_2$ is plotted in Fig. 4 against the squares of the solubility parameters of a number of solvents. A high amount of regularity is evident for all except the gases SF_6 and CF_4, whose molecules attract molecules of the solvents very selectively. Similar irregularity is evident in the case of the solvent $(C_4F_9)_3N$. In all other cases the positions of missing points could be predicted with confidence.

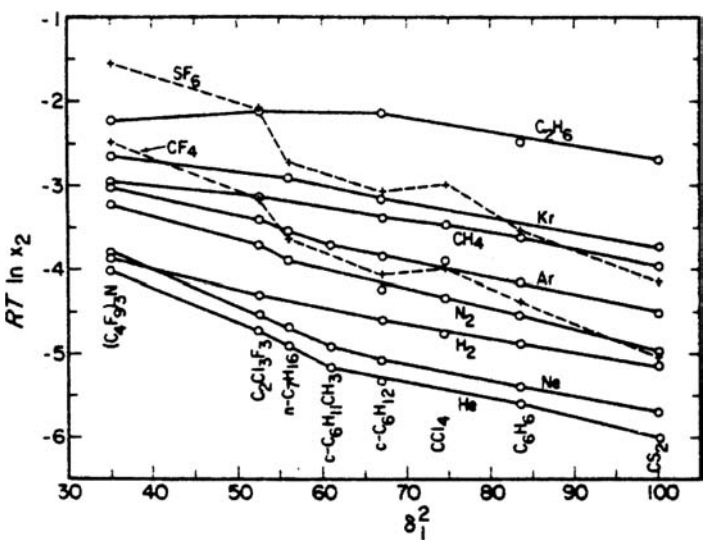

Fig. 4. Solubility of gases, log x_2 at 25 °C and 1 atm versus square of solubility parameter of solvents.

Variations of solubility with temperature are illustrated in Fig. 4 for 10 gases in cyclohexane. The slopes of the lines times the gas constant R give values for the entropy of solution. In decending from C_2H_6 to He the entropy increases from −8.7 cal/deg mole to +8.1 partly from increases in entropy of dilution, $-R \ln x_2$, but also because the successive gases attract the surrounding solvent molecules less and less strongly, but since they have the same kinetic energy they finally almost blow bubbles permitting more freedom of motion to adjacent molecules of solvent.

The foregoing interesting phenomena are treated at length in *Regular and Related Solutions*, by J.H. Hildebrand, J.M. Prausnitz, and R.L. Scott, Van Nostrand Reinhold, New York, 1970.

Solid Solutions

The formation of a solid solution requires not only attractive forces which are not too different, but also identical crystal structures. The latter condition is found most frequently among solids whose molecules are rotating, giving highly symmetrical crystals. See **Crystal**.

Metallic Solutions

In the absence of compounds, these follow the foregoing rules to a fair extent, but with added complications on account of the states of their electrons. The metals have a wide range of solubility parameters and exhibit many cases of incomplete miscibility in the liquid state.

Salt Solutions

The most obvious requirement necessary in a solvent for a salt is that it shall have a high dielectric constant, as is the case with water, liquid

ammonia, hydrogen fluoride, and, in a smaller degree, methyl alcohol, in order to weaken the coulombic attraction of its ions for one another. It is possible to formulate the equilibrium between a solid salt and a solution of its ions by considering the changes in energy and entropy involved in vaporization of the solid to gaseous ions, and hydration of the ions. This would be relatively simple if the lattice energy of the solid and the hydration of the ions were solely electrostatic; but the process involves also van der Waals forces, polarization, covalent forces, hydrogen bonding, and entropy changes, which, in the case of water, are considerable, by reason of the ice structure persisting in water and the different structure of water of hydration. Consequently, such a breakdown of the problem, while it may serve to suggest comparisons, is better for explanation than for prediction.

The Periodic System offers the most useful guide by virtue of the trends it reveals; e.g., the decreasing solubility in water of the sulfates and the increasing solubility of the hydroxides of the elements of Group II in descending the group.

Liquid ammonia, because of its lower dielectric constant, is in general a much poorer solvent for salts than water; but this is offset to some extent toward salts of electron-acceptor, Lewis acid cations by its greater basic, electron-donor character.

Insight into the nature of electrolytes in water solutions is afforded by their effects in varying concentration upon the freezing point of water, Δt, at varying concentrations, m moles per 1000 grams. In Fig. 5 $\Delta t/m$ is plotted against m on a logarithmic scale.

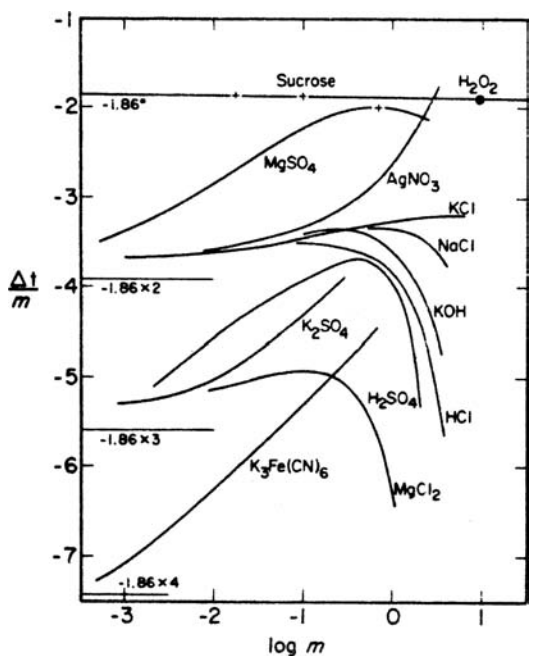

Fig. 5. Molal lowering of freezing points at different concentrations.

The molal lowering of nonelectrolytes is illustrated by sucrose and H_2O_2. These enter so easily into the hydrogen bonded structure of water that they give the theoretical lowering, 1.86° up to 0.1 M in the case of sucrose and to 10 M by H_2O_2.

Binary electrolytes, such as KCl, although completely ionized, even in the solid state, lower the freezing point less than $2 \times 1.86°$, even when as dilute as $10^{-3}M$. This was at first attributed to incomplete ionization but is now explained by the long range of electrostatic forces. Note that Mg^{++} and SO_4^{--} are less independent than K^+ and $Cl^- \cdot AgNO_3$, unlike KCl, etc., is a weak salt, and undissociated molecules increase rapidly with concentration. The ions nearer to an ion of one sign are those of opposite sign, therefore electric conductivity is less than the sum of ionic conductivities extrapolated to zero concentration.

This effect has been formalized in the concept of *ionic strength*, expressed as

$$I = \frac{1}{2}(m_1 z_1^2 + m_2 z_2^2 + m_3 z_3^2 + \ldots)$$

where z is the ionic charge. Applied to solutions of KCl, K_2SO_4 and $MgSO_4$ the values of I are respectively, 0.01, 0.03, and 0.04. Ionic strength is significant for dealing with the equilibrium and kinetic properties of an ion in mixtures of electrolytes.

Concentrated solutions are strongly affected by ionic hydration. Its strength depends upon ionic radius and charge, therefore it is in general stronger for cations than anions. K_2SO_4 and $MgSO_4$ both yield 3 ions, but the hydration is stronger for Mg^{++} than K^+, Na^+ than K^+, Na^+ than Ag^+. The line for K_2SO_4 ascends whereas the one for $MgSO_4$ plunges downward, (a) because the strong hydration of Mg^{++} diminishes the coulombic attraction of SO_4^{--} and (b) because it ties up molecules of water, decreasing the amount of solvent.

JOEL H. HILDEBRAND, University of California, Berkeley, CA

SOLVENT. The recorded history of solvent use spans several millennia, but only during the last few decades have been solvents subjected to scrutiny regarding their effects on human health, atmospheric changes, and soil and water pollution. Some experts predicted their complete elimination and the majority of chemists have been working on engineering the means to prevent solvent release and on the composition of solvents used in different applications aiming at reduction of their negative impacts on health and safety.

Figure 1 shows that the total use of solvents in the United States is expected to increase. This is consistent with a study by The Fredonia Group, http://www.freedoniagroup.com/ which predicted an increase of 2.3% per year. The total use of solvents parallels development of new products and ever increasing production output, especially now when many new markets emerge. For example, solvents are projected to grow by 4.8% in the Asia-Pacific region. This growth also shows that it is very unlikely that solvents will be eliminated from industrial production and commercial products, not only because they are efficacious and economically viable, but also because in many instances their use helps to preserve natural resources (for example, energy required to evaporate a solvent is substantially less than energy required to remove water used as a solvent).

Figure 1 also shows changes in the chemical composition of solvents. The use of high performance oxygenated solvents is increasing. Solvents, known to affect environment (hydrocarbons and chlorinated solvents) have been reduced.

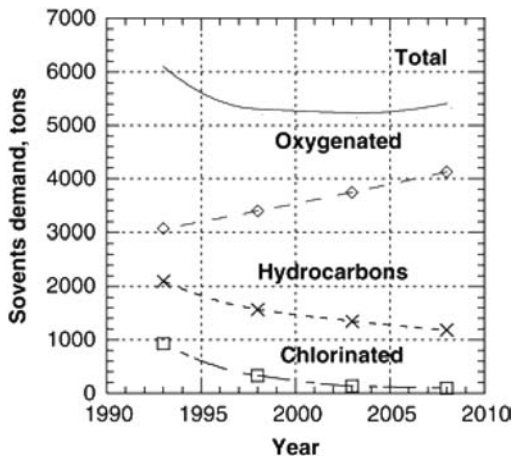

Fig. 1. Past, present, and future demand for various solvents in the United States.

The use of solvents requires better knowledge of properties, extensive research, and engineering controls.

The term solvent generally denotes a liquid that dissolves another compound to form a homogeneous liquid mixture in one phase. More broadly, the term is used to mean that component of a liquid, gaseous, or solid mixture which is present in excess over all other components of the system. A *chemical solvent* is the term used for solvents in those instances where the process of solution is attended by a chemical reaction between

the solvent and the solute. In contrast, a *physical solvent* is one that does not react with the solute. A *dissociating solvent* is one in which solutes that associate in many other solvents enter into solution as single molecules. For instance, various carboxylic acids associate and thus give abnormal elevations of the boiling point, abnormal depressions of the freezing point, etc., in many organic solvents; but in water, however, they do not associate. For this reason water is called a dissociating solvent for such solutes. A liquid that dissolves or extracts a substance from solution in another solvent without itself being very soluble in that other solvent is termed an *immiscible solvent*. A solvent whose constituent molecules do not possess permanent dipole moments and do not form ionized solutions, is termed a *nonpolar solvent*. *Polar solvents*, on the other hand, consist of polar molecules, that is, molecules that exert local electrical forces. In such solvents, acids, bases, and salts, that is, electrolytes, in general, dissociate into ions and form electrically conducting solutions. Water, ammonia, and sulfur dioxide are typical polar solvents. A *normal solvent* is one that does not undergo chemical association, namely, the formation of complexes between its molecules.

A *leveling solvent* is a solvent in which the acidity or basicity of a solute is limited (or leveled) by the acidity or basicity of the solvent itself. For example, the strongest acid that can exist in water is oxonium ion, H_3O^+. Consequently, even though HCl (for example) is intrinsically a much stronger acid than H_3O^+, its acidity in aqueous solution is "leveled" to that of H_3O^+ through the reaction $HCl + H_2O \rightleftharpoons H_3O^+ + Cl^-$. Likewise the very strong base KNH_2 is leveled in water to the basicity of OH^-

$$KNH_2 + H_2O \rightleftharpoons K^+ + OH^- + NH_3$$

The solvents that are leveling to both acids and bases are self-ionized solvents, e.g., water, ammonia, alcohols, carboxylic acids, nitric acid, etc. Basic non-protonic solvents are leveling to acids, but not to bases (i.e., they are differentiating toward bases), e.g., pyridine, ethers, ketones, etc., since the strongest acid attainable is the protonated solvent molecule (e.g., $C_5H_5N + HCl \rightleftharpoons C_5H_5NH^+ + Cl^-$), whereas there is no corresponding basic species derived from the solvent. Though solvents leveling to bases but not to acids are in principle much more difficult to find, in practice, very strong acids like H_2SO_4 and $HClO_4{}^-$ are limiting to bases because the species $HSO_4{}^-$ and $ClO_4{}^-$, which will be formed by almost any basic substance, are the strongest bases attainable in these solvents — $B^- + HClO_4 \rightleftharpoons HB + ClO_4-$ — whereas practically no other acid is capable of producing the cations $H_3SO_4{}^+$ and $H_2ClO_4{}^+$ in these solvents (i.e., they are differentiating toward acids).

Differentiating solvents are solvents in which neither the acidity of acids nor the basicity of bases is limited by the nature of the solvent. These solvents are not self-ionized. The aliphatic hydrocarbons and the halogenated hydrocarbons are such solvents.

In industry it is generally understood that solvents are simple or complex, pure or impure, compounds or mixtures of compounds (either natural or synthetic), which dissolve many water-insoluble products like fats, waxes, resins, etc., forming homogeneous solutions; that such organic solvents dissolve these water-insoluble products in various proportions depending on the solvent power of the solvent, the degree of solubility of the solute, and the temperature; and that the solute can be recovered with its original properties by the removal of the solvent from the solution. It is also understood in industry that there is a much more limited number of solvents which do not have the properties given above but which nevertheless are of considerable importance; they are the inorganic solvents like water, liquid ammonia, liquid metals, and the like.

Solvents have been classified on various arbitrary bases: (1) boiling point, (2) evaporation rate, (3) polarity, (4) industrial applications, (5) chemical composition, (6) proton donor and proton acceptor relationships, and (7) behavior toward a dye, Magdala Red. Thus on the basis of industrial application one can classify solvents as those for (1) acetylcellulose, (2) pyroxylin, (3) resins and rubber, (4) cellulose ether, (5) chlorinated rubber, (6) synthetic resins, and (7) solvents and blending agents for cellulose ester lacquers. Solvents classified according to chemical composition are noted below.

The term *solvent action* is understood to mean any process of making substances water-soluble; but in a broader interpretation the term is understood to be the phenomenon of making a substance soluble in a solvent. Solvent power, diluting power, solvency and similar expressions indicate the property of solvents to disperse the molecules of a solute or vehicle thereby causing a decrease in viscosity.

The most common solvent is water. Water dissolves a great many gases, liquids, and solids, and is much used for this purpose. Other liquids similarly dissolve many substances without reacting chemically with them. Important considerations in connection with the choice of solvent for a given case are (1) vapor pressure and boiling point, (2) solvent power under stated conditions of temperature, (3) ease and completeness of recoverability by evaporation and condensation, and completeness of separation from dissolved material by evaporation, (4) heat of vaporization, (5) miscibility with water or other liquid, if present, (6) inertness to chemical reaction with the materials present, and with the apparatus, (7) inflammability and explosiveness, (8) odor and toxicity; (9) cost of solvent, loss in process, cost of recovering.

Colligative Properties of Solutions. When solute is added to a pure solvent, thus forming a solution, properties of the solvent are altered, including (1) osmotic pressure; (2) vapor pressure (lowered); (3) melting point (lowered); and (4) boiling point (elevated). These properties bear a relationship to the number of solute molecules in solution and not to the nature of the molecules. These phenomena are explained by enhanced tension in the solvent. Complete explanation of these changes is beyond the scope of this book, but reference is suggested to H.T. Hammel's article on "Colligative Properties of a Solution" (*Science*, **192**, 748–756, 1976).

Environmental Impact

Organic solvents are released into the environment by air emissions, industrial and waste-treatment effluents, accidental spillages, leaking tanks, and the land disposal of solvent-containing wastes.

There are numerous physical and chemical mechanisms that control solvent movement in the environment. As solvents are released into the environment, they may partition into air, water, and soil phases. While in these phases, solvents may be chemically transformed into other compounds that are less problematic (or more toxic) to the environment. Understanding how organic solvents partition and behave in the environment is one of important requirements for environmental protection.

Solvents in Water. The fate of solvents in water is determined by their solubility, volatilization, degradation, and adsorption.

Solvent solubility affects its extent of leaching into groundwater. The movement of water-soluble solvent in rivers and water reservoirs, and groundwater is much easier and thus danger of pollution is increased. Solvent water-solubility also diminishes the efficiency of efforts of its removal through dissolution and precipitation.

Solvent initially released into water may be removed by natural volatilization (although it will then increase air pollution). If the Henry Law constant of solvent is smaller than 10^{-4} atm-mol/m^3 volatilization is probably not significant.

Chemical reactions, photodegradation, or abiotic and biotic processes may transform solvents to chemically different compounds. Depending on the properties of these compounds, water contamination may become less or more severe after these transformations. This subject is a matter of extensive studies.

Solvents may also be removed from water by their adsorption on sediment or soil. In most cases, water-soluble solvent have lesser tendency to be adsorbed.

Solvents in Soil. Solvents can be removed from soil because of volatilization, desorption, and degradation.

Volatilization is an important mechanism of solvent removal from soil. The efficiency and the rate of solvent removal depends on solvent properties, such as vapor pressure, its solubility in water, solvent-soil interaction, and many physical parameters such as temperature, air flow rate, diffusion characteristics of soil, and water content in soil.

Solvent movement in soil depends on adsorption and desorption rates. An adsorption isotherm is usually used to describe solvent partitioning between liquid phase and soil. Organic carbon-water partitioning coefficient is a well-known measure of solvent partitioning between water and soil.

Similar to water, solvents can be degraded in soil by similar mechanisms. The probability of biodegradation increases with the extent of water

solubility of the compound. Biodegradation can depend on the concentration of the solvent itself, competing processes that can make the solvent less available to microorganisms (such as adsorption), the population and diversity of microorganisms, and numerous soil properties such as water content, temperature, and reduction-oxidation potential. Based on results of testing, the half-life of solvent is calculated which is a good measure of its persistence in soil.

There are several indicators of solvent biodegradation. Most solvents have a biodegradation half-life of days to weeks and some biodegrade even faster.

The amount of oxygen required for its biodegradation is a measure of a solvent's impact on natural resources. Several factors are used to estimate this, such as biological oxygen demand, BOD, after 5-day and 20-day aerobic tests, chemical oxygen demand, COD, and theoretical oxygen demand, TOD. All results are given in grams of oxygen per gram of solvent. COD is the amount of oxygen removed during oxidation in the presence of permanganate or dichromate. TOD is the theoretically calculated amount of oxygen required to oxidize solvent to CO_2 and H_2O. Most alcohols and aromatic hydrocarbons have the highest BOD5. They consume twice their own weight in oxygen.

Solvents in Air. Degradation is one means of solvent removal from air (also dissolution of contaminants in rain). Some solvent molecules are capable of absorbing uv radiation and form radicals, but in the majority of the cases, the radicals are formed from solvent reaction with molecular oxygen or other radical-generating species. Once radicals are formed, solvent molecules may undergo internal conversions without chemical changes or degrade forming products of degradation which may continue to degrade, ultimately producing simple compounds such as water or carbon dioxide.

Atmospheric residence times or half-lives of solvents are usual measures of their persistence in atmosphere. More on the subject of photolytic degradation can be found elsewhere.

Some solvents have been found to affect the ozone layer that filters solar radiation and protects the Earth from extensive uv radiation. The ozone depletion potential is measured relative to CFC-11, and it represents the amount of ozone destroyed by the emission of a vapor over its entire atmospheric lifetime relative to that caused by the emission of the same mass of CFC-11.

On the other hand, some solvents are precursors of ozone formation close to the Earth surface. This ozone is dangerous to human health. Urban ozone formation potential is expressed relative to ethene. It represents the potential of an organic solvent vapor to form ozone relative to that of ethene [(g O_3/g solvent)/(g O_3/g ethene)]. Several groups of solvents, including alcohols, aldehydes, amines, aliphatic and aromatic hydrocarbons, esters, ethers, and ketones are active in ozone formation. Aldehydes, xylenes, some unsaturated compounds, and some terpenes are the most active among these. See also **Pollution (Air)**.

Indoor Pollution. Solvents are usually the most significant emission products coming from building materials and interior furnishing. All painted products are potential sources of emission. Similarly sealants, glues, and many other building materials are potential sources of solvent emissions.

Most emissions occur immediately following material application. This emission process is initially rapid. It is then followed by a long-term emission of residual quantities. Emission processes of solvents (and other volatile materials) are determined by surrounding conditions: eg, parameters of the ambient air, indoor air parameters, eg, ventilation (ventilation rates), air distribution, air movements, composition of ambient air, concentrations of air compounds, humidity, temperature, volume of the indoor air, and extreme conditions.

Many recent studies indicate that indoor pollution causes that indoor air to carries up to several times higher concentrations of industrial pollutants than the external air.

Contamination Cleanup. Chlorinated solvents and their natural degradation or progeny products have become some of the most prevalent organic contaminants found in the shallow groundwater. Many of these solvents have long half-lives (eg, dichloroethane, 990 days; dichloroethene, 173 days; trichloethene, 151 days). Some chlorinated solvents have shorter half-lives (eg, vinyl chloride and carbon tetrachloride, 14 days).

Subsurface contamination of soils and aquifers by chlorinated hydrocarbons (CHC) and nonchlorinated hydrocarbons (HC) is likely the largest environmental issue in industrialized nations worldwide. Decades without controlled disposal practices, inadequate storage and distribution systems, and accidental releases have resulted in a large number of contaminated drinking water and aquifer systems. In addition, an untold number of ecosystems are subject to future contamination by impinging hydrocarbon plumes. The extent of potential contributors ranges from local facilities, such as laundries or gasoline stations, to major fuel refineries, industrial operations and chemical manufacturing facilities. Many impacted areas, however, do not represent a significant risk to human health or the environment. In other areas, natural attenuation processes are effective in controlling the migration of the dissolved-phase plume.

Although the majority of the CHC is used in a safe and conscientious manner, some materials result in environmental contamination. This is often a result of accidental releases, although improper disposal is also a common problem. Unfortunately, as a group, CHCs represent the most problematic of the environmental contaminants because of their toxicity and environmental persistence. Thus, effective means of remediating soil and water potentially impacted by CHCs is often necessary.

When the degree of impact or nature of contamination exceeds safe conditions then environmental remediation is needed. If the contamination is confined and physically accessible, impacted soils can be excavated and disposed in a safe manner. In other cases, more complex remediation techniques are used. These can be divided into:

- *in situ* biotreatment (microbial-enhanced natural attenuation and phytoremediation).
- *in situ* treatment technologies (vertical groundwater circulation wells, surfactant-enhanced product recovery, foam-enhanced product recovery, thermal desorption, steam-enhanced extraction, and permeable reactive barriers).

Many other technologies were developed for managing hydrocarbon remediation (eg, pump and treat or air sparging) and other emerging technologies do exist. The basic themes of preventing migration passively, and the removal of contaminant via degradation (biotic and abiotic) are present in all the technologies. The proper use of particular technology and strategy is very dependent on the extent and type of contamination, the site characteristics (hydrology, lithology, etc.), the cleanup goals, and applicable regulations to name a few. Unfortunately, there are no hard and fast rules for the use of a particular technology; past experience suggests that the more that is known about site characteristics, the greater the success of technology applied. More information on contamination, results of self-attenuation and remediation can be found elsewhere.

Toxic Effects of Solvent Exposure

Exposure to solvents may cause many chronic reactions, such as: hepatotoxicity; nephrotoxicity; reproductive toxicity; hemopoietic toxicity; neurotoxicity; ocular toxicity; brain, lung, and heart effects; and allergic reactions (immunological effects).

Solvents which are inhaled, or introduced to organism in any other way, are processed by the liver, therefore it is no surprising that they may cause liver damage. The circumstances of exposure to hepatotoxic agents are divided to:

Occupational: either through a routine daily inhalation or skin absorption of solvents which have been shown to be toxic to the liver (accidental exposure).

Domestic during either accidental or intentional suicidal exposure, ingestion in foods or as a toxic contaminant of food, exposure to toxic agents such as in the form of glue sniffing.

Environmental, most common exposure through contaminated water with solvents (drinking water contamination) or through atmospheric pollution such as a release to the environment from plants utilizing solvents.

The following solvents are considered potential hepatotoxic agents: bromobenzene, bromotrichloromethane, CCl_4, chlorobenzenes, chloroform, dichloropropane, dinitrobenzene, dinitrotoluene, ethylene dichloride, methylene chloride, and naphthalene.

There is a number of pathologic manifestations of solvent induced hepatotoxicity, including inflammation, fat accumulation in the liver (steatosis),

hepatocellular necrosis and carcinogenesis. Functional disturbances in liver physiology have also been associated with solvent exposure.

The metabolites of the organic solvents are eliminated via the kidneys through urine excretion and to some extent, by exhalation of the unchanged original solvent. Commonly, the parent solvent is eliminated by the kidneys and this amounts to less than 1%. The metabolites are the main source of excretion of the metabolized parent solvent.

Nephrotoxicity is believed to be caused by hydrocarbon solvents, such as gasoline-based, turpentine, and Stoddard solvent. The most common pathological process described in association with solvent exposure and chronic glomerular nephritis has been that of IgA nephropathy, Good Pasture's syndrome, and proliferative glomerulonephritis.

Occupational exposure to organic solvents during pregnancy is associated with an increased risk of major fetal malformations. This risk appears to be increased among women who report symptoms associated with organic solvent exposure.

Many organic solvents are teratogenic and embryotoxic in laboratory animals depending on the specific solvent, dose, route of administration and particular animal species. The various malformations described include hydrocephaly, exencephaly, skeletal defects, cardiovascular abnormalities and blood changes. Also, some studies suggest poor fetal development and neurodevelopmental deficits.

Benzene is a proven human carcinogen. The toxicity of benzene has been known since the 19th century when aplastic anemia was first reported. Indeed the causal link between benzene and bone marrow toxicity in the form of hematoxicity and bone marrow suppression was described in 1897. In addition to pure benzene, many other solvents contain from 1 to 3.5% benzene and these should also be considered dangerous in the context of hematopoietic cell-type toxicity of benzene.

Many organic solvents used in industry are neurotoxic, and may lead to a range of largely irreversible cognitive and psychological or psychiatric impairments in workers who are exposed over long periods of time, or who have had a peak exposure (an episode in which they were briefly exposed to a larger than normal level of solvent). The most vulnerable workers are those who work in the spray painting, boat building, printing, textile, plastic, agricultural and pharmaceutical industries.

The chronic, and often slow and insidious effects of occupational solvent neuro-toxicity (OSN) include psychological and psychiatric symptoms, impairments in cognitive functioning, and negative psychosocial consequences.

Many victims of OSN do not realize that their chronic fatigue, irritability, poor memory and other problems may be associated with solvents in their workplace.

Effects of trichloroethylene, xylene, toluene, styrene, and some other solvents on brain, lung, and heart functions were documented. Many allergic effects caused by solvents are well-known as ocular irritancy caused by solvents.

SOLVENT EXTRACTION. A separation operation that may involve three types of mixture:

- A mixture composed of two or more solids, such as a metallic ore.
- A mixture composed of a solid and a liquid.
- A mixture of two or more liquids.

One or more components of such mixture are removed (extracted) by exposing the mixture to the action of a solvent in which the component to be removed is soluble. If the mixture consists of two or more solids, extraction is performed by percolation of an appropriate solvent through it. This procedure is also called leaching, especially if the solvent is water; coffee making is and example. Synthetic fuels can be made from coal by extraction with a coal-derived solvent followed by hydrogenation.

In liquid–liquid extraction one or more components are removed from a liquid mixture by intimate contact with a second liquid that is itself nearly insoluble in the first liquid and dissolves the impurities and not the substance that is to be purified. In other cases, the second liquid may dissolve i.e., extract from the first liquid, the component that is to be purified, and leave associated impurities in the first liquid. Liquid–liquid extraction may be carried out by simply mixing the two liquids with agitation and then allowing them to separate by standing. It is often economical to use counter-current extraction, in which the two immiscible liquids are caused to flow past or through one another in opposite directions. Thus fine droplets of heavier liquid can be caused to pass downward through the higher liquid in a vertical tube or tower.

The solvents used vary with the nature of the products involved. Widely used are water, hexane, acetone, isopropyl alcohol, furfural, xylene, liquid sulfur dioxide, and tributyl phosphate. Solvent extraction is an important method of both producing and purifying such products as lubrication and vegetable oils, pharmaceuticals, and nonferrous metals.

SOLVOLYSIS. A generalized conception of the relation between a solvent and a solute (i.e., a relation between two components of a single-phase homogeneous system) whereby new compounds are produced. In most instances, the solvent molecule donates a proton to, or accepts a proton from a molecule of solute, or both, forming one or more different molecules. A particular case of special interest occurs when water is used as solvent, in which case the interaction between solute and solvent is called *hydrolysis*.

SOMALI CURRENT. See **Ocean Currents**.

SOMATOPLASM. The tissue of an organism exclusive of the reproductive cells (germ plasm). The somatoplasm of animals typically has the diploid chromosome number, and the reproductive cells have the haploid chromosome number.

SOMITE. One of the longitudinal series of segments into which the bodies of many animals are divided. These segments are clearly shown in a simple form in the earthworms. In humans, they are made evident by the structure of the spinal column and the series of spinal nerves, but they are overshadowed externally by the high development of the appendages. The term is synonymous with metamere.

The segmental masses of mesoderm in the vertebrate embryo are also called somites. They are the primordia of the axial skeleton, voluntary muscles of the body and appendages, and the inner layer of the skin.

SOMMELET REACTION. Preparation of aldehydes from aralkyl or alkyl halides by reaction with hexamethylenetetramine followed by mild hydrolysis of the formed quaternary salt.

SONAR. A coined word derived from the phrase, "sound navigation and ranging." The term generally refers to the principles employed in the design and operation of systems that utilize acoustic energy transmitted in an ocean medium; while the systems themselves are referred to as sonar systems. Thus, sonar may be defined as a branch of applied acoustics concerned with the utilization of the ocean as the transmitting medium.

The problem of sonar is threefold: (a) understanding the transmission of acoustic energy through the transmitting medium, (b) developing sources which convert mechanical or electrical energy into acoustic energy, and (c) developing receivers which convert the acoustic energy back into mechanical or electrical energy. See Fig. 1.

Whenever a body vibrates in a fluid, longitudinal waves are formed, which propagate outward from the vibrating body. The particles of the

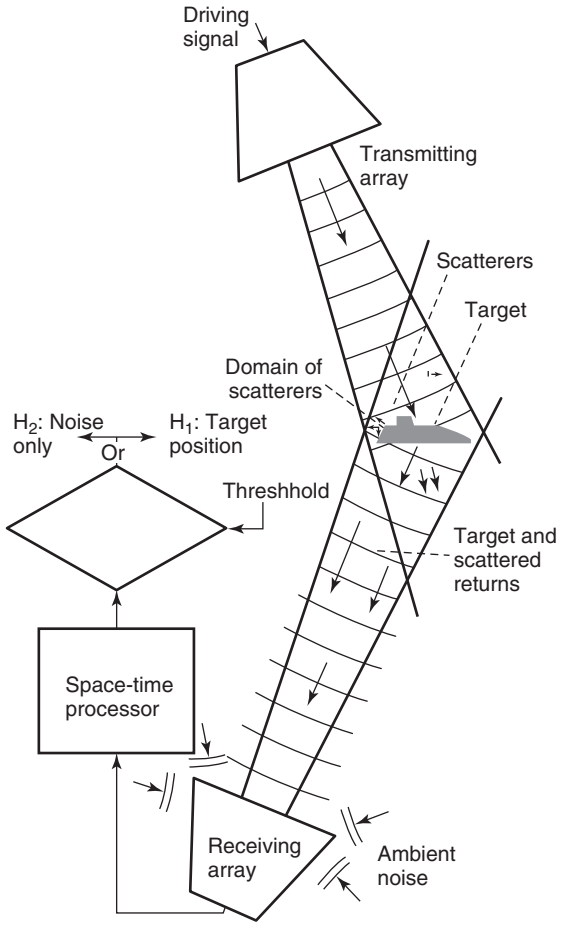

Fig. 1. General operating principle of sonar detection system. (*U.S. Naval Underwater Systems Center, Newport, Rhode Island.*)

fluid are set in motion, and temporary stresses are produced which increase and decrease during each vibration. The motion of the particles gives the fluid kinetic energy while the stresses induce potential energy. The sum of the two energies is called acoustic energy.

Traditionally, the starting point for a discussion of the transmission of acoustic energy in a fluid is to assume a point source radiating acoustic energy in an ideal homogeneous nonabsorptive medium of infinite extent. Under these assumptions, the energy from the source will radiate outwards with the wave front forming a spherical shell. As the radius of the shell increases, the sound intensity decreases. In practice, it is customary to express the sound intensity by means of a logarithmic scale. The most generally used logarithmic scale is the decibel. The intensity level in decibels of a sound of intensity I is defined as $10\log(I/I_0)$ where I_0 is a reference intensity. The intensity level can also be expressed as $20\log(P/P_0)$ where P is the pressure and P_0 the reference pressure, usually 1 dyne/cm^2 in underwater acoustics. In this discussion, the terms in all equations are expressed in decibels. The decrease in intensity as the shell increases in radius is called the spreading loss. The spreading loss from a unit range of R_0 to a range of R is $10\log[(\text{intensity at } R_0)/(\text{intensity at } R)] = 10\log(R^2/I^2) = 20\log R$. In most applications the use of such a simple model has been inadequate.

A more realistic model considers the following factors: the water-earth interface (bottom), the water-atmosphere interface (surface), the absorption of acoustic energy in the medium, the presence of foreign material in the medium, and the distribution of sound velocity. Considered as an acoustic medium, the waters of the ocean form a thin layer on the Earth's surface. Some of the acoustic energy radiated into this layer by a source will reach either the surface or the bottom. At either of these surfaces abrupt discontinuities in acoustic properties occur. Because of these discontinuities part of the intercepted energy is reflected, part may be transmitted across the interface, and part may be scattered within the medium. Since the transmission of an acoustic wave in water is accompanied by a compression and expansion of the medium, friction will occur between water molecules. This friction results in the conversion of some of the acoustic energy into thermal energy. In addition to this frictional, or viscous, loss there is another loss of energy in seawater related to the salts that continuously undergo chemical changes because of pressure fluctuations. Energy losses associated with both of these phenomena are called absorption losses. Due to the presence of foreign bodies in the volume of water, reflection and scattering is not limited to the surface and bottom boundaries. Foreign matter and biological content vary widely in size and acoustic characteristics. All ocean waters contain such bodies that modify the direction in which the acoustic energy is transmitted. In sufficient number they may also modify and increase the total absorption loss. The effect of variations in sound velocity is to bend the wave front in the direction of the lower velocity. This bending of the wave front is referred to as refraction. Both refraction and reflection can result in the guiding of acoustic energy in certain directions.

The factors above affect the propagation of acoustic energy in seawater in two different ways. The first results in a spreading loss already mentioned, and the second results in a loss referred to as attenuation. Attenuation consists of both the scattering and absorption losses. The spreading and attenuation are related to the distance the acoustic energy travels in different ways. An important difference is that the spreading loss frequently is relatively independent of frequency while the attenuation is a function of frequency.

There are three basic types of sonar systems: direct listening systems, echo-ranging systems, and communication systems.

In direct listening the acoustic energy is radiated by the target, which is the primary source. The acoustic transmission is a one-way process. In their more elementary forms direct listening sonar systems may be nondirectional and only give a warning that a primary source is in the vicinity of the searching vehicle; or directional, and permit determination of the bearing of individual primary sources relative to the listening platform. They generally do not give range. Direct listening is limited by the magnitude of the signal when it reaches the receiving point and the magnitude of the interfering noise that tends to obscure its reception.

In echo ranging, the sonar system projects acoustic energy into the water with the expectation that this energy will strike a target and enough of the energy will be reflected back to the searching platform so that it can be recognized as a target echo. The primary source of acoustic energy is in the searching platform, with the target, upon reflection of the energy, becoming a secondary acoustic source. The transmission of the energy is a two-way process. Echo-ranging sonar systems permit a determination of the bearing of a silent target, and by timing the echo-signal transmission and by knowing the velocity of sound in seawater, a range may also be obtained. Echo ranging is limited by the relative magnitudes of the signal and of the locally generated interference. In some cases the sonar performance is limited by reverberation, which is the acoustic energy returning by reflectors other than the target of interest.

Acoustically, sonar communications systems are similar to direct listening systems in that they utilize a one-way transmission path. Instrumentally, they are similar to echo-ranging systems, one located at each of the two points between which communications is to be established. In these systems coded pulses or voice modulated signals are transmitted by one system and received by the other.

To hear a target by direct listening, it is necessary that the acoustic level of the target less the transmission loss along the acoustic path from the target to the listening equipment be equal to or greater than the level of the background noise. This may be expressed as $L - H \geq N$ where L is the source level of the target, H is the one-way transmission loss, and N is the noise level. The size of this inequality depends upon operator skill, signal processing, and method of presentation. It is called the signal excess, E. This inequality can be written as an equation where $E = L - H - N$. This equation is called the direct-listening sonar equation for an omnidirectional listening hydrophone. When using directional hydrophones a factor called the directivity index must be added to the right-hand member of the equation. The source level, L, is a measure of the amount of acoustic energy put into the water by the target vehicle and is equal to 10 log (sound intensity at unit distance from the source). The transmission loss, H, is the sum of the losses related to refraction, surface and bottom reflection, absorption, and scattering. The noise, N, results from unwanted acoustic

energies arriving from many different sources and normally consists of thermal, ambient, and self noises.

To see a target by echo ranging, it is necessary that the acoustic level of the primary source, less twice the transmission loss along the acoustic path from source to target plus the target strength, be equal to or greater than the noise. This may be expressed, for a nondirectional receiver against a noise background, as $L - 2H + T \geq N$ where T is the target strength, a function of the reflecting characteristics of the target. Against a reverberation background the inequality becomes $L - 2H + T \geq R$ where R is the reverberation level. As in the case of direct listening, the inequalities can be expressed in terms of the signal excess as $E_N = L - 2H + T - N$ or $E_R = L - 2H + T - R$ where E_N and E_R are the signal excesses for noise and reverberation. The noise, N, comes from own-ship's noise and target noise. Reverberation, R, is the energy that is returned from the outgoing acoustic energy to the receiving equipment after having been reflected from reflectors in the medium other than the target. Reverberation sources usually are backscattering from the surface, bottom, and foreign particles in the water.

Echolocating bats (*Eptesicus fuscus*) are capable of detecting changes as short as 500 nanoseconds in the arrival time of sonar echoes when these changes appear as jitter or alternations in arrival time from one echo to the next. The psychophysical function relating the bat's performance to the magnitude of the jitter corresponds to the half-wave rectified cross-correlation function between the emitted sonar signals and the echoes. The bat perceives the phase or period structure of the sounds, which cover the 25- to 100-kilohertz frequency range. The acoustic image of a sonar target is apparently derived from time-domain or periodicity information processing by the nervous system. The biological sonar of bats in the suborder Microchiroptera is of much interest because bat sonar represents a rather well-defined example of a biological communications system.

SONE. A unit of loudness. A simple tone of frequency 1000 cycles per second, 40 decibels above a listener's threshold, produces a loudness of 1 sone. The loudness of any sound that is judged by the listener to be n times that of the 1-sone tone is n sones. A millisone is equal to 0.001 sone. The loudness scale is a relation between loudness and level above threshold for a particular listener. In presenting data relating loudness in sones to sound pressure level, or in averaging the loudness scales of several listeners, the thresholds (measured or assumed) should be specified.

SONIC ANEMOMETER. An anemometer that measures linear components of the wind vector by determining the effect of the wind on transit times of acoustic pulses transmitted in opposite directions across known paths. It operates on the principle that the propagation velocity of a sound wave in a moving medium is equal to the velocity of sound with respect to the medium plus the velocity of the medium. The wind velocity vector is determined by measuring the wind speed along three independent linear paths, for example, three orthogonal paths. The sonic anemometer is an absolute instrument and has the advantages of a very short time constant and an absence of moving mechanical parts. See also **Anemometer** and **Wind and Air Velocity Measurements**.

SONIC BARRIER. A popular term for the large increase in drag that acts upon an aircraft approaching acoustic velocity; the point at which the speed of sound is attained and existing subsonic and supersonic flow theories are rather indefinite. Also called *sound barrier*.

SONIC BOOM. A noise caused by a shock wave that emanates from an aircraft or other object traveling at or above sonic velocity. A shock wave is a pressure disturbance and is received by the ear as a noise or clap.

SONICS. The technology of sound in processing and analysis. Sonics includes the use of sound in any noncommunication process.

SONIC SPEED. Acoustic velocity; by extension, the speed of a body traveling at a Mach number of 1.

SONN-MULLER METHOD. Preparation of aromatic aldehydes from anilides by conversion of an acid anilide with phosphorus pentachloride to an imido chloride, reduction of the imido chloride with stannous chloride, and hydrolysis of the obtained anil.

SONOCHEMISTRY. Ultrasonic irradiation of liquids causes high energy chemical reactions to occur, often with the emission of light. The origin of sonochemistry and sonoluminescence is acoustic cavitation: the formation, growth, and implosive collapse of bubbles in liquids irradiated with high intensity sound. The collapse of bubbles caused by cavitation produces intense local heating and high pressures, with very short lifetimes. In clouds of cavitating bubbles, these hot-spots have equivalent temperatures of roughly 5000 K, pressures of about 1000 atmospheres, and heating and cooling rates above 10^{10} K/s. In single-bubble cavitation, conditions may be even more extreme. Thus, cavitation can create extraordinary physical and chemical conditions in otherwise cold liquids.

When liquids that contains solids are irradiated with ultrasound, related phenomena can occur. When cavitation occurs near an extended solid surface, cavity collapse is nonspherical and drives high speed jets of liquid into the surface. These jets and associated shock waves can cause substantial surface damage and expose fresh, highly heated surfaces. Ultrasonic irradiation of liquid–powder suspensions produces another effect: high velocity interparticle collisions. Cavitation and the shockwaves it creates in a slurry can accelerate solid particles to high velocities. The resultant collisions are capable of inducing dramatic changes in surface morphology, composition, and reactivity

Sonochemistry can be roughly divided into categories based on the nature of the cavitation event: homogeneous sonochemistry of liquids, heterogeneous sonochemistry of liquid–liquid or liquid–solid systems, and sonocatalysis (which overlaps the first two). In some cases, ultrasonic irradiation can increase reactivity by nearly a million-fold. Because cavitation can only occur in liquids, chemical reactions are not generally seen in the ultrasonic irradiation of solids or solid-gas systems.

Sonoluminescence in general may be considered a special case of homogeneous sonochemistry; however, recent discoveries in this field have heightened interest in the phenomenon in and by itself. See also **Ultrasonics**.

Acoustic Cavitation

The chemical effects of ultrasound do not arise from a direct interaction with molecular species. Ultrasound spans the frequencies of roughly 15 kHz to 1 GHz. With sound velocities in liquids typically about 1500 m/s, acoustic wavelengths range from roughly 10 to 10^{-4} cm. These are not molecular dimensions. Consequently, no direct coupling of the acoustic field with chemical species on a molecular level can account for sonochemistry or sonoluminescence. Instead, sonochemistry and sonoluminescence derive principally from acoustic cavitation, which serves as an effective means of concentrating the diffuse energy of sound. Compression of a gas generates heat. The compression of bubbles during cavitation is more rapid than thermal transport, which generates a short-lived, localized hot-spot.

If the acoustic pressure amplitude of a propagating acoustic wave is relatively large (greater than $\approx$0.5 MPa), local inhomogeneities in the liquid (e.g., gas-filled crevices in particulates) can give rise to the explosive growth of a nucleation site into a cavity of macroscopic dimensions,

primarily filled with vapor. Such a bubble is inherently unstable, and its subsequent collapse can result in an enormous concentration of energy (Fig. 1). This violent cavitation event has been termed "transient cavitation". A normal consequence of this unstable growth and subsequent collapse is that the cavitation bubble itself is destroyed. Gas-filled remnants from the collapse, however, may give rise to reinitiation of the process. The generally accepted explanation for the origin of sonochemistry and sonoluminescence is the hot-spot theory, in which the potential energy given the bubble as it expands to maximum size is concentrated into a heated gas core as the bubble implodes.

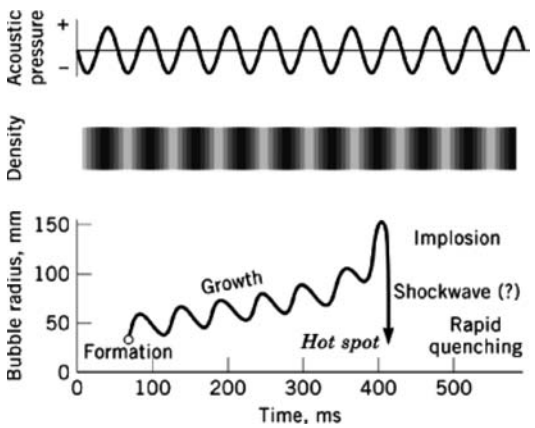

Fig. 1. Transient acoustic cavitation: the origin of sonochemistry and sonoluminescence.

Two-Site Model of Sonochemical Reactivity

The transient nature of the cavitation event precludes conventional measurement of the conditions generated during bubble collapse. Chemical reactions themselves, however, can be used to probe reaction conditions. The effective temperature realized by the collapse of clouds of cavitating bubbles can be determined by the use of competing unimolecular reactions whose rate dependencies on temperature have already been measured. The sonochemical ligand substitutions of volatile metal carbonyls were used as these comparative rate probes (eq. 1), where the symbol $\overset{)))}{\longrightarrow}$ represents ultrasonic irradiation of a solution, and L represents a substituting ligand. These kinetic studies revealed that there were in fact

$$\mathrm{M(CO)}_x \overset{)))}{\longrightarrow} \mathrm{M(CO)}_{x-n} + n\ \mathrm{CO} \overset{\mathrm{L}}{\longrightarrow} \mathrm{M(CO)}_{x-n}(\mathrm{L})_n$$

$$\text{where M} = \text{Fe, Cr, Mo, W} \qquad (1)$$

two sonochemical reaction sites: the first (and dominant site) is the bubble's interior gas-phase while the second is an *initially* liquid phase. The latter corresponds either to heating of a shell of liquid around the collapsing bubble or to droplets of liquid ejected into the hot-spot by surface wave distortions of the collapsing bubble as shown schematically in Figure 2.

Microjet Formation during Cavitation at Liquid–Solid Interfaces

A very different phenomenon arises when cavitation occurs near extended liquid–solid interfaces. There are two proposed mechanisms for the effects of cavitation near surfaces: microjet impact and shockwave damage. Whenever a cavitation bubble is produced near a boundary, the asymmetry of the liquid particle motion during cavity collapse can induce a strong deformation in the cavity. The potential energy of the expanded bubble is converted into kinetic energy of a liquid jet that extends through the bubble's interior and penetrates the opposite bubble wall. Because most of the available energy is transferred to the accelerating jet, rather than the bubble wall itself, this jet can reach velocities of hundreds of meters per second. Because of the induced asymmetry, the jet often impacts the solid boundary and can deposit enormous energy densities at the site of impact. Such energy concentration can result in severe damage to the boundary surface. The second mechanism of cavitation-induced surface

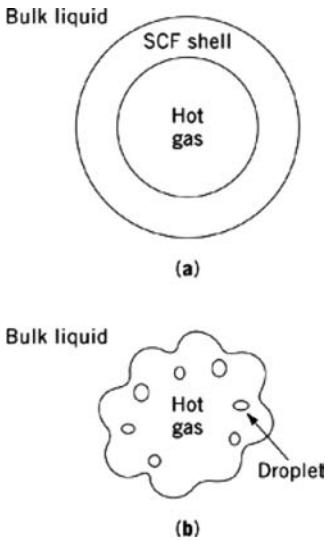

Fig. 2. Two-site models of the sonochemical reactions sites. (**a**) Thermal diffusion shell model; (**b**) surface wave droplet model.

damage invokes shockwaves created by cavity collapse in the liquid. The impingement of microjets and shockwaves on the surface creates the localized erosion responsible for much of ultrasonic cleaning and many of the sonochemical effects on heterogeneous reactions. In this process, the erosion of metals by cavitation generates newly exposed, highly heated surfaces that are highly reactive.

Sonoluminescence

In addition to driving chemical reactions, ultrasonic irradiation of liquids can also produce light. As with sonochemistry, sonoluminescence derives from acoustic cavitation. There are two separate forms of sonoluminescence: multiple-bubble sonoluminescence (MBSL) and single-bubble sonoluminescence (SBSL). Since cavitation is a nucleated process and liquids generally contain large numbers particulates that serve as nuclei, the cavitation field generated by a propagating or standing acoustic wave typically consists of very large numbers of interacting bubbles, distributed over an extended region of the liquid. If this cavitation is sufficiently intense to produce sonoluminescence, then this phenomenon is called multiple-bubble sonoluminescence (MBSL).

Under the appropriate conditions, the acoustic force on a bubble can be used to balance against its buoyancy, holding the single bubble isolated in the liquid by acoustic levitation. This permits examination of the dynamic characteristics of the bubble in considerable detail, from both a theoretical and an experimental perspective. Such a bubble is typically quite small, compared to an acoustic wavelength (e.g., at 20 kHz, the resonance size is approximately 150 μm). For rather specialized but easily obtainable conditions, a single, stable, oscillating gas bubble can be forced into such large amplitude pulsations that it produces sonoluminescence emissions on each (and every) acoustic cycle. This phenomenon is called single-bubble sonoluminescence.

Sonochemistry

In a fundamental sense, chemistry is the interaction of energy and matter. In large part, the properties of a specific energy source determine the course of a chemical reaction. Ultrasonic irradiation differs from traditional energy sources (such as heat, light, or ionizing radiation) in duration, pressure, and energy per molecule. The immense local temperatures and pressures and the extraordinary heating and cooling rates generated by cavitation bubble collapse mean that ultrasound provides an unusual mechanism for generating high energy chemistry. Furthermore, sonochemistry has a high-pressure component, which suggests that one might be able to produce on a microscopic scale the same macroscopic conditions of high temperature–pressure "bomb" reactions or explosive shockwave synthesis in solids.

Experimental Design. A variety of devices have been used for ultrasonic irradiation of solutions. There are three general designs in use

presently: the ultrasonic cleaning bath, the direct immersion ultrasonic horn, and flow reactors. The originating source of the ultrasound is generally a piezoelectric material, usually a lead zirconate titanate ceramic (PZT), which is subjected to a high a-c voltage with an ultrasonic frequency (typically 15 to 50 kHz).

The ultrasonic cleaning bath has been used successfully for a variety of liquid–solid heterogeneous sonochemical studies. Lower acoustic intensities can often be used in liquid–solid heterogeneous systems, because of the reduced liquid tensile strength at the liquid–solid interface. The low intensity available in these devices ($\approx$1 W/cm^2), however, can prove limiting. The most intense and reliable source of ultrasound generally used in the chemical laboratory is the direct immersion ultrasonic horn (50 to 500 W/cm^2) which can be used for work under either inert or reactive atmospheres or at moderate pressures (<10 atmospheres). Commercially available flow-through reaction chambers which will attach to these horns allow the processing of multiliter volumes. Homogeneous sonochemistry typically is not a very energy efficient process (although it can be more efficient than photochemistry), whereas heterogeneous sonochemistry is several orders of magnitude better. Unlike photochemistry, whose energy inefficiency is inherent in the production of photons, ultrasound can be produced with nearly perfect efficiency from electric power. A primary limitation of sonochemistry remains the small fraction of the acoustic power actually involved in the cavitation events. Sonochemistry is strongly affected by a variety of external variables, including acoustic frequency, acoustic intensity, bulk temperature, static pressure, ambient gas, and solvent. The frequency of the sound field is not a commonly altered variable in most sonochemistry. Changing sonic frequency alters the resonant size of the cavitation event and to some extent, the lifetime of the bubble collapse, but the overall process remains unchanged.

Acoustic intensity has a dramatic influence on the observed rates of sonochemical reactions. Below a threshold value, the amplitude of the sound field is too small to induce nucleation or bubble growth. Above the cavitation threshold, increased intensity of irradiation (from an immersion horn, for example) will increase the effective volume of the zone of liquid which will cavitate, and thus, increase the observed sonochemical rate.

The effect of the bulk solution temperature lies primarily in its influence on the bubble content before collapse. With increasing temperature, in general, sonochemical reaction rates are *slower*. This reflects the dramatic influence which solvent vapor pressure has on the cavitation event: the greater the solvent vapor pressure found within a bubble prior to collapse, the less effective the collapse. Increases in the applied static pressure increase the acoustic intensity necessary for cavitation, but if equal numbers of cavitation events occur, the collapse should be more intense. In contrast, as the ambient pressure is reduced, eventually the gas-filled crevices of particulate matter which serve as nucleation sites for the formation of cavitation in even "pure" liquids, will be deactivated, and therefore the observed sonochemistry will be diminished.

The choice of ambient gas will also have a major impact on sonochemical reactivity. Monatomic gases give much more heating than diatomic, which are much better than polyatomic gases (including solvent vapor). The choice of the solvent also has a profound influence on the observed sonochemistry. In addition to vapor pressure, other liquid properties, such as surface tension and viscosity, will alter the threshold of cavitation. The chemical reactivity of the solvent is often much more important. No solvent is inert under the high temperature conditions of cavitation.

Homogeneous Sonochemistry: Bond Breaking and Radical Formation. The primary products of ultrasound in aqueous solutions are H_2 and H_2O_2; there is strong evidence for various high-energy intermediates, including HO_2, H·, OH·, and perhaps $e^-_{(aq)}$. The sonolysis of water, which produces both strong reductants and oxidants, is capable of causing secondary oxidation and reduction reactions.

Suslick and co-workers established that virtually all organic liquids will generate free radicals upon ultrasonic irradiation, as long as the total vapor pressure is low enough to allow effective bubble collapse. The sonalysis of sample hydrocarbons, (e.g., *n*-alkanes) creates the same kinds of products associated with very high temperature pyrolysis.

Applications of Sonochemistry to Materials Synthesis. Of special interest is the development of sonochemistry as a synthetic tool for the creation of unusual inorganic materials. More generally, ultrasound has proved extremely useful in the synthesis of a wide range of nanostructured materials, including high surface area transition metals, alloys, carbides, oxides and colloids. Sonochemical decomposition of volatile organometallic precursors in high boiling solvents produces nanostructured materials in various forms with high catalytic activities. Nanometer colloids, nanoporous high surface area aggregates, and nanostructured oxide supported catalysts can all be prepared by this general route. Sonochemistry has important applications with polymeric materials. Substantial work has been accomplished in the sonochemical initiation of polymerization and in the modification of polymers after synthesis.

Another important application has been the sonochemical preparation of biomaterials, most notably protein microspheres. Using high intensity ultrasound and simple protein solutions, a remarkably easy method to make both air-filled microbubbles and nonaqueous liquid-filled microcapsules has been developed. These microspheres are stable for months, and being slightly smaller than erythrocytes, can be intravenously injected to pass unimpeded through the circulatory system. The mechanism responsible for microsphere formation is a combination of *two* acoustic phenomena: emulsification and cavitation. Ultrasonic emulsification creates the microscopic dispersion of the protein solution necessary to form the proteinaceous microspheres. The long life of these microspheres comes from a sonochemical crosslinking of the protein shell. These protein microspheres, have a wide range of biomedical applications.

Heterogeneous Sonochemistry: Reactions of Solids and Liquids. The use of ultrasound to accelerate chemical reactions in heterogeneous systems has become increasingly widespread. The use of high intensity ultrasound to enhance the reactivity of reactive metals as stoichiometric reagents has become an especially routine synthetic technique for many heterogeneous organic and organometallic reactions. Applications of ultrasound to electrochemistry have also seen substantial recent progress. Another important application for sonoelectrochemistry is the electroreductive synthesis of sub-micrometer powders of transition metals.

Sonocatalysis. Ultrasound has potentially important applications in both homogeneous and heterogeneous catalytic systems. The inherent advantages of sonocatalysis include *(1)* the use of low ambient temperatures to preserve thermally sensitive substrates and to enhance selectivity; *(2)* the ability to generate high energy species difficult to obtain from photolysis or simple pyrolysis; and *(3)* the mimicry of high temperature and pressure conditions on a microscopic scale. Homogeneous catalysis of various reactions often uses organometallic compounds that are often catalytically inactive until loss of metal-bonded ligands (such as carbon monoxide) from the metal. Ultrasound can induce ligand dissociation, permitting initiation of homogeneous catalysis by ultrasound. Heterogeneous catalysts often require rare and expensive metals. The use of ultrasound may permit activating less reactive, but also less costly, metals.

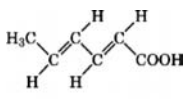
SONOLYSIS. The breaking up (molecular fragmentation) of molecules by ultrasonic radiation. Examples: sonolysis in pure water produces hydrogen atoms, hydroxyl radicals, molecular hydrogen, oxygen peroxide; acetonitrile in an argon atmosphere produces molecular hydrogen, nitrogen, and methane.

SONORA WEATHER. See **Meteorology**.

SORBIC ACID. Sorbic acid [CAS: 110-44-1] is a white crystalline solid first isolated in 1859 by hydrolysis of the oil distilled from unripened mountain-ash berries. The name is derived from the scientific term for the rowan tree, *Sorbus aucuparia Linne*, which is the parent plant of the mountain ash. Sorbic acid was first synthesized in 1900. Interest in this compound was minimal until independent researchers, E. Mueller of Germany and C.M. Gooding of the United States, discovered its antimicrobial effect in 1939 and 1940, respectively. Early interest in manufacturing sorbic acid centered around its use as a tung oil replacement when tung oil supplies were curtailed in the United States during World War II. High manufacturing costs prohibited expanded use until its approval as a food preservative in 1953. Sorbic acid is widely used in foods having a pH of 6.5 or below, where control of bacteria, molds, and yeasts is essential for obtaining safe and economical storage life.

The sorbic acid crystal has a well-ordered morphology as a result of its hydrogen bonding and trans,trans structure (**1**).



(1)

Physical properties are given in Table 1, along with those of the commercially most used salt, *E*,*E*-potassium sorbate [CAS: 24634-61-5]. Sorbic acid dust, as well as any organic dust, can accumulate a static charge and become an explosion hazard, particularly when mixed with highly flammable solvents or oxidizing agents. Minimum explosive limits are 0.02 g/L of air for sorbic acid.

TABLE 1. PHYSICAL PROPERTIES OF SORBIC ACID

Properties	Value
Mol wt	112.13
Melting point, °C[a]	134.5
Boiling point at 101.3 kPa (= 1 atm), °C	228
Density, g/cm^3, at 19 °C[b]	1.204
Flash point, °C	126–130
Dissociation constant at 25 °C, mol/L	1.73×10^{-5}
pK_a^{25}	
H_2O	4.76
50 wt% ethanol	4.62
pK_a, 0.1 *M* NaCl	4.51
Dissociation constant of dimer, K^{24} (CCl_4), mol/L)	1.96×10^{-4}
Specific heat, J/(g.K)[c]	1.84
Latent heat of fusion, kJ/mol[c]	13.6
Heat of combustion, kJ/mol[c]	3107
Heat of neutralization, kJ/mol[c]	6.07
Vapor pressure, kPa[d]	
130 °C	1.3
150 °C	3.7
170 °C	9.3

[a] Potassium sorbate, mol wt 150.22, decomposes at 270 °C (518 °F).
[b] Density for potassium sorbate at 20 °C (68 °F) = 1.363 g/cm^3.
[c] To convert J to cal, divide by 4.184.
[d] To convert kPa to mm Hg, multiply by 7.5.

Chemical Properties. The chemical reactivity of sorbic acid is determined by the conjugated double bonds and the carboxyl group.

Sorbic acid is brominated faster than other olefinic acids. Reaction with hydrogen chloride gives predominately 5-chloro-3-hexenoic acid.

Reactions with amines at high temperatures under pressure lead to mixtures of dehydro-2-piperidinones. A yellow crystalline complex melting at 198 °C (388 °F) is formed from sorbic acid and iron tricarbonyl.

Similar coordination occurs also in the presence of other di- and trivalent metals. Reduction of the double bonds can produce various hexenoic acid mixtures.

Sorbic acid is oxidized rapidly in the presence of molecular oxygen or peroxide compounds. The decomposition products indicate that the double bond farthest from the carboxyl group is oxidized. More complete oxidation leads to acetaldehyde, acetic acid, fumaraldehyde, fumaric acid, and polymeric products. Sorbic acid undergoes Diels-Alder reactions with many dienophiles and undergoes self-dimerization, which leads to eight possible isomeric Diels-Alder structures.

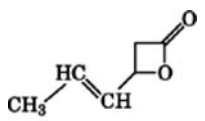
Polymerization catalyzed by free radicals occurs with sorbic acid.

Copolymers with acrylonitrile, butadiene, isoprene, acrylates, piperylene, styrene, and polyethylene have been studied. The high cost of sorbic acid as a monomer has prevented large-scale uses. The ability of sorbic acid to polymerize, particularly on metallic surfaces, has been used to explain its corrosion inhibition for steel, iron, and nickel.

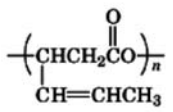
Sorbic acid undergoes the normal acid reactions forming salts, esters, amides, and acid chlorides. Industrially, the most important compound is the potassium salt because of stability and high water solubility. Sodium sorbate [CAS: 7757-81-5] (*E*,*E* form [CAS: 42788-83-0]) is less stable and not commercially available. The calcium salt [CAS: 7492-55-9], which has limited solubility, has use in packaging materials.

Sorbic acid anhydride [CAS: 13390-06-2] can be prepared by heating the polyester of 3-hydroxy-4-hexenoic acid with sorboyl chloride [CAS: 2614-88-2] or by reaction of sorbic acid with oxalyl chloride. Preparation of the esters of sorbic acid must be controlled to prevent oxidation and polymerization. The lower sorbic acid esters have a pleasant odor.

Synthesis and Manufacturing. The first synthesis of sorbic acid was from crotonaldehyde [CAS: 4170-30-3] and malonic acid [CAS: 141-82-2] in pyridine in 32% yield. The yield can be improved with the use of malonic acid salts. One of the first commercial methods involved the reaction of ketene and crotonaldehyde in the presence of boron trifluoride in ether at 0 °C (32 °F). A β-lactone (**2**) forms and then reacts with acid, giving a 70% yield.



(2)



(3)

Most commercial sorbic acid is produced by a modification of this route. Catalysts composed of metals (zinc, cadmium, nickel, copper, manganese, and cobalt), metal oxides, or carboxylate salts of bivalent transition metals (zinc isovalerate) produce a condensation adduct with ketene and crotonaldehyde, which has been identified as (**3**).

An excess of crotonaldehyde or aliphatic, alicylic, and aromatic hydrocarbons and their derivatives is used as a solvent to produce compounds of molecular weights of 1000–5000. After removal of unreacted components and solvent, the adduct referred to as polyester is decomposed in acidic media or by pyrolysis. Proper operation of acidic decomposition can give high yields of pure *trans*,*trans*-2,4-hexadienoic acid, whereas the pyrolysis gives a mixture of isomers that must be converted to the pure trans,trans form. The thermal decomposition is carried out in the presence of alkali or amine catalysts. A simultaneous codistillation of the sorbic acid as it forms and the component used as the solvent can simplify the process scheme. The catalyst remains in the reaction batch. Suitable solvents and entraining agents include most inert liquids that boil at 200–300 °C (392–572 °F), eg, aliphatic hydrocarbons. When the polyester is split thermally at 170–180 °C (338–356 °F) and the sorbic acid is distilled directly with the solvent, production and purification can be combined in a single step. The solvent can be reused after removal of the sorbic acid. The isomeric mixture can be converted to the thermodynamically more stable trans,trans form in the presence of iodine, alkali, or sulfuric or hydrochloric acid.

Food-grade specifications require further purification in the form of carbon treatments and recrystallization from aqueous or other solvent systems.

The ketene–crotonaldehyde route through polyester with various modifications and improvements is reportedly practiced by several companies. Differences in their processes consist mostly in the methods of polyester splitting and first-stage purification. Production of the potassium salt can be from finished sorbic acid or from a stream in the sorbic acid production route before the final drying step. Several patents on the process for producing sorbic acid and potassium sorbate from this route are given in the literature.

Union Carbide abandoned the ketene–crotonaldehyde route in 1953 in favor of the oxidation of 2,4-hexadienal made by acetaldehyde condensation. A silver compound used as the catalyst prevented peroxidation of the ethylenic bonds. Their plant operated until 1970.

Preparing sorbic acid by reaction of crotonaldehyde and acetone followed by oxidation of the crotonylidenacetone is of interest in the former Soviet Union.

Other methods include ring opening of parasorbic acid [CAS: 108-54-3] (†-lactone of 5-hydroxy-2-hexenoic acid) in hydrochloric acid or in alkaline solutions, the ring opening of γ-vinyl-γ-butyrolactone in various catalysts, or isomerization of 2,5-hexadienoic acid esters.

Sorbic acid and its salts are highly refined to obtain the necessary purity for use in foods. The quality requirements are defined by the *Food Chemicals Codex*. Codistillation or recrystallization from water, alcoholic solutions, or acetone is used to obtain sorbic acid and potassium sorbate of a purity that passes not only the *Codex* requirements but is sufficient for long-term storage. Measurement of the peroxide content and heat stability can further determine the presence of low amounts of impurities. The presence of isomers, other than the trans,trans form, causes instability and affects the melting point.

Uses. Sorbic acid and its potassium salt, collectively called sorbates, are used primarily in a wide range of food and feed products and to a lesser extent in certain cosmetics, pharmaceuticals, and tobacco products. There are limited applications of the calcium and sodium salts, but the acid and its potassium salt are used almost exclusively.

Since the first demonstration of antimicrobial activity in the 1940s, sorbates have been shown to inhibit a wide spectrum of yeasts, molds, and bacteria, including most foodborne pathogens. As bacterial inhibitors, sorbates are least effective against lactic acid bacteria. Although this can be a problem for foods that suffer from lactic spoilage, it has proven to be a positive point in cases of yeast and mold suppression during lactic fermentations. The effectiveness of sorbates can be influenced by a number of factors, including pH, microbial load, water activity, temperature, and atmosphere. The antimicrobial activity of sorbates has been reviewed. See also **Antimicrobial Agents (Foods)**.

The inhibitory activity of sorbates is attributed to the undissociated acid molecule. The activity, therefore, depends on the pH of the substrate. The upper limit for activity is approximately pH 6.5 in moist applications; the degree of activity increases as the pH decreases. The upper pH limit can be increased in low water activity systems. The following indicates the effect of pH on the dissociation of sorbic acid, ie, percentage of undissociated sorbic acid at various pH levels.

pH	Wt %
3.0	98
3.5	95
4.0	86
4.5	65
4.76 (pK_a)	50
5.0	37
5.5	15
6.0	6
6.5	2
7.0	<1

The activity of the sorbates at a higher pH is one distinct advantage over the two other most commonly used food preservatives, benzoic and propionic acids, because the upper pH limits for activity of these compounds are approximately pH 4.5 and 5.5, respectively. Although the effect of sorbates can be microbiocidal under certain conditions, activity is most often manifested as a microbial growth retardant.

The exact mechanism of inhibition by sorbic acid has not been thoroughly elucidated, even though it has been the subject of extensive research and numerous hypotheses. A number of enzyme systems in fungi and bacteria have been designated as sites of sorbate inhibition. Sorbic acid has been shown to inhibit the transport of carbohydrates into yeast cells, inhibit oxidative and fermentative assimilation, and uncouple oxidative phosphorylation in a variety of bacteria in studies conducted for various systems, including whole cells, cell-free extracts, and isolated enzyme systems. Although all events may occur under specific conditions, no single proposed mechanism seems to account wholly for the inhibitory activity of sorbates. More likely, microbial inhibition by sorbates is the result of a combination of events that may differ from one organism to another and from one set of conditions to another.

There has been no evidence to indicate that microorganisms can develop resistance to sorbates, as occurs with antibiotics and certain other antimicrobial chemicals. However, there is variation in the sorbate sensitivity of microorganisms from one genus to another, between different species in the same genus, and even between different strains of the same species. *Saccharomyces bailii* is resistant to sorbates, benzoates, and other short-chain monocarboxylic acids because of an inducible enzyme system that transports these compounds out of the cell. Some molds, when present in extremely high numbers, can metabolize sorbates. This has been attributed to typical β-oxidation as occurs with other fatty acids. Species of *Penicillium*, particularly *P. roquefortii*, can decarboxylate sorbates to 1,3-pentadiene, resulting in a hydrocarbon odor. *Desulfoarculus baarsii* was found to oxidize sorbic acid completely to carbon dioxide, whereas at higher concentrations the bacteria produced pentanone-2 and isopentanone-2.

Food applications of sorbates expanded rapidly after issuance of the original patents in 1945. The first uses were based on their excellent fungistatic properties and thus involved foods with low pH and/or low water activity in which yeasts and molds are the primary spoilage agents. More recent application research has been directed toward utilizing the bacteriostatic properties of sorbates.

Sorbates are classified as generally recognized as safe (GRAS) in the United States, with no upper limit set for foods that are not covered by Standards of Identity. They are also allowed in more than 70 food products having Standards of Identity. Examples of products that often contain sorbates are natural and processed cheeses, other cheese products, salad dressings, bakery products, prepared salads, fermented vegetable products, dried fruits, fruit juices, margarine, wine, fish products, jams, and jellies. Use levels in food products are 0.01–0.5 wt%. Compared with other antimicrobial preservatives, sorbates can be used in higher concentrations without affecting the flavor of foods. The level of sorbates necessary for preservation of a specific product depends on numerous factors, including product composition (pH, moisture, presence of other inhibitors, fat content), initial contamination level, packaging, and storage temperature. Maximum shelf life extension with sorbates is achieved when products have low initial levels of microbial contamination and are properly handled and stored. Therefore, the preservative cannot be used to mask poor quality product or poor handling practices.

Sorbates can be applied to food by any of several methods, including direct addition, dipping in or spraying with an aqueous sorbate solution, dusting with sorbate powder, or addition to food packaging materials. The potassium salt is used in applications where high water solubility is desired.

Margarine. Improvements in the technology of making margarine have greatly reduced the associated spoilage problems. Sorbates and benzoates are both used in margarine; sorbates is the more effective because of the high product pH and the comparative oil:water distribution coefficients for the two compounds, ie, sorbic acid 3:1, benzoic acid 6:1. A greater proportion of the sorbate thus remains in the water phase, where microbial spoilage occurs. Sorbates are generally used at 0.1 wt% and are most often used in product forms with higher spoilage potential, eg, unsalted or reduced-, low-, or no-fat margarine, or product packaged in plastic tubs leaving headspace.

Wine. Sorbic acid is used in table wines to prevent secondary fermentation of residual sugar. It is used at 0.01–0.025 wt% in addition to sulfur dioxide. Adding sorbic acid affords protection against recontamination by yeasts for wines that have been heated or filter-sterilized, but at those low levels it does not provide adequate protection against undesirable malolactic or acetic acid bacteria. It has been found that bacteria in red wine containing residual sugar can metabolize potassium sorbate, resulting in off-odors and -flavors even in trace amounts. The most offensive by-product was 2-ethoxy-3,5-hexadiene, which produces a geranium-like odor. Other odors identified were 1-ethoxyhexa-2,4-diene (mint/garlic) and ethyl sorbate (honey/apple).

Dairy Products. The dairy industry is the largest commercial user of sorbates, with the largest portion used in processed cheeses. The most common application methods include dipping or spraying with potassium sorbate solutions for natural cheeses and direct addition of sorbic acid to processed cheeses and cold-pack cheeses. Sorbate-impregnated wrapping material can be used for packaged cheese slices and pieces. For cottage cheese, sorbic acid is added to the cream dressing prior to pasteurization to a level of 0.075 wt% in the finished product. Common cheese processing and storage conditions, particularly heat treatment, do not affect the stability or efficacy of sorbic acid. Most cheese products are covered by Standards of Identity and, except for cottage cheese, a maximum use level is set.

Seafood. Sorbates are used to extend the shelf life of many seafood products, both fresh and processed. For smoked or dried fish, an instantaneous dip in 5 wt% potassium sorbate or a 10-minute dip in 1.0 wt% potassium sorbate prior to drying or smoking inhibits the development of yeast and mold. For fresh fish, sorbates can be incorporated at approximately 0.5 wt% into the ice, refrigerated seawater, or ice-water slush in which fish are packed, or applied as a 2.5–5.0 wt% potassium sorbate dip for fillets. Sorbates inhibit the growth of psychrotrophic spoilage bacteria, but the treatment must be applied while the product is fresh. Sorbates can extend shelf life and delay *Clostridium botulinum* type-E toxigenesis in fish that has been packaged in modified atmospheres.

Fruit and Vegetable Products. Sorbates are applied at 0.05–0.1 wt% as a fungistat for prunes, pickles, relishes, maraschino cherries, olives, and figs. The same levels extend shelf life of prepared salads such as potato salad, cole slaw, and tuna salad. In fermented vegetables, sorbates protect the finished product by retarding yeasts during fermentation or in the cover brine.

Sorbates reduce post-harvest losses of fresh citrus fruit, particularly when the spoilage fungi are resistant to chemical treatments. Post-harvest treatment of apples and apple juice with potassium sorbate decreases spoilage and may prevent mycotoxin production. A combination of potassium sorbate and sodium benzoate greatly reduces mold caused by mold during drying and gives the additional benefit of reducing the drying time required.

Sorbate combined with mild heat has a synergistic effect with regard to microbial destruction; thus, in the presence of 0.025–0.06 wt% sorbate, products such as apple juice, peach and banana slices, fruit salads, and strawberries can be treated with less severe heat treatments to extend shelf life. Sorbates increase the heat sensitivity of various spoilage fungi under varying conditions of pH and water activity. A similar synergistic effect has been reported for the combination of sorbate with irradiation.

Bakery Products. Sorbates are used in and/or on yeast-raised and chemically leavened bakery products. The internal use of sorbates in yeast-raised products at one-fourth the amount of calcium–sodium propionate that is normally added provides a shelf life equal to that of propionate without adversely affecting the yeast fermentation. Sorbates added at one-tenth the propionate level reduce the mix time by 30%. This internal treatment combined with an external spray of potassium sorbate can provide the same or an increased shelf life of pan breads, hamburger and hot-dog buns, English muffins, brown-and-serve rolls, and tortillas. The total sorbate useful in or on these baked goods ranges from 0.03 wt% for pan breads to 0.5 wt% for tortillas; 0.2–0.3 wt% sorbic acid protects chemically leavened yellow and chocolate cakes. Fruit-pie fillings and icings can be protected with 0.03–0.1 wt% sorbates.

Meat and Poultry. The only sorbate treatment of meat permitted by the United States Department of Agriculture (USDA) is a potassium sorbate dip for dry sausages to prevent mold growth. Numerous research studies support increased sorbate use in meat and poultry, but most of these applications have not been approved for use in the United States. A combination of 0.26 wt% potassium sorbate with 0.004 wt% sodium nitrite in curing bacon has been shown to reduce nitrosamine formation during frying and provide a safe antibotulinal shelf life. In cooked cured sausages (beef, pork, and chicken frankfurter emulsions), 0.004 wt% nitrite/0.20 wt% sorbic acid delayed germination and outgrowth of *Clostridium botulinum*. In sausage or tryptose broth, potassium sorbate alone or combined with sodium nitrate caused an initial minimal reduction of *L. monocytogenes*.

For fresh poultry, a potassium sorbate dip significantly reduces total viable bacteria and doubles the refrigerated shelf life of ice-packed broilers. In cooked, uncured, vacuum-packaged turkey and poultry stored at 4 °C (39 °F), 0.2–0.25 wt% potassium sorbate suppresses microbial growth for up to 10 days. Sorbic acid at 0.5% in a marinade mixture for chicken drummettes extends refrigerator shelf life. Country-cured hams sprayed with a 10 wt% potassium sorbate solution showed no mold growth for up to 30 days.

Pet Foods and Commercial Animal Feeds. For many years, it has been known that stable, long-shelf-life, intermediate-moisture pet foods can be prepared through the use of 0.1–0.3 wt% sorbates. In these products, the antimicrobial effectiveness of sorbates is enhanced by a combination of moderate heat treatment, pH adjustment, and reduced water activity via humectants such as propylene glycol, or by adjusting sugar and salt content.

As energy costs have escalated in recent years, the use of high moisture food by-products in commercial animal feeds has also escalated, particularly in beef cattle and dairy rations, as a means of reducing production costs. Because of the broad activity spectrum, sorbates are extremely effective in the preservation of wet by-products, e.g., brewers' and distillers' grains, beet pulp, citrus pulp, and condensed whey.

Treating alfalfa hay with potassium sorbate and potassium carbonate at cutting decreases drying time and improves preservation. Potassium sorbate applied to tobacco at a pH below 5.0 inhibits a number of spoilage fungi. A longer, safe storage period results in high moisture corn from the treatment of potassium sorbate alone or combined with propylene glycol.

Sorbic acid is not only suitable for preservation of feedstuffs but also improves the feed utilization and weight gain of chickens. This has proven to be of economic value under practical conditions when sorbic acid is added to the feed at 0.02–0.04 wt%. Similar effects have been observed for the use of sorbic acid in swine feeds.

SORBITOL. See **Sugar Alcohols**.

SORGHUM *(Andropogon Sorghum; Gramineae)*. Sorghums are annual grasses of tropical origin. They have an extensive system of wiry roots and solid stems 3–15 feet (0.9–45 meters) tall. The leaves are smaller than those of corn, and capable of rolling up tightly during periods of drought, and quickly unrolling and starting to function when favorable moisture

conditions return. Because of this habit sorghums are often grown in regions subject to frequent drought. The inflorescence is a panicle usually of very compact habit. Ordinarily the spikelets are paired, one of the pair being sessile or stemless, the other having a short stem or pedicel. The former is fertile, the latter staminate. The grains are enclosed in the glumes and vary considerably in shape in different varieties. There are two main groups of sorghums; the sweet or saccharine sorghums, the juicy pitch of which is a source of syrup; and the grain sorghums, which yield grain, stock food and ensilage. Kaffir is one of the latter group. In Asia, grain sorghums are employed in a countless variety of ways, as for fuel, brooms, mats, fences, windbreaks, roof thatch, and in making a fermented drink. In the United States, grain sorghums are finding increasing popularity in several industrial processes, as a source of starch, wax, and other products. See Figs. 1 and 2. See also **Broomcorn**.

SORPTION. A generalized term for the many phenomena commonly included under the terms adsorption and absorption when the nature of the phenomenon involved in a particular case is unknown or indefinite.

SOUNDING ROCKETS. The Sounding Rocket Program Office (SRPO), located NASA Goddard Space Flight Center's Wallops Flight Facility, provides suborbital launch vehicles, payload development, and field operations support to NASA and other government agencies.

Sounding rockets take their name from the nautical term "to sound", which means to take measurements. Sounding rockets are used to study the Earth's upper atmosphere, ionosphere, and aurora. Also, since sounding rockets can get above the atmosphere, they are used to study astronomical targets in the ultraviolet and x-ray portions of the electromagnetic spectrum.

In support of science, SRPO conducts approximately 20 flights annually from launch sites around the world. Operations are conducted from fixed launch sites such as Wallops Test Range (Virginia), http://www.wff.nasa.gov/code840/capa_launchpage.html, Poker Flat Research Range (Alaska), http://www.gi.alaska.edu/pfrr/ and White Sands Missile Range (New Mexico) http://www.wsmr.army.mil/, as well as sites such as Andoya Rocket Range (Norway) http://www.rocketrange.no/arr/index.html and Esrange (Sweden) http://www.esrange.com/.

Launch operations are also conducted from mobile sites set up by the Wallops Test Range. Mobile "campaigns" have been conducted from Australia, Puerto Rico, Brazil, and the Kwajalein Atoll. The mobile capability offered by the Wallops Test Range allows scientists to conduct their science "where it occurs".

Ten different Sounding Rocket vehicles (see below), ranging from a single stage Orion to a four stage Black Brant XII, are available to fulfill science altitude requirements of 100 to 1,400 kilometers (62 to 870 miles). Payloads up to 1,500 pounds (680 kilograms) can be accommodated.

Improved Orion. The Improved Orion is 14 inches in diameter and 110 inches long. The Improved Orion fins are nominally canted to provide a four revolution per second spin rate at burnout. The rocket carries an 85 pound payload to 88 kilometers and a 150 pound payload to 71 kilometers when launched from sea level at an 85° launch angle. The standard payload for the Improved Orion has a principle diameter of 14 inches and utilizes many nose cone shapes.

The normal payload length varies from 72 to 100 inches although this is not the maximum envelope. Payload diameters as small as 4.5 inches are flown on the Orion and performance characteristics are most favorable for 85 to 150 pound payloads.

Black Brant VB/VC. The 26 KS 20,000 Black Brant V rocket motor produces an average thrust level of 15,596 pounds and an action time of 32.42 seconds. The primary diameter of the Black Brant V is 17.26 inches and it is 210 inches long. Loaded weight of the motor including hardware is 2,803 pounds which includes 2,243 pounds of propellant.

The standard payload configuration for the Black Brant V vehicle is 17.26 inches diameter with a 3:1 ogive nose cone shape. Payload length for the Black Brant V is limited to approximately 200 inches and weight is limited to approximately 1,200 pounds. Because of the relatively high dynamic pressures, bulbous (larger than 17.26 inches diameter) payloads cannot be accommodated on the Black Brant V vehicle.

Terrier-Malemute. The average thrust is 9,604 pounds; maximum thrust level is approximately 14,200 pounds which results in a maximum longitudinal acceleration during second stage burning of 32g's for a 200 pound payload. Liftoff weight of the Terrier-Malemute launch vehicle, less payload, is approximately 3260 pounds. This vehicle is usually rail launched and can be accommodated at most established launch ranges.

The Terrier-Malemute vehicle is particularly suited for lower weight payloads; performance drops appreciably as payload weight increases. Bulbous diameter payloads can be accommodated on the Terrier-Malemute; however, the high dynamic pressures encountered by this vehicle result in

high aerodynamic heating rates and high vehicle structural loads Thus, payload design characteristics must be carefully considered.

Terrier-Orion. The Improved Orion motor has a bi-phase propellant system (boost-sustain) that results in thrust levels of approximately 19,000 pounds during the first four seconds of motor burn then trailing off to approximately 3,000 pounds until burnout around 25 seconds. The fins are generally configured to provide a burn out spin rate of four cycles per second. The Orion motor utilizes a clamp-released/load-bearing tail can to interface with the Terrier motor. This is a rail-launched configuration that can be supported at most fixed and mobile launch ranges.

Payload configurations supported by this vehicle include 14 inch and bulbous 17.25 inch diameters. Payload weights ranging from 200 to 800 pounds can achieve altitudes of approximately 200 to 80 kilometers respectively.

Available support systems include the standard 14 inch Ignition Recovery Module Assembly (IRMA), ACS systems, and nose cones of various configurations. The complete cadre of 17.25 inch diameter support systems is available for use with the bulbous payloads. These include fixed and deployable nose cones; fine, course, rate control, and magnetic ACS systems; separation and despin systems; and forward and aft recovery systems.

Terrier-Lynx. The basic Terrier MK70 motor is 155 inches long with a principal diameter of 18 inches. There is a 3 inch interstage adapter which allows for drag separation at Terrier burnout. Typically, the Terrier booster will utilize two spin motors to reduce dispersion and also serve as drag plates. Each Terrier fin is 4.6 square feet in area. Normally, the fins are canted to provide two revolutions per second spin rate at Terrier burnout. The weight of the Booster system is 2,288 pounds.

The Lynx is 14 inches in diameter and 110 inches long. The Lynx fins are normally canted to provide for four revolutions per second spin rate at burnout.

The standard payload for the Terrier MK70-Lynx has a principal diameter of 14 inches and utilizes a 3:1 ogive nose cone, although an 11 deg total angle cone can also be flown. The envelope of payload lengths that can be flown has not been established yet, however, it is expected to be similar to the boosted Orion family. The rocket system will carry a 250 pound payload to 378 kilometers and a 500 pound payload to 254 kilometers when launched from sea level at an 85 degree launch angle.

Black-Brant IX. There are three versions of the BBIX vehicle used. Each vehicle configuration is flight qualified and is available for mission selection: BBIX Mod 0: Terrier MK 12 - BBVC; BBIX Mod 1: Terrier MK 70 - BBVC; and BBIX Mod 2: Terrier MK 70 - BBVC (with extended cone)

The first stage booster consists of either a Terrier MK 12 Mod 1 rocket motor or a Terrier MK 70 rocket motor, both of which are equipped with four 340 square inch fin panels arranged in a cruciform configuration. The Terrier booster has a diameter of 18 inches.

The 26 KS 20,000 Black Brant VC rocket motor produces an average thrust level of 17,005 pounds and an action time of 26.9 seconds. The primary diameter of the Black Brant VC is 17.26 inches and it is 210 inches long. Loaded weight of the motor including hardware is 2,789 pounds which includes 2,198 pounds of propellant.

The standard payload configuration for the Black Brant IX vehicle is 17.26 inches in diameter with a 3:1 ogive nose shape. Payload length and weight limits are not defined as they are for the Black Brant V and specific limitations will be determined as the situation warrants. The burnout roll rate for the second stage Black Brant is three to four cycles per second.

Black-Brant X. The first stage booster consists of a Terrier MK 12 Mod 1 rocket motor with four 340 square inch fin panels arranged in a cruciform configuration. The Terrier booster has an overall diameter of 18 inches.

The 26 KS 20,000 Black Brant V rocket motor produces an average thrust level of 17,025 pounds with an action time of 26.9 seconds. The primary diameter of the Black Brant V is 17.26 inches and it is 210 inches long. Loaded weight of the motor including hardware is 2,789 pounds which includes 2,198 pounds of propellant. The Nihka rocket motor was developed specifically for the Black Brant X rocket system by Bristol Aerospace. The average thrust is 12,000lbs. with a total impulse of 193,500lb-sec. The primary diameter is 17.26 inches and the length is 76 inches. The Nihka motor weighs 894lbs. including 756lbs. of propellant.

The standard payload configuration for the Black Brant X vehicle is 17.26 inches in diameter with a 3:1 ogive nose shape. Payload length and weight limits for the Black Brant X are not defined as they are for the Black Brant V and specific limitations for this system are determined as the situation warrants.

Black-Brant XI. The Talos motor is 132 inches long with a diameter of 31 inches. It is fitted with a conical adapter for mating to the second stage. Differential drag forces cause separation. Four fins are arranged at the aft end in a cruciform configuration and drive the vehicle to approximately one revolution per second burnout roll rate.

The Taurus motor is 165 inches long with a principal diameter of 22.75 inches. The motor has the interstage adapter bolted to the forward end, which is then clamped to the aft end of the Black Brant motor. Each Taurus fin is 4.8 square feet. Normally, the fins are canted to provide two revolutions per second spin rate at Taurus burnout. The weight of the booster system (with hardware) is 3005 pounds, including 1678 pounds of propellant.

The 26 KS 20,000 Black Brant V rocket motor has been modified for use as the third stage of the Black Brant XII. The nozzle cone has been extended as has the tailcan, and the diameter at the aft end of the conical extension is 22 75 inches. The motor case wall is thicker which permits use with significantly higher thrust lower stages. The standard Black Brant V fin panels are used even though the tail assembly is different. The modified Black Brant V rocket motor produces an average thrust of 17,025 pounds with an action time of 26 9 seconds. The primary diameter of the Black Brant V is 17.26 inches and it is 223 inches long. Loaded weight of the motor is 2,847 pounds which includes 2,198 pounds of propellant.

The standard payload configuration for the Black Brant XI vehicle is 17.26 inches in diameter with a 3:1 ogive nose shape. Payload length and weight limits for the Black Brant XI are not defined as they are for the Black Brant V and specific limitations for this system will be determined as the situation warrants. For payload weights of 700 pounds, apogee altitudes of 500 km can be expected. A payload of 1200 pounds will reach 350 km. Both values use a launcher elevation angle of 85 degrees from a sea level launch location.

Black-Brant XII. The first and second stage are the Mk 11 Mod 5 Talos rocket motor and the Taurus motor. The third stage is a modified Black Brant VC motor. The Black Brant nozzle is extended for exoatmospheric use and the tailcan has been changed to enclose the nozzle. The aft end of the tailcan has a restraining device to keep the Taurus and Black Brant connected while coasting. The Talos motor is l32 inches long with a diameter of 31.1 inches. It is fitted with a conical adapter for mating to the second stage and differential drag forces cause separation. Four fins are arranged at the aft end in a cruciform configuration and drive the roll rate to approximately one revolution per second at burnout. Each fin is 6.9 square feet in area.

The Taurus motor is 165 inches long with a principal diameter of 22.75 inches. The motor has the interstage adapter bolted to the forward end, which is then clamped to the aft end of the Black Brant motor. Each Taurus fin is 4.8 square feet in area. Normally, the fins are canted to provide two revolutions per second spin rate at Taurus burnout. The weight of the booster system (with hardware) is 3005 pounds, including 1678 pounds of propellant.

The 26 KS 20,000 Black Brant V rocket motor has been modified for use as the third stage of the Black Brant XII. The nozzle cone has been extended as has the tailcan, and the diameter at the aft end of the conical extension is 22 75 inches. The standard Black Brant V fin panels are used even though the tail assembly is different. The 26 KS 20,000 Black Brant V rocket motor produces an average thrust level of 15,596 pounds and an action time of 32.42 seconds. The primary diameter of the Black Brant V is 17.26 inches and it is 210 inches long. Loaded weight of the motor including hardware is 2,803 pounds which includes 2243 pounds of propellant.

The Nihka rocket motor, previously developed for the Black Brant X, is used on this vehicle system. The average thrust is 10,592 lb, with a total impulse of 188.434lb-sec. The primary diameter is 17.26 inches and the length is 76 inches. The loaded motor weight of 898.5 lbs. which includes 694.7 lbs. of propellant.

The standard payload configuration for the Black Brant XII vehicle is 17.26 inches in diameter with a 3:1 ogive nose shape. Payload length and weight limits for the Black Brant XII are not defined as they are for the Black Brant V and specific limitations for this system will be determined as the situation warrants. Because of relatively high dynamic pressures, bulbous (larger than 17.26 inches) diameter payloads are carefully considered before flight on the Black Brant XII. For payloads weighing as little as 300 pounds, 1500 km apogee altitudes can be reached. The 500 km altitude region is attainable with 1150 pound payloads from sea level, when the launcher elevation is 85 degrees.

Terrier-Oriole. The Terrier motor is 155 inches long with a principal diameter of 18 inches. There is a 14 inch interstage adapter which allows for drag separation after Terrier burnout. Typically, the Terrier booster will utilize two spin motors to reduce dispersion and also serve as drag plates. Each Terrier fin is 4.8 square feet in area. Normally, the fins are canted to provide two revolutions per second spin rate at Terrier burnout. The weight of the Booster system is 2,207 pounds. The Oriole fins are normally canted to provide for four revolutions per second spin rate at burnout.

The standard payload for the Terrier Oriole has a principal diameter of 22 inches and utilizes a 19° total angle nose cone, although an Ogive cone can also be flown. The envelope of payload lengths that can be flown has not been established yet. The rocket system will carry a 800 pound payload to 340 kilometers and a 1500 pound payload to 184 kilometers when launched from sea level at an 85 degree launch angle. Standard hardware includes a nose cone and a capacitive discharge ignition system. Separation systems can be provided to separate the payload from the motor during ascent.

NASA/Wallops Flight Facility, Nasa/Goddard Space Flight Center

SOUTH ATLANTIC CENTRAL WATER. An oceanic water mass, extending at the surface roughly from southern Africa to Patagonia, where the Subantarctic Water is on the surface. This region of junction is south of the subtropical convergence in the South Atlantic. Temperature range 6–18 °C (42.8–64.4 °F), salinity range, 34.5%–36.0%.

SOUTH ATLANTIC CURRENT. An eastward flowing current of the South Atlantic Ocean that is continuous with the northern edge of the Antarctic Circumpolar Water. See also **Ocean Currents**.

SOUTH EQUATORIAL COUNTERCURRENT (SECC). See **Ocean Currents**.

SOUTH EQUATORIAL CURRENT. In the Atlantic and Pacific Oceans, the westward counterclockwise drift of surface water in the Equatorial latitudes south of the Equator that is separated from the North Equatorial Current by the Equatorial countercurrent. Driven westward by the trade winds, these great currents are deflected by the land masses and also by the Coriolis effect. In the Southern hemisphere they are deflected to their left. Upon turning poleward, the current becomes a part of the west-wind drift, a product of the prevailing westerlies. See also **Ocean Currents**.

SOUTH FOEHN. See **Winds and Air Movement**.

SOUTH INDIAN OCEAN CURRENT. See **Ocean Currents**.

SOUTH PACIFIC CENTRAL WATER. Due to the great size of the Pacific Ocean, it contains more well-developed oceanic water masses than the Atlantic. Thus there are both an Eastern and Western South Pacific Central Water mass. Extending from the Pacific Equatorial Water on the north to the Subantarctic Water on the south, and covering the width of the Ocean, except for a transition zone on the eastern side, they differ from each other in properties to a greater degree than the Eastern and Western masses in the North Pacific because the Western South Central Water is closely similar to the Central Water of the Indian Ocean, having a temperature range of 8–15 °C (46.4–59 °F) and the salinity of 34.6–35.5%. The Eastern South Pacific Water has a temperature range of 10–18 °C (50–64.4 °F) and the salinity of 34.0–35.0%.

SOUTH PACIFIC CURRENT. An eastward flowing current of the South Pacific Ocean that is continuous with the northern edge of the Antarctic Circumpolar Water. See also **Ocean Currents**.

SOWBUG *(Crustacea, Isopoda).* Related to crayfish, the sowbug is a crustacean and not an insect. The sowbug is a common but not severely damaging pest on food crops. The pest is found most often in connection with glasshouse or home gardening operations. The sowbug does feed on the tender portions of some plants and also attacks mushrooms. The sowbug (*Porcellio leavis*, Koch) reproduces by way of eggs, but the eggs remain in a marsupium for approximately 2 months. The pest is slow in maturing, requiring nearly a year to become a fully developed adult. The sowbug is a notable pest of watercress. See Fig. 1.

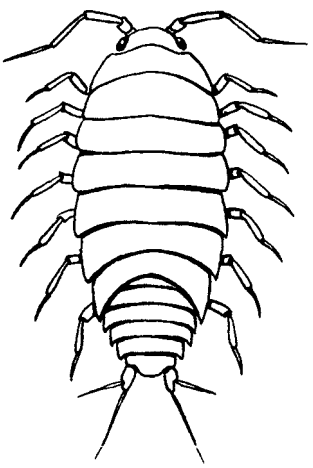

Fig. 1. Sowbug. (*USDA.*)

The *pillbug* (*Armadillidium vulgate*, Latrielle), is closely related to the sowbug and is of similar habit. The pillbug is distinguished by its ability to curl up into nearly a perfect spheroidal form when disturbed.

SOYBEAN. Of the family *Leguminosae*, subfamily *Papilionaceae*, and the genus *Glycine max*, the soybean is a typical legume seed differing in color, size, and shape, depending upon variety. The common field varieties grown in the United States are nearly spherical and are yellow in color, (e.g., the Lincoln soybean). See Fig. 1. The food reserves of the seed are stored in the cotyledons (90% seed), the interior of which is filled with elongated palisade-like cells, themselves filled with proteins and oil. The bulk of the protein is stored in protein bodies varying between 2 μm (microns or micrometers) and 20 μm in diameter. The oil is located in smaller structures, the spherosomes, 0.2 μm to 0.5 μm, interspersed between the protein bodies. Isolated protein bodies may contain as much as 90% protein and together account for 60 to 70% total protein of defatted soy flour. Proximate analysis of the whole bean shows that protein (40%) and oil (21%) make up about 60% of the bean, the remaining

third consisting of nonstarch carbohydrates, including polysaccharides, stachyose (3.8%), raffinose (1.1%), and sucrose. Nucleic acids are present only as minor constituents of the soybean, unlike some of the new single-cell protein sources, where nucleic acids can account for between 5 and 20% cell weight and may be included within the total nitrogen value of the isolate. Other minor constituents, such as the antitrypsin factor and so-called "beany flavor" components, have caused some adverse comment against the use of soybean products in the human dietary. Moreover, every legume (bean, pea, field bean) also has the flatus problem, but in processing this problem is not insurmountable.

Fig. 1. Recently pulled soybean plant lying on table for examination. Root structure is at right. Mature pods drop from vines. (*USDA photo*.)

Importance of the Soybean. During the past couple of decades, a major source of protein, namely that derived from the soybean, has developed. In times when there is concern over the ability of the world to feed its growing population, soybean protein technology is one of several scientific tools for disproving the Malthusian prophecy.

In terms of present knowledge, soybeans are capable of producing the greatest amount of protein per unit of land of any major plant or animal source used as food by people today. See Table 1.

TABLE 1. COMPARISON OF PROTEIN-YIELDING COMMODITIES

Protein Source	Kilograms from 1 Hectare	Pounds from 1 Acre
Beef cattle	65	58
Wheat	202	180
Maize (corn)	362	323
Soybean	560	500

In considering the present importance and future potential of the soybean, there are at least two factors of merit: (1) Large numbers of people in the lesser developed areas of the world suffer from a protein deficiency in their diets, leading to serious health problems; and (2) in the more developed areas, many people are accustomed to meat, milk, and eggs and desire to expand consumption of these products at lower costs. Many countries have the capacity to expand livestock and poultry production and, in the process, to lower prices of these products. This potential accounts for much of the market growth opportunity for soybeans and other feedstuffs. But, even in areas where livestock and poultry development may come more slowly, there is the opportunity to expand protein consumption in other ways. Soy protein provides a means of both extending the animal proteins and of replacing them with high-quality protein that is relatively inexpensive to produce–thus, the opportunity to further utilize soybeans directly as human food.

A technical factor of large significance is the general excellence of soybean protein as a protein. Soybean protein has a high content of essential amino acids, particularly lysine, leucine, and isoleucine. Detailed analysis is given later. Only in the sulfur-containing amino acids, cystine and methionine, is the soybean low, indicating that methionine is the first limiting amino acid to be considered when using soy products in a diet. Full fat soy flour also offers a valuable nutritional contribution from the high proportion of essential fatty acids, linoleic (51%) and linolenic (9%), that its oil contains. Since the oil represents some 20% of the total flour, the use of soy flour as a supplement in high-protein breads also elevates the essential fatty acid content of the product.

The soybean originated in the northern provinces of China and was first described in about 2000 B.C. as one of the most important cultivated legumes and one of the five sacred grains essential to Chinese civilization. The soybean was used as a basic food and a source of medicinals from the Middle Ages until the early 1700s, when greater interest was shown in the legume. Two major developments occurred at that time: (1) The first extraction of oil from the soybean, which led to the development of a new industry in Manchuria; and (2) introduction of the soybean to Europe in 1712 and the United States in 1804.

SOYBEAN OIL. See **Vegetable Oils (Edible)**.

SOY PROTEIN. See **Protein**.

SPACE CHARGE. The electric charge on a conductor is to be regarded as confined to an infinitely thin layer at the surface and thus, in a sense, as geometrically two-dimensional. Even when a current is flowing through the conductor, the quantities of positive and negative electricity within any element of volume at any instant are equal, thus neutralizing each other's electrostatic effect. For this reason, Laplace's equation applies to the interior of a current-bearing conductor as well as to a complete vacuum. This is true whether the conductor be of the metallic or the electrolytic type.

Quite different are the conditions in a vacuum tube, where streams of electrons or of positive ions (e.g., canal rays) may occupy sizable regions to the virtual exclusion of carriers of the opposite sign. See also **Ionized Gases**. The electricity thus monopolizing such a region is called a "space charge," and may exert marked influence on the performance of the tube.

A typical instance of this occurs in thermionic rectifiers. If the cathode is emitting no electrons, the potential gradient across from cathode to anode is nearly uniform; that is, the potential increases by the same number of volts for each centimeter from the one electrode to the other. If now a small emission begins from the cathode (because of its being heated), the electron swarm is more dense near the cathode, due to their accelerated motion, much as the stream of water descending from a faucet is broader near the faucet than farther down. The potential gradient is no longer uniform, and the total increase of potential, that is, the "plate voltage," is less than before. Further increase in emission may result in an actual drop of potential near the cathode (followed by a rise farther on), with still further decrease of plate potential. Such a potential minimum is contrary to the condition expressed by Laplace's equation, which therefore does not hold in a region occupied by a space charge. (Another formula, called Poisson's equation, here applies instead. It is $\nabla^2 V = 4\pi\rho$, where V is the potential and r is the electric volume density at the point in question.)

In gas-filled discharge tubes the effect of electronic space charge is largely offset by the presence of great numbers of less mobile positive ions. As a result, such tubes not only have much lower resistance but

have a more uniform potential gradient and give a better approximation to Ohm's law.

In atmospheric electricity, space charge refers to a preponderance of either negative or positive ions within any given portion of the atmosphere.

SPACE CHARGE LIMITATION OF CURRENTS. It has been shown by Child that the current between a plane cathode and a parallel plane anode at a distance d from it, when the anode potential is V, cannot exceed a certain maximum value, determined by the modification of the electric field near the cathode as a result of the space charge of electrons in that region. If the electrons leave the cathode with zero speed, the maximum current per unit area of the cathode is

$$i = \frac{4\varepsilon_0}{9}\sqrt{\frac{2e}{m}}\frac{v^{3/2}}{d^2}$$

where e and m are the electronic charge and mass, respectively, and ε_0 is the electric permittivity constant in any self-consistent system of units. Langmuir has extended the equation to include the case of a cylindrical cathode of radius a, surrounded by a coaxial cylindrical anode of radius b. The maximum current per unit length is then

$$i = \frac{8\pi\varepsilon_0}{9}\sqrt{\frac{2e}{m}}\frac{v^{3/2}}{b(\ln b/a)^2}$$

The dependence of the current on the $\frac{3}{2}$ power of the potential difference is general, and is the basis of the definition of perveance.

SPACE CHEMISTRY. Experiments carried out on the space shuttle in the early 1980s indicate that unique types of chemical reactions occur in outer space, and the actual products may result that are not achievable under the terrestrial environment. Several factors are believed to account for this, primarily zero gravity, through absence of oxygen and enhanced magnetic effects may also play a part. Several encouraging results have already been obtained. Among projects that have that have been carried out or are contemplated are the following:

- Uniform polymer microspheres that are over twice as large as possible on earth have been made due to zero gravity.
- More effective electrophoresis reactions for making biological biological materials have been discovered, probably also because of zero gravity.
- Possibilities exist for (a) making unique alloys in space that are not possible on earth, for example lead-copper, lead-zinc, and aluminum indium (b) purer crystals for microelectronics; (c) better glass for fiber optics; (d) new drugs and pharmaceuticals.

Future experiments will involve human cells, enzymes, and hormones. See also **Space Processing**.

SPACECRAFT DESIGN FOR PLANETARY EXPLORATION. Having only begun in the early 1960s, planetary-exploration spacecraft design is a fairly new art. Between 1962 and 1973, NASA designed, built, and launched 10 spacecraft named Mariner to explore Venus, Mars, and Mercury for the first time. In 1962, the Jet Propulsion Laboratory (JPL) launched the Mariner 2 spacecraft (Fig. 1) to explore Venus. In 1965, Mariner 4 flew by Mars and captured the first close-up photos of another planet.

Each year since 1962, NASA, the USSR, Japan, or the European Space Agency has launched at least one planetary-exploration spacecraft. Two of the best known are NASA's Voyagers (Fig. 2), which were launched in 1977, two years after NASA's Viking mission sent landers and orbiters to Mars (Fig. 3). Today, 24 years after launch, Voyager 2 has completed a tour of Jupiter, Saturn, Uranus, and Neptune, and still returns data from a distance of 64 AU (astronomical units, the average Earth–Sun distance; one AU is 150 million kilometers), which takes nearly nine hours of light time. NASA spacecraft have visited every planet in the solar system except Pluto, and orbited Venus, Mars, and Jupiter. In 1975, the USSR's Venera 9 and 10 spacecraft sent the first photos from the surface of another planet (Venus); in 1986, the European Space Agency's

Fig. 1. Mariner 2, launched in 1962, became the first spacecraft to fly by another planet, studying the Venusian atmosphere and surface. During its $3\frac{1}{2}$-month journey to Earth's neighbor, the craft made the first-ever measurements of the solar wind, a constant stream of charged particles flowing outward from the Sun. It also measured interplanetary dust, which turned out to be scarcer than predicted. In addition, Mariner 2 detected high-energy charged particles coming from the Sun, including several solar flares, as well as cosmic rays from outside the solar system. As it flew by Venus on 14 December 1962, Mariner 2 scanned the planet with infrared and microwave radiometers, revealing that Venus has cool clouds and an extremely hot surface. Mariner 2's signal was tracked until 3 January 1963. The spacecraft remains in orbit around the Sun. (*Image courtesy of NASA/JPL*).

Giotto spacecraft captured the first detailed photos of a comet's nucleus (Halley's). The NASA/JPL Cassini spacecraft entered Saturn orbit in 2004. The NASA/APL MESSENGER spacecraft is due to orbit Mercury in 2009. MESSENGER is being built by the Johns Hopkins Applied Physics Laboratory (APL), which also built the Near Earth Asteroid Rendezvous 10 (NEAR) spacecraft (Fig. 4) that orbited and touched down on the asteroid Eros in February 2001. See also **Mars**; **Viking Mission to Mars**; and **Voyager Missions to Jupiter and Saturn**.

Requirements and Constraints on Planetary-Exploration Spacecraft Design. PES design is a process that is driven by the unique nature of planetary-exploration missions and their scientific investigations. Mission and science requirements are used to determine spacecraft system-level requirements, and in turn subsystem requirements, as shown in Fig. 5. Basically, where the mission goes, how it gets there, and what it does drives the spacecraft design. The remainder of this section presents a brief discussion of important mission and system requirements and constraints that drive the design of a planetary-exploration spacecraft.

Mission Objective. The mission objective is to perform scientific exploration and investigation. To conduct the desired scientific investigation, it is necessary to transport the scientific payload to the destination and provide power, environmental protection, the proper instructions and orientation for performing measurements and the necessary communications technology for transmitting the resulting data to Earth. A large complex of people, computers, communication lines, and tracking antennae on Earth is needed to guide and support the mission.

Very High Standards. Two paramount constraints for all missions are that, once launched from Earth, spacecraft hardware can never be repaired,

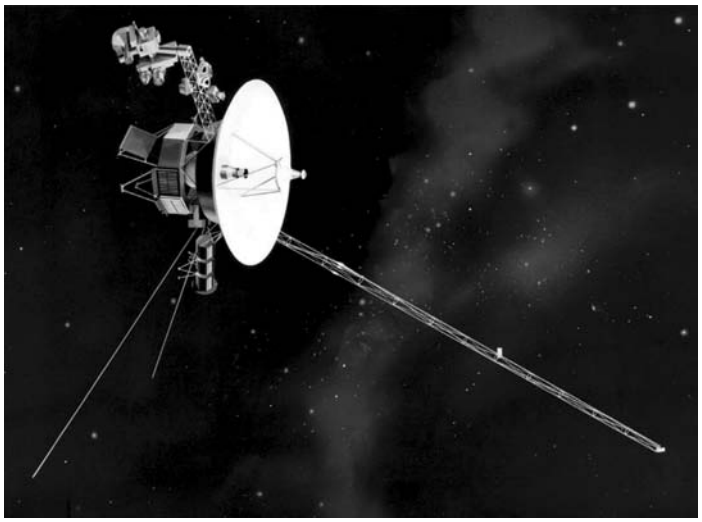

Fig. 2. The twin spacecraft Voyager 1 and 2 flew by and observed Jupiter and Saturn; Voyager 2 went on to visit Uranus and Neptune. In 1998, Voyager 1 became the most distant human-made object in space. (*Image courtesy of NASA/JPL*).

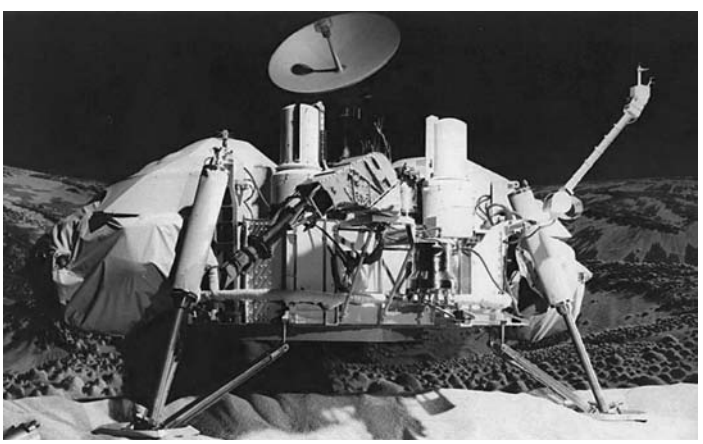

Fig. 3. The Viking Mars Lander spacecraft is shown here. Viking 1 landed on Mars on 20 July 1976, and Viking 2 landed on 3 September 1976. Viking 1 was the first successful soft landing of a spacecraft on Mars. The two Viking spacecraft were identical, and they sent back photographs of the Martian surface. They also collected a wealth of data on atmospheric composition, meteorological conditions, soil samples, and seismic activity. Each Viking spacecraft also carried a set of experiments that looked for biological activity on the surface of Mars. The results were negative. Viking 1 transmitted data for more than six years. Viking 2 was shut down on 11 April 1980. (*Image courtesy of NASA/JPL*).

and there is very low tolerance for any failure. Because overwhelming media coverage ensures that the world will instantly learn of any problem, no space agency that commits public resources to build, launch, and operate a PES welcomes even the perception of failure. All of this creates enormous pressure on a PES and its mission to succeed. Consequently, the spacecraft must be designed, built, and operated to extraordinarily high standards.

Instruments. The fundamental function of a PES, (what it does) is to transport the instruments needed to perform the scientific and exploratory investigations. Most of these instruments are passive devices that operate in parts of the electromagnetic spectrum, including long-wavelength radio waves, the infrared (IR), visible, the ultraviolet, X-Rays, and gamma rays. Some instruments, such as radar and light detection and ranging (LIDAR), are active-sensing. The instruments place requirements on the spacecraft, such as mass, power, pointing, data rate, and data volume. Some instruments place special requirements on the PES. Spacecraft that carry sensitive magnetometers must be "magnetically clean"; that is, designs must specify special electronic parts, shielded components, and sometimes equipment to generate and maintain offsetting magnetic fields. To avoid

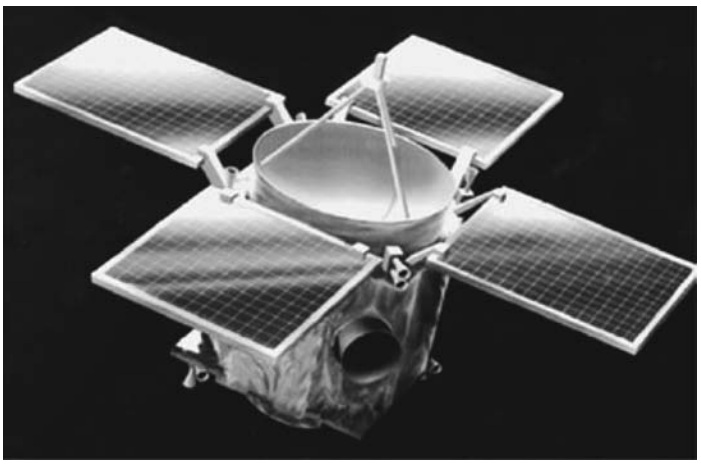

Fig. 4. In 1996, NEAR-Shoemaker was the first Discovery Program spacecraft to be launched, and five years later, in February 2001, it became the first ever to orbit and land on an asteroid. Using six highly specialized instruments to gather data about its primary target, asteroid 433 Eros, NEAR has answered many fundamental questions about the nature and origin of asteroids and comets. The spacecraft snapped 69 detailed pictures during the final 3 miles (5 km) of its descent, the highest resolution images ever of an asteroid that showed features as small as one centimeter across. (*Image courtesy of NASA/JPL*).

receiving its own spacecraft emissions, for example, a magnetometer may need to be flown at the end of a long boom; this greatly affects the attitude control-system design. A gamma-ray detector onboard means that overall spacecraft emissions must be checked and components altered or removed so that their output does not swamp the target planet's signals.

Planetary Protection. Planetary protection is a unique requirement for planetary spacecraft. It means protecting another planet's environment from Earth's biological contamination and protecting Earth's environment from extraterrestrial contamination. Usually applied to landers, it is critically important for those missions whose objective is to return a sample of another planet to Earth; it also applies to orbiters whose orbit may someday degrade, causing the spacecraft to hit the surface. To illustrate, consider the Mars orbiter that NASA o launched in 2005. The planetary protection requirements for this mission are that:

- all flight hardware is to be assembled and maintained in class 100,000 clean rooms (or better);
- the probability of an impact on Mars by any part of the launch vehicle (including the upper stage) that leaves the vicinity of Earth must not exceed 10^{-4}; and
- the probability of an impact on Mars by the orbiter due to all causes must not exceed 0.01 for the first 20 years after launch and 0.05 for the succeeding 30-year period. To meet part of the third requirement, the flight system must be designed with a reliability for the mission (launch through the attainment of the final orbit) better than 0.99, and the spacecraft-ballistic coefficient must be considered.

Solar System. The most important influence on the design of a planetary-exploration spacecraft is the solar system itself. A spacecraft designed to travel the solar system must successfully operate in the solid-particle and radiative environments of the solar system. The spacecraft must operate far from Earth and at a Sun range greatly different from 1 AU. The large Earth range implies a significant light time for signals sent to and from the spacecraft, long trip times to the final destination, and the need for precise navigation. Launch dates for PES are inflexible, may occur only once every 2 years (or less frequently), and are set by the well-known, but totally inflexible motion of the planets around the Sun.

Rigid and Infrequent Launch Windows. Solar system dynamics are well known, totally fixed, and make for rigid, inflexible, and infrequent launch windows separated by many years — even decades. There is enormous pressure to deliver interplanetary missions to the launch pad on time because missing a window results in intolerable consequences for missions and careers alike. For Mars, for example, a mission may have to wait two years for the next opportunity. Missions to the outer planets may wait much

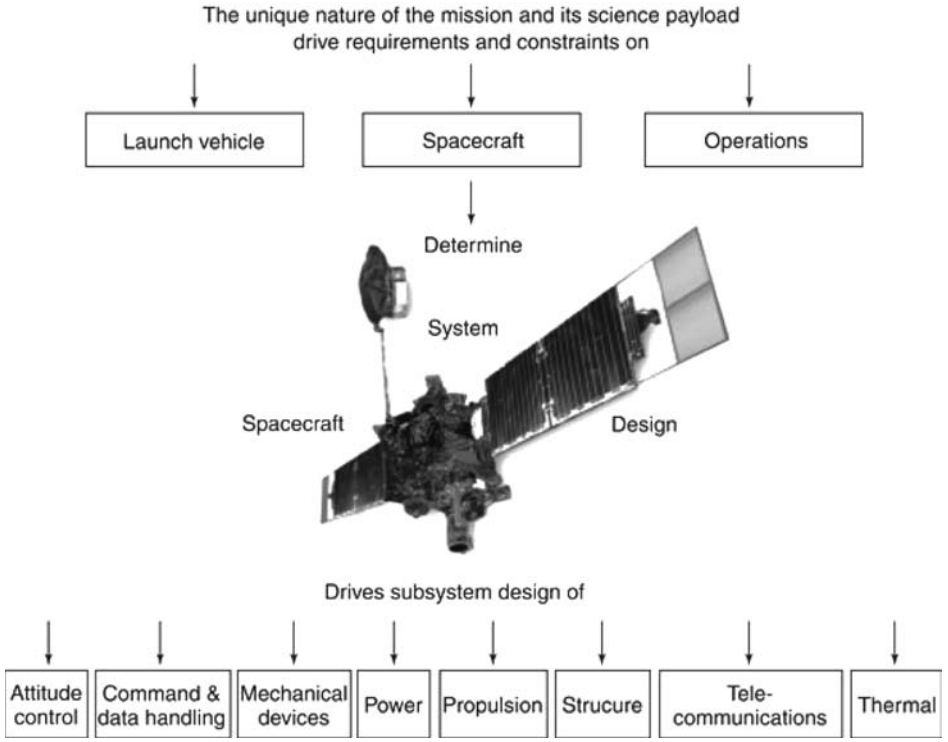

Fig. 5. Planetary spacecraft design flow.

longer. The alignment of the planets Jupiter, Saturn, Uranus and Neptune that the Voyager 2 spacecraft used for minimum trip time occurs about once every 175 years. In contrast, if an Earth-orbiting spacecraft arrives late for a launch window, another one will open in the following week or month. Compared to a typical Earth orbiter, a planetary spacecraft's launch opportunities are very infrequent, and the consequences of failure are especially severe. This consequence of failure creates a greater need for high reliability that is usually implemented through greater robustness in design (parts quality, fault protection, and use of redundancy).

Round-Trip Light Time. An important spacecraft-design constraint is round-trip light time — the minutes or hours that it takes for a distant spacecraft's signal to reach Earth, plus the control-signal return time. Because of the solar system's vast expanse, a typical Earth-to-PES distance is usually many orders of magnitude greater than the Earth-to-Earth-orbiter distance. A PES at 1 AU from Earth, for example, is 4200 times farther away than a geosynchronous Earth orbiter (GEO), which receives a ground signal from Earth in only a tenth of a second. A spacecraft at Mars may be as much as 2.5 AU from Earth — a one-way, light-travel time of 20 minutes. At Saturn, Cassini's maximum distance to Earth requires a one-way, light-travel time of more than 1.5 hours. Despite PES radio signals traveling at the speed of light, the spacecraft designer must consider the long time signals take between spacecraft and Earth.

To minimize mission risk so that it is similar to that of an Earth orbiter, distant spacecraft must operate more autonomously, especially regarding fault detection and recovery. Long round-trip light time affects the way planetary spacecraft are commanded. An Earth orbiter can wait for a command signal before it transmits its recorded telemetry; a planetary spacecraft cannot. Spacecraft that perform split-second events, such as landing on Mars, cannot afford to wait for a command to be acknowledged before another is sent. For example, if a spacecraft transmits a distress signal, while executing split-second events, such as entering Mars' atmosphere, Earth would receive it only after the probe is on Mars' surface — too late for ground controllers to help.

Earth Range. A spacecraft's telecommunications subsystem is especially driven by a planetary explorer's large Earth range (distance to Earth). The strength of the received signal is inversely proportional to the square of the range. The power per unit area received from a GEO spacecraft is 4200 squared or 72 dB larger than that from the planetary spacecraft at a range of 1 AU from Earth. To receive low-strength signals, NASA built special ground stations collectively called the Deep Space Network (DSN) (Fig. 6). The DSN is an international asset that tracks planetary spacecraft from many countries, and the DSN receiving network has special interface requirements for planetary spacecraft. Because navigating interplanetary space requires extremely accurate clocks, the DSN uses a hydrogen-maser-based frequency reference whose accuracy is equal to the gain or loss of 1 second in 30 million years. The maser is a reference that generates an extremely stable uplink frequency that the spacecraft uses, in turn, to generate its coherent downlink.

Even using the DSN, a planetary probe's uplink and downlink data rates are lower than those of an Earth orbiter. If a planetary spacecraft is turning very quickly because of a mission need or tumbling because of a fault, low uplink rates can preclude commanding. Because of the high signal strength, an Earth orbiter can receive a command in nearly any attitude, but distant planetary probes must be in specific attitudes or they will not receive the signal. A limited downlink rate can strongly drive data storage, data compression, and optimal recording of data. A limited downlink rate may also mean that a spacecraft can transmit only a small part of the data that its instruments can produce.

Mission Energy and Trip Time. The destinations for planetary spacecraft are energetically a "long way from Earth." The mission energy manifests itself not only in the required change in spacecraft velocity (known as ΔV) for departure from Earth and after launch but also in trip time to the destination. Because the required mission energies are so large, most planetary mission trajectories are "minimum energy" trajectories. A consequence of these "minimum energy" trajectories and the vast distances are long trip times to the destination. The largest ΔV for Earth-orbiting spacecraft is normally required by a geosynchronous communication spacecraft where the ΔV required to go from low Earth orbit (LEO) to GEO is about 4200 m/s. The total ΔV beyond LEO for some typical planetary missions are as follows. For a low, circular Mercury orbiter where the trip time is about 4 years, the required ΔV is 7000 m/s. A direct 0.4-year trip to a low Venus orbit requires about 6900 m/s. For a Pluto orbiter that has a 20-year trip time, 15,000 m/s is required. Usually, the launch vehicle for both Earth orbiters and planetary spacecraft supplies part of this ΔV. Several of these planetary missions have not been performed because the combination of ΔV and trip time is so large.

Because of the large ΔV for many planetary missions, methods besides traditional chemical propulsion have been developed, such as electric propulsion systems and the use of the target-body atmosphere to aid

Fig. 6. The Deep Space Network (DSN) is an international network of antennae that supports interplanetary spacecraft missions and radio and radar astronomy observations that explore the solar system and the Universe. Via its vital, two-way communications link, the network guides and controls interplanetary explorers and brings back the images and new scientific data that they collect. All DSN antennae are steerable, high-gain, parabolic-reflector antennae. (*Image courtesy of NASA/JPL*).

in capture at the planet. Aerobraking, as this is known, is a technique wherein the spacecraft is deliberately flown into the top of the target planet's atmosphere. There, the drag on the spacecraft acts like a brake, and spacecraft energy is dissipated. Aerobraking uses almost no propellant to provide ΔV to change the kinetic energy of the spacecraft. The NASA/JPL Mars Global Surveyor spacecraft (Fig. 7) and also the Mars Odyssey spacecraft (Fig. 8) that arrived at Mars in 2001 used aerobraking. See also **Mars Global Surveyor Mission**; and **Mars Odyssey Mission**.

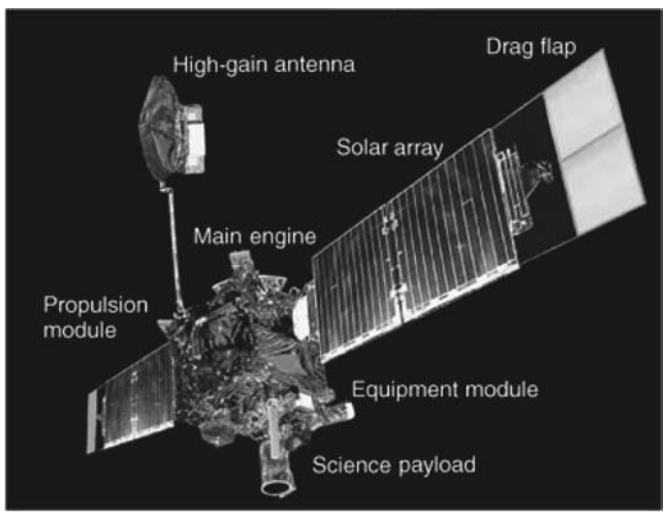

Fig. 7. The Mars Global Surveyor (MGS) entered Mars' orbit in late 1997 and was the first successful mission to the red planet in two decades. MGS scientific instruments include a high-resolution camera, a thermal-emission spectrometer, a laser altimeter, a magnetometer/electron reflectometer, an ultrastable oscillator, and a radio-relay system. Beginning its prime mapping mission in early 1999, MGS studied the entire Martian surface, atmosphere, and interior from a low-altitude, nearly polar orbit during one Martian year (almost two Earth years). Having completed its primary mission in early 2001, it continues in an extended mission phase. MGS has returned more data about the red planet than all other Mars missions combined. (*Image courtesy of NASA/JPL*).

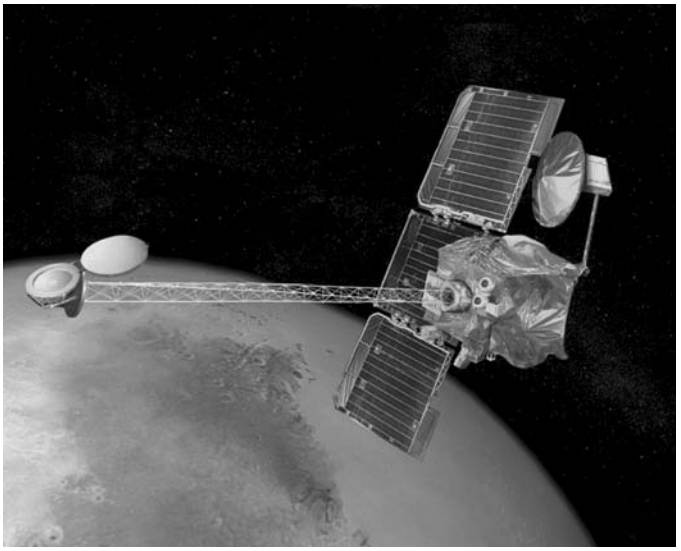

Fig. 8. Mars Odyssey has a mass of 758 kg and carries scientific instruments, including a thermal emission imaging system, a gamma-ray spectrometer, and a Mars radiative environment experiment. It arrived at Mars in late 2001. The Odyssey orbiter's mission is to determine the planet's surface composition; detect water and shallow, buried ice; and to study the radiation environment. In May, 2002 Odyssey scientists announced that their instruments had detected enormous quantities of water ice just below Mars surface. It has long been thought that Mars' surface consists of rock, soil, and icy material, but the exact composition is largely unknown. Odyssey will help identify soil minerals and surface rocks, and it will study small-scale geologic processes, as well as future landing-site characteristics. By measuring the amount of hydrogen in the entire planet's upper meter of soil, the spacecraft will uncover the amount of water available for future exploration and also more clues about Mars' climatic history. The orbiter will also collect radiation data to help assess risks to future human explorers, and it will act as a communications relay for future Mars Landers. (*Image courtesy of NASA/JPL*).

Long trip times and minimum-energy trajectories require that planetary spacecraft be extraordinarily reliable. Some Earth orbiters may live as long as 15 years, but their operations in orbit begin only a few weeks after launch. For many planetary spacecraft, their missions do not begin until they reach their targets, which could take years. For example, Voyager 2 traveled 12 years before it successfully encountered Neptune. The Cassini probe must travel for 6.6 years before its Saturn orbital operations begin. So, it is many years after launch that these spacecraft maneuver for orbit insertion and open into their final mechanical configuration. The ship's mechanisms, components, and instruments must remain workable during those years traveling through space and when activated, must perform perfectly.

Extended missions also affect spacecraft operations. For example, when cruise time is lengthy, additional operational modes, software, and procedures are needed. Because of personnel turnover during missions measured in decades, retraining is also absolutely critical if fatal errors are to be avoided in the mission's end game, when the people who designed the final procedures have moved on. To reduce peak-year costs for multiyear-missions, command sequences for planetary encounters are not developed until after launch. Therefore, spacecraft design must accommodate new flight software that will be tested "on the fly." Changes in data-system technology also affect lengthy missions, and vice versa. Ground-system components, for example, may be upgraded during the mission. On the positive side, for long-cruise-time missions, there is time to diagnose and hopefully correct any errors before the primary mission begins.

Space Radiation Environments. Because the planetary-spacecraft environment is very different from that of an Earth orbiter, it also impacts the system. Although usually stable, this distant environment is uncertain; one of the mission goals may be to learn more about it. To keep the risk level close to that of an Earth orbiter, a distant mission may require more environmental analysis and margin. PES design must accommodate

space radiation and solid particles. The three types of space-radiation environments are planetary-trapped radiation, galactic cosmic radiation, and solar-energetic particles.

Because the trip through them is short, spacecraft are not affected by Earth's radiation belts, but other planetary belts can be a serious threat. Even short gravity-assist passages through Jupiter's system, for example, will expose the spacecraft to most of a mission's total radiation dose. Heavy-ion fluxes will also disrupt critical mission functions that have single-event effects (SEE).

Galactic cosmic radiation (GCR) is composed of high-energy nuclei. Earth's magnetic field provides some shielding against this radiation for spacecraft in low-to-medium Earth orbits. Even so, the radiation flux from GCR in interplanetary space is low and does not contribute significantly to the mission's total ionizing dose, but sufficient heavy ions are present in the GCR populations to create a SEE threat to some electronic parts throughout the mission.

Solar-energetic particles are also attenuated by Earth's magnetic field, but in interplanetary space, fluxes due to a given solar event may be two to three times more intense than near Earth and thus present both a total dose and SEE threat. When they are outside Earth orbit, solar-event fluences dissipate in inverse proportion to the square of the heliocentric distance. So, outer planet missions are reasonably safe. But inside 1 AU, it is a different story. The hazards of solar-event radiation can be considerable for missions that visit Venus or Mercury. For instance, even a moderate solar event can incapacitate a spacecraft that passes close to the Sun.

The solid-particle danger to interplanetary spacecraft has two origins: micrometeroids (particles that orbit the Sun) and dust (particles that orbit other solar-system bodies). Artificial debris is encountered only in a mission's immediate post launch phase. Although there are few particles in interplanetary space, encounter velocities are high ($\sim$15–50 km/s) and can be very damaging. The nature of the encounter dictates the velocity. Because Cassini will go into a Saturn orbit, its encounter velocity with the planet's ring particles is much lower than Voyager's speed when it passed close to Saturn to obtain a gravity assist. See also **Space Radiation**.

Sun Range. The Sun range (distance to the Sun) especially affects PES power and thermal-control subsystems. Widely varying spacecraft–Sun distances — especially when they change during a mission — dramatically impact the design. For example, Cassini flew by Venus (0.6 AU) for gravity assists and headed out to Saturn (10 AU) to conduct its prime mission. See also **Cassini Mission to Saturn**. A Mercury orbiter encounters a huge thermal range: its illuminated side receives 10.6 suns (mainly short-wave IR), and the other side sees 8.5 suns (long-wave IR reflected from the planet's surface). And a few hours later in solar eclipse, the orbiter will see no "suns" on either side.

Sun-range effects on the power subsystem are directly opposite, depending on whether the mission destination is less than or greater than 1 AU. Spacecraft going to the inner planets have the problem that their power output increases with mission time, up to a point where solar cells developed for Earth orbiters are no longer usable without special coatings, or they are not usable at all. The spacecraft may solve its excess-heat problem by pointing away from the Sun or by shunting the excess power and radiating the excess as heat.

The opposite problem is true for a spacecraft bound for an outer planet, because its solar-array power gradually drops off and finally stops. Special solar arrays designed for low-light, low-temperature conditions are required. In some cases, a PES will use a radioisotope thermoelectric generator (RTG) for electric power production. Another problem for outbound spacecraft is that unless "makeup heat" is provided or heat is conserved, components may cool below safe operating temperatures. Experience dictates that outer-planet missions must invest more of their development time and money in power-efficient technologies.

Navigation. Because of the size of the solar system and the motions of the planets, a planetary-exploration spacecraft must be carefully navigated to its destination. Radiometric data can be used to determine spacecraft position relative to a planet — to within a few kilometers at best. Velocity data are accurate to within a few tenths of a mm/s. Nongravitational acceleration caused by unplanned or unmodeled spacecraft accelerations such as outgassing, leakage, or uncoupled attitude-control maneuvers can greatly affect spacecraft navigation. Acceleration due to these forces must be kept within a few mm/s^2, accurately modeled, and reported. In 1999, perhaps because of an error in modeling these forces, engineers believe that the Mars Climate Orbiter entered the Mars atmosphere too low to achieve orbit and probably burned up. See also **Spacecraft Guidance, Navigation And Control Systems**.

Planetary-Exploration Spacecraft Subsystem Design. Subsystems are individually tailored and integrated to implement the overall system design. Subsystems include structure, thermal, mechanical devices, command and data handling, attitude control, telecommunications, power and propulsion.

Structure. The structural subsystem includes primary and secondary mechanical and structural members that support and align all spacecraft flight subsystems and equipment during ground handling, launch, and flight. Structure also protects against natural and induced environments such as vibration, meteoroids, radiation, and electromagnetic interference. Generally, the structure subsystem of an Earth-orbiting and a planetary spacecraft are alike.

Thermal. The thermal subsystem heats or cools spacecraft components to maintain them within operating (and nonoperating) temperature ranges. This function includes meeting special temperature requirements of components such as batteries and cryogenic instruments. Temperature control must be effective throughout the mission's prelaunch, launch, cruise, and operational phases.

Stated simply, this is a planetary spacecraft's thermal-design strategy: Use passive components whenever possible because they use less power, operate more simply, and are thus more reliable than active ones. The idea is to minimize temperature sensitivity due to external and internal heat fluctuations and emphasize passive techniques (for example, blankets, radiators, coatings) over active ones (for example, heat pipes, fluid loops, thermostatically controlled heaters).

Earth orbiters have "in Sun" and "in eclipse" design points, whereas planetary orbiters have "in Sun" and "in eclipse" conditions that may vary dramatically during the mission because of the change in Sun range. To design the thermal subsystem confidently for a planetary mission, additional thermal analyses and testing are required. In addition, for those missions going closer than 1 AU to the Sun, available thermal-control materials and paints may be limited, and entirely new ones may need to be developed. A requirement to keep large amounts of propellant at a given temperature during a long cruise between launch and orbit insertion may be the main power and thermal design driver.

All spacecraft use multilayer blankets for thermal control. For PES, the multilayer thermal-insulation blankets also provide some protection against micrometeoroid impacts. They are made of Kapton, Kevlar, or other fabrics strong enough to absorb energy from high-velocity micrometeoroids before they damage spacecraft components. Impact hazards are greatest when crossing the ring planes of the Jovian planets. Voyager recorded thousands of hits in these regions, fortunately from particles no larger than smoke particles. Spacecraft, sent to comets such as Stardust, carry massive shields to protect them from hits by larger particles. See also **Stardust Mission**.

Mechanical Devices. Mechanical devices perform functions such as separating a spacecraft from its launch vehicle, deploying booms, articulating high-gain antennae and solar arrays, jettisoning aeroshells and deploying parachutes, releasing instrument covers, and controlling fluid flow in propulsion and pressurization systems. These devices must operate at 100% reliability for many years after launch. Earth orbiters achieve their final spacecraft mechanical configuration early in their lifetime. But, because cruise time to a mission site is very long, it may be many months or years before a PES assumes its final mission configuration. The final deployment of the Mars Observer spacecraft's solar panels, high-gain-antenna boom, and a science-instrument boom were to have occurred after insertion at Mars, nearly 1 year after launch.

The Cassini spacecraft released a large Titan atmospheric probe 7 years after launch. There is always concern that mechanical-actuation devices may be less reliable after a long time in space. Because these devices are candidates for single-point failures, a design remedy is to add redundant actuators. Mars Pathfinder, which successfully deployed Sojourner rover (Fig. 9) on Mars, depended on 42 pyrotechnic events during its successful atmospheric entry, descent, and landing. Design practices emphasize large strength or force margins, redundancy where

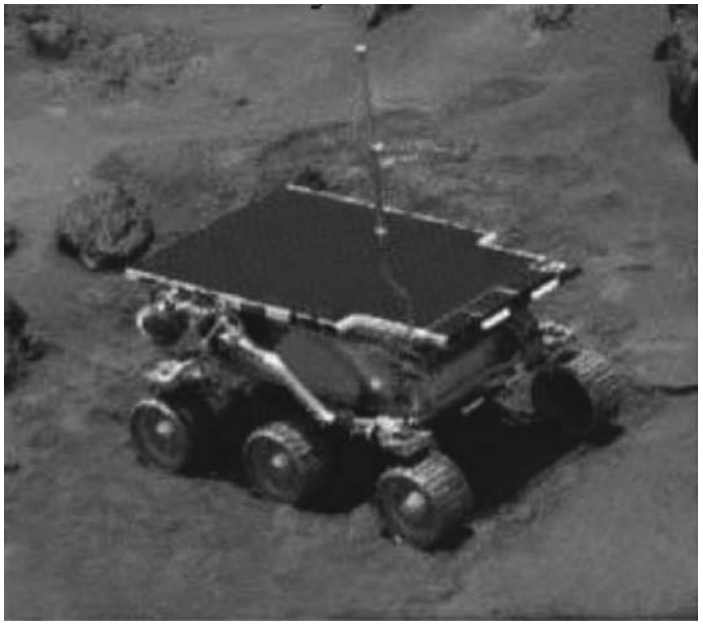

Fig. 9. The Mars Pathfinder's Sojourner rover is 280 mm high (11 inches), 630 mm (25 inches) long, and 480 mm (19 inches) wide. Using rover and lander images, an Earth-based operator controlled the rover. But, because of the light-time delay of 10–15 minutes, an onboard, hazard-avoidance system allowed it some autonomous control as it explored the surface, so it would not always have to wait for commands from Earth. On the rover, 0.2 square meters (0.7 square feet) of solar cells, provide energy for several hours of operations per sol (1 Martian day = 24.6 Earth hours). (*Image courtesy of NASA/JPL*).

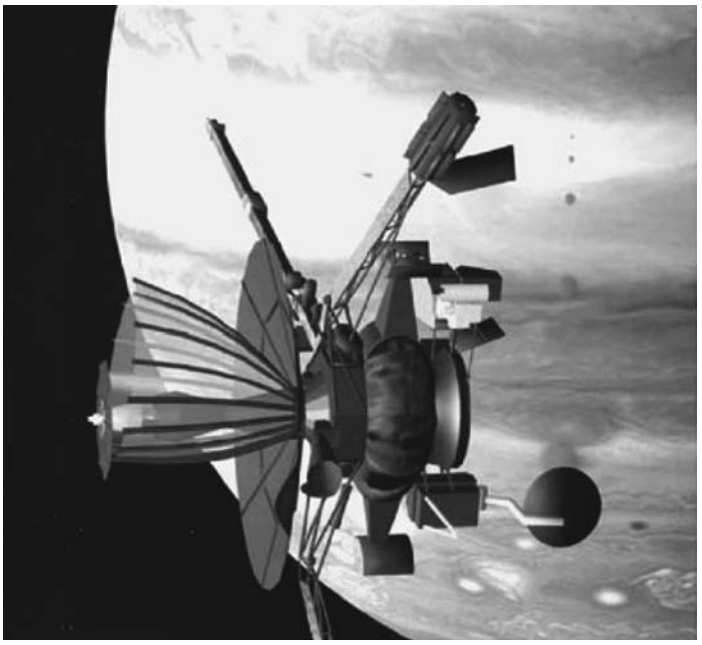

Fig. 10. The Galileo spacecraft arrived at Jupiter in late 1995, entered orbit, and dropped its instrumented probe into the giant planet's atmosphere. Since then, it has made dozens of orbits around Jupiter and flown close to each of its four major moons. Galileo discovered that the cratered surface of Jupiter's moon, Europa, is mostly water ice, and there is strong evidence that it may cover an ocean of water or slushy ice. Galileo also found indications that two other moons, Ganymede and Callisto, have layers of liquid saltwater as well. Half of the spacecraft contains pointable instruments, such as cameras, and is held fixed in relation to space; the other half, containing instruments that measure magnetic fields and charged particles, slowly rotates to optimize the measurements. Other major scientific results include details of varied and extensive volcanic processes on the moon Io, measurements of conditions within Jupiter's atmosphere, and the discovery of a magnetic field generated by Ganymede. Despite heavy radiation doses, Galileo continues to return scientific data in an extended mission phase. (*Image courtesy of NASA/JPL*).

practical (for example, bearings within bearings), vacuum-compatible materials and lubricants, and special attention to the effects of thermal expansion and contraction. All mechanical devices are extensively tested to verify margins and lifetime, and intentional "fouling" tests are conducted to achieve extra confidence. A mechanical actuation system that successfully operated on an Earth orbiter may fail to work on a planetary spacecraft. An example is the Galileo (Fig. 10) spacecraft's high-gain antenna that failed to open completely. Though the actual cause will never be known, extensive prelaunch handling — rather than the long-storage time en route to Jupiter — may have been the culprit.

Command and Data Handling. The brain and memory of a spacecraft are the command and data–handling subsystem (C&DH). Consisting mainly of computers, memory, and input/output devices, it also provides the spacecraft's time reference. The C&DH also performs real-time and preprogrammed functions such as decoding ground commands; distributing discrete and coded commands to subsystems; responding to onboard-generated events; and collecting, managing, and storing scientific and engineering data. Primary design considerations include processor speed, quantity, and access speed of memory, as well as fault-detection-and-correction techniques. In some cases, onboard processing of optical-navigation images may be required to reduce the quantity of data transmitted to Earth or to reduce response time for critical events. The need for autonomous fault-diagnosis and recovery on planetary spacecraft requires that designers develop, design, and validate additional onboard software. And in turn, fault-protection software needs computer memory, processing power, and additional telemetry data.

Compared with an Earth orbiter, a planetary spacecraft must have additional intelligence and autonomy to monitor and control itself. The PES is always a great distance from home, is tracked as little as once per day or week, and cannot communicate with Earth during certain periods. For example, during superior conjunctions (when the spacecraft and Earth are on opposite sides of the Sun), autonomous fault-protection software must intervene in case of an onboard failure. Light time and tightly constrained tracking schedules prohibit ground teams, who control and monitor the spacecraft, from immediately responding to onboard anomalies. When failures occur, C&DH fault-protection algorithms must detect them and in the case of a communications interrupt, reestablish contact with Earth. A spacecraft may have many different fault-protection monitoring algorithms running simultaneously and must be prepared to request C&DH to take action. The command-loss timer, for example, is reset to a predetermined value, for example 1 week, each time a command arrives from Earth. If the timer runs down to zero, it is assumed that the receiver or another component in the command string suffered a failure. The fault-protection response may then be to switch to redundant hardware to reestablish radio contact with Earth.

Other fault-protection responses include requesting safe mode; shutting down or reconfiguring components to prevent damage; or performing an automated, methodical search to re-establish Earth-pointing to regain communications. Though entering safe mode may temporarily disrupt scientific data gathering, it provides reliable spacecraft and mission protection. Read-only memory (ROM) usually carries a minimal set of safe-mode instructions (the Magellan spacecraft (Fig. 11) ROM contained only 1 kB of this code); commands can hide in ROM for the worst imaginable scenarios of runaway-program executions or power outage. More intricate safe-mode and fault-protection routines (for example, "contingency modes") and parameters for use by the ROM code typically reside in random access memory (RAM), where they can be updated as needed during the mission lifetime. See also **Magellan Mission to Venus**.

Attitude Control. The attitude control subsystem keeps spacecraft motions stable and precisely points and orients the spacecraft (or single instruments) despite gravity gradients, propulsion-system torque, solar pressure, and sometimes micrometeoroid impacts. Precise pointing is important because the high-gain antenna has to acquire Earth contact; scientific instruments must collect data; thermal radiators have to be properly positioned; Sun-and-star sensors must provide attitude references; and to generate maximum power, solar panels have to be Sun-oriented.

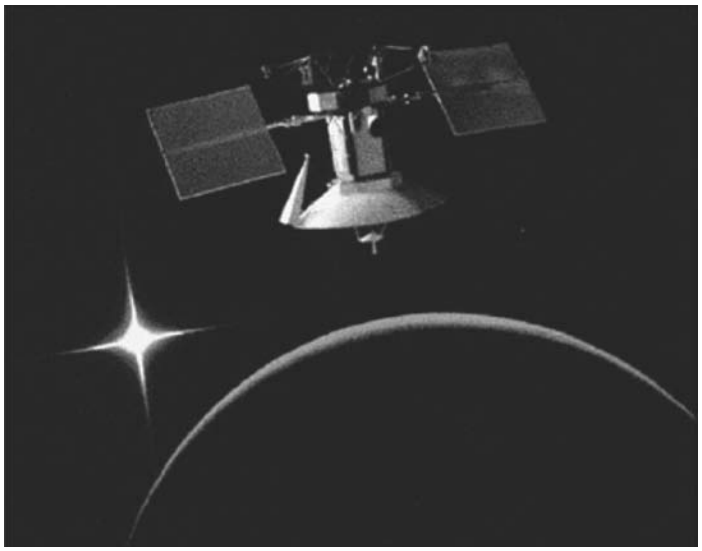

Fig. 11. The Magellan spacecraft was carried into Earth orbit by the Space Shuttle Atlantis and was propelled to Venus by a solid-fuel motor. Entering orbit in late 1990, Magellan pierced Venus' veil of swirling clouds, mapped its surface with its imaging radar, and dramatically improved upon the mapping resolution of orbiters that the United States and the Union of Soviet Social of Republics sent in the 1970s and early 1980s. Flight controllers tested a new maneuvering technique called aerobraking that uses a planet's atmosphere to slow a spacecraft. At mission end in 1994, Magellan's orbit was lowered a final time, and it plunged to the planet's surface; contact was lost the following day. (*Image courtesy of NASA/JPL*).

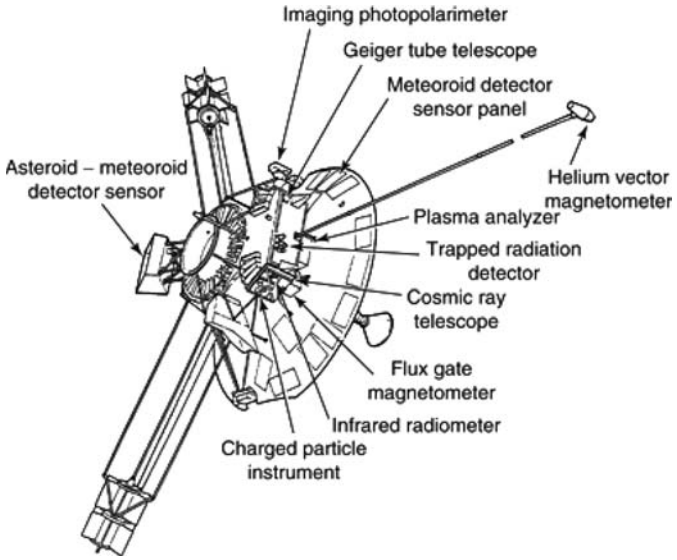

Fig. 12. Pioneer 10 and 11 spacecraft: Pioneer 10 was launched in 1972 and flew past Jupiter in 1973. The spacecraft measured the radiative field, the magnetic field, and other elements of the environment to prepare the way for the Voyager spacecraft that was launched in 1977 (see Fig. 2). Pioneer 10 was the first spacecraft to fly past the asteroid belt, to fly past Jupiter, and the first-human-made object to leave the solar system as defined in extent by the orbit of Pluto in 1983. Pioneer 11 was launched in 1973 and was the first spacecraft to fly past both Jupiter and Saturn. In 1979, Pioneer 11 passed between Saturn and the ring plane just outside the A-ring and its visible ring to ensure that Voyager 2 could make a thorough investigation of the Saturn system during its flyby in 1981. (*Image courtesy of NASA/JPL*).

The spacecraft must also point in the correct direction to make precise trajectory-control maneuvers.

Because large amounts of propellant can be expended, the attitude-control subsystem design must take into account the resulting dramatic changes in a spacecraft's inertial properties as a function of mission time. A PES is not orbiting Earth, so the attitude-control subsystem must operate differently. Spacecraft orbiting other planets sometimes use horizon sensors, so Earth-horizon sensors must be adapted to a different atmosphere or no atmosphere. GPS receivers cannot be used for orbit or attitude information. Without Earth as an attitude reference, planetary spacecraft become highly dependent on celestial sensors and celestial-attitude determination. Without a well-characterized, adequately strong magnetic field, magnetic-torque rods cannot be used for attitude maneuvers or to desaturate reaction wheels. Planetary spacecraft may be sent to orbit planets that have magnetic fields (Jupiter), but usually the magnetic field is not well enough known to be used for attitude determination and control.

Because of the various forces acting on it, an unstabilized spacecraft will acquire rotational motion and tumble chaotically. Like Earth-orbiting spacecraft, a PES may be spin-stabilized or three-axis controlled. Spinners that are relatively inexpensive have been used in precursor missions to the outer solar system. Pioneers 10 and 11 (Fig. 12.) were intended to explore the environments of Jupiter and Saturn through which the more sophisticated Voyager spacecraft would have to pass. For spinners, the gyroscopic action of the rotating spacecraft mass is the stabilizing mechanism. Propulsion-system thrusters are fired only occasionally to make desired changes in the spin-stabilized attitude.

Spinners have also been used to launch probes into planetary atmospheres. In this case, the mother ship imparts the proper attitude and spin rates. Examples of this are the Pioneer Venus Multiprobe Spacecraft (Fig. 13) and the Galileo Probe into the atmosphere of Jupiter (Fig. 10). Finally, spinners can be used effectively for radar-altimetry mapping missions such as the Pioneer Venus Orbiter (1978) and the recently completed Lunar Prospector Mission (Fig. 14). See also **Lunar Prospector Mission**.

Alternatively, a spacecraft may be designed for active three-axis stabilization. One method is to use small propulsion-system thrusters to nudge the spacecraft back and forth continuously within a dead band of allowed attitude error. Voyagers 1 and 2 have been doing this since 1977 and have consumed about 70 kg (154 lbs) of their 106 kg (234 lbs)

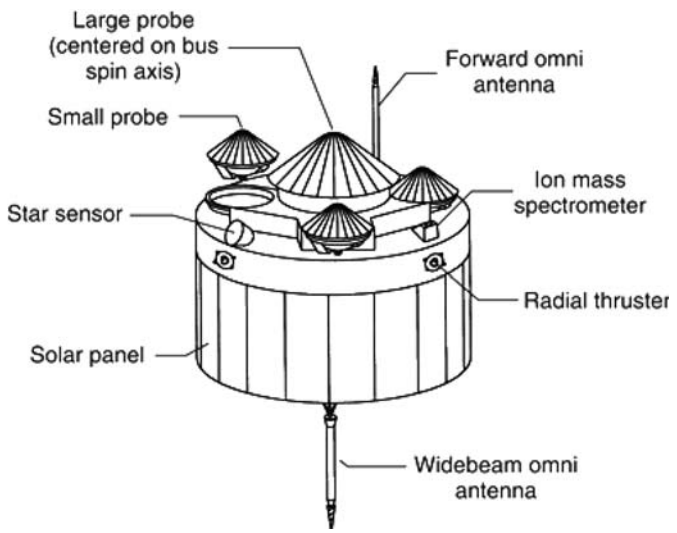

Fig. 13. The Pioneer Venus Multiprobe Spacecraft was launched in 1978. It investigated the Venusian clouds and atmosphere by releasing one large probe and three small probes to sample the structure and composition of the clouds, winds, chemical composition, temperature, density, pressure, infrared radiation, and the planet's interaction with the solar wind. (*Image courtesy of NASA/JPL*).

of propellant as of April 2001. They are using propellant at the rate of about 7 grams (0.25 ounce) per week. Another method is to use electrically powered reaction wheels, as on Mars Global Surveyor and the recently launched Mars Odyssey. Reaction wheels provide a means to trade angular momentum back and forth between spacecraft and wheels. To rotate the vehicle in one direction, you spin up the proper wheel in the opposite direction. To rotate the vehicle back, you slow the wheel. Excess momentum that builds up in the system due to external torques, caused for example by solar-photon pressure or gravity gradient, must be occasionally removed from the system by applying torque to the spacecraft and allowing the wheels to acquire a desired speed under computer control. This is done

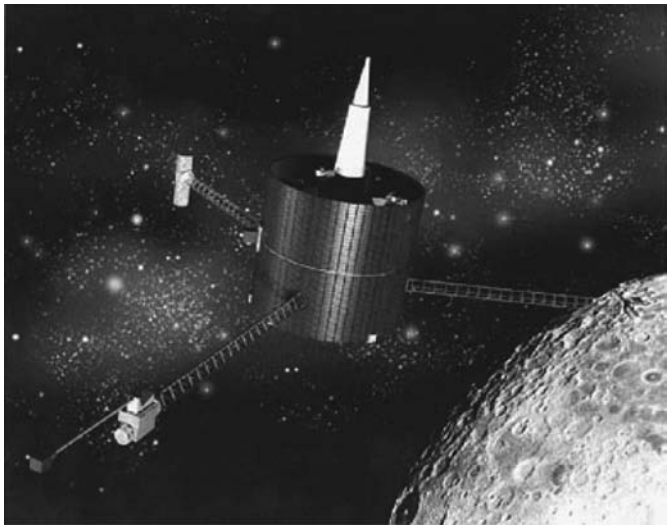

Fig. 14. Lunar Prospector's controlled crash into a crater near the South Pole of the Moon in 1999 produced no observable signature of water, but from Prospector's data collected during the mission while in orbit, scientists estimate that up to six billion metric tons of water ice may be buried in craters near the Moon's South and North Poles. Mission findings were also used to develop the first precise gravititational map of the entire lunar surface. (*Image courtesy of NASA/JPL*).

during maneuvers called momentum desaturation or momentum-unload maneuvers.

Telecommunications. The telecommunications subsystem provides communication to and from Earth for spacecraft navigation, commanding, and telemetry. Its hardware includes antennae, transponders, and amplifiers. The key functions are signal modulating, demodulation, and some types of data encoding. The key performance parameter is the number of bits per second (bps) that can be transmitted. Among other parameters, the data-rate performance is proportional to transmitter power, the area of the transmitting and receiving antennae, and the square of the transmitting frequency. Planetary-exploration spacecraft use the same Ka-, S-, and X-frequencies as other spacecraft, but there are special frequency allocations for deep space that differ from those for Earth-orbiting spacecraft. During the past 25 years, there has been a trend toward higher frequencies for spacecraft telecommunications, from S- to X- and now to Ka-band (32 GHz). Researchers are developing optical communication systems that provide greatly increased performance because of their higher frequency. The current state-of-the-art interplanetary data transmission rate over the Mars range ($\sim$2 AU) is about 85 kbps, but currently NASA is considering a Mars mission in 2005 that may use a data rate as high as 2 Mbps.

In addition to the primary function of transmitting data to Earth and receiving commands, the telecommunications subsystem is an important element in the navigation system for PES and sometimes is used as part of a scientific investigation. Because of the extreme distances across which planetary spacecraft must be navigated, highly accurate radiometric data are required. To obtain typical accuracy requirements of a few meters for range measurements and 0.1 mm/s for Doppler, a well-calibrated, coherent-ranging transponder is needed. Radio-science experiments use the spacecraft radio and the DSN together as their instrument, rather than using only an instrument aboard the spacecraft. Radio-science experiments record the attenuation, scintillation, refraction, rotation, Doppler shifts, and other direct modifications of the radio signal as it is affected by the atmosphere of planets, moons, or by structures such as planetary rings or gravitational fields. From these data, scientists can derive a great deal of information such as the structure and composition of an atmosphere and particle sizes in rings. See also **Deep Space Network**.

The receiver-acquisition-and-tracking characteristics are unique for planetary spacecraft. Compared to those of typical Earth orbiters, the receiver threshold is very low, the loop bandwidth is very narrow, and the received-signal strength at the ground station is very low, typically as low as -150 dBm. The DSN provides the largest, most sensitive ground stations available in the world, but closing the telecommunications link (both up and down) is still so difficult that the margin left in the link for planetary spacecraft is far less than the typical 10 dB used on Earth orbiters. Planetary-exploration spacecraft use high-gain antennae for communications; they must be pointed to within a small fraction of 1°. The stringent requirements on the telecommunications link for planetary spacecraft have caused the development of sophisticated channel-coding techniques. Coding is a technique using logic and mathematics to help ensure error-free data transmission. One coding scheme that most interplanetary spacecraft use is a forward-error correction scheme called convolutional coding with Viterbi decoding. Another coding technique is Reed–Solomon coding, which adds bits, and is generally imposed before the convolutional code. A recent advance in coding is called turbo code, which may be used on a mission to Mars in 2005.

Power. The power subsystem generates, conditions, controls, and distributes onboard power. Power sources may include solar-cell arrays, RTGs, or batteries. Electrical power must be conditioned for particular end users, distributed, made stable, and safely controlled to protect the entire system from power failure. Experience shows that a PES requires a few hundred watts up to about 1 kW of electricity to power all of the computers, radio transmitters and receivers, motors, valves, heaters, data storage devices, instruments, a host of sensors, and other devices.

For a PES going beyond about the orbit of Jupiter, the first power-design question is whether to use RTGs or solar arrays. This decision is based upon the Sun range of the mission, the state of readiness of the various power-source options, the acceptable level of mission risk, safety considerations, and the amount of resources (time and dollars) available to the mission. If RTGs are chosen, spacecraft design dramatically departs from that of Earth-orbiter design. Currently, RTGs contain several kilograms of an isotopic mixture of radioactive plutonium in the form of an oxide pressed into a ceramic pellet. The primary constituent of these fuel pellets is the plutonium 238 isotope. Plutonium 238 emits low-energy alpha particles (which can be stopped by a sheet of paper) and very small amounts of gamma radiation. This, coupled with its relatively long half-life (87.7 years) and high melting point ($\sim$2300 K), makes it the isotope of choice, even though it is expensive and has a much lower power density (4 W/g) than isotopes of cesium, cobalt, and polonium.

The natural radioactive decay of plutonium produces heat (RTGs do not use fission or fusion), some of which is converted into electricity by an array of thermoelectric thermocouples. Thermoelectric conversion does not employ moving components but instead uses the phenomenon of temperature-induced current flow in materials (Seebeck effect). In this system, a pair of dissimilar semiconductor materials (silicon and germanium), where each end is at a different temperature, is joined in a closed circuit to produce a voltage. Unfortunately, the conversion efficiency is quite low (typically 5%), and RTGs radiate to space about 20 watts for every watt of electric power produced. The spacecraft must accommodate this thermal radiation as well as the nuclear-radiation environment. Although gamma rays and neutrons from RTGs pose no SEE threat, they contribute a major part of the total dose to nearby electronic components. These radiation forms are considered "unshieldable" in the sense that no amount of shielding that would be practical on a spacecraft is effective against these particles. Often, some of the IR sensing scientific instruments can be "blinded" by the warm RTG, and a RTG shade is required. Sometimes a cooling system must be included to keep the spacecraft from overheating when it is enclosed in the launch vehicle. The RTG probably must be conductively isolated from the rest of the spacecraft unless the designer tries to use the RTG waste heat to keep the spacecraft warm, which is a good idea, but makes the thermal design of the spacecraft much more complicated than that of an ordinary Earth orbiter.

Besides complicating the design, RTG-powered spacecraft must be compliant with important environmental and safety issues. The National Environmental Policy Act, for example, requires that an impact statement address nuclear-safety risks. Earth-gravity-assist missions must mitigate the possibility of inadvertent Earth reentry and prove that those risks are negligible. See also **Spacecraft Power Systems**.

Propulsion. The propulsion system provides thrust that is used to maintain three-axis stability, control spin, execute maneuvers, and make minor adjustments in trajectory. The propulsion subsystem includes the engines, propellant tanks, pressurant tanks, and associated valves and plumbing. The larger engines may be used to provide the large torques

necessary to maintain stability during a solid-rocket motor burn, or they may be the only engines used for orbit insertion. Smaller thrusters that generate between less than 1 N and 10 N are typically used to provide the ΔV for interplanetary trajectory-correction maneuvers, orbit-trim maneuvers, reaction-wheel desaturation maneuvers, or routine three-axis stabilization or spin control.

The requirements and constraints of planetary-exploration missions make the propulsion subsystem designer pay attention to several special issues. Because navigation is so difficult for planetary missions, unmodeled accelerations, such as those from outgassing and leakage must be avoided, and thrusters should be arranged to provide attitude-control torques in coupled pairs to avoid any translational ΔV. For some missions, scientific objectives drive the choice of propulsion system. Sensitive optical surfaces, cryocooled sensors, and low-temperature thermal radiators are vulnerable to contamination produced by the propulsion system. Spacecraft using such devices require propulsion systems that do not exhaust condensable species that can accumulate on these sensitive surfaces. In some cases, a particular propulsion option is eliminated because a spacecraft instrument is designed to detect the same chemical species that are present in the propulsion-system exhaust.

Trajectories used for some planetary missions often require large maneuvers en route these maneuvers use the primary propulsion system many times in a series of large "burns" required for orbit insertion; insertion can occur years after launch. The primary engine used to deliver the mission ΔV on a planetary spacecraft may have to operate for up to 10 hours and perform 200 cycles, compared to a similar engine used on an Earth orbiter that may need to operate only for 2 hours and perform 5 cycles. For a planetary spacecraft, the propellant supply and pressurization system may have to last for many years. Earth orbiters, such as GEO-communication spacecraft, use most of their propellant during the first few weeks of the mission, After that, the bipropellant main engine and pressurization system are isolated for the remainder of the mission. The long-life requirement for the propellant supply and pressurization system for planetary spacecraft requires careful consideration of pressurant leakage and interactions between propellant and tankage material, which can lead to blocked propellant lines. To reduce the probability of propellant-line blockage, the Galileo spacecraft bipropellant subsystem is activated routinely to reduce the accumulation of corrosion products. The requirement for long storage of the propulsion subsystem in space can drive the requirement for special isolation between the propellants that require using additional pyro-and-latch valves. Lack of proper design and isolation within the bipropellant pressurization system on the Mars Observer spacecraft, was probably a leading cause of its failure. The Magellan spacecraft, which orbited Venus, used a large solid-rocket motor (SRM) for orbit insertion. The long duration of "storage" in space caused concern whether the SRM would ignite and burn properly. Earth-orbiter SRMs are fired usually within days of launch.

Because of the large ΔV required for many planetary-exploration missions, electric propulsion using ion engines has long been viewed as an attractive alternative to chemical propulsion. Ion propulsion using xenon as a propellant has been demonstrated on the NASA/JPL Deep Space 1 spacecraft (Fig. 15). Ion propulsion provides an exhaust velocity about 10 times larger than that of a traditional chemical-propulsion subsystem, and therefore it uses only about one-tenth the amount of propellant to provide the same ΔV. There is a significant savings in propellant, but electric-propulsion systems require additional power-generating and conditioning equipment that offsets to some degree the savings in propellant mass. Interplanetary spacecraft using ion-propulsion systems can undertake the very high ΔV missions that would be prohibitively massive and therefore expensive using traditional chemical-propulsion techniques.

PES Principles and Margins. The preceding pages have described the key requirements and constraints on planetary-exploration spacecraft and the way those requirements and constraints influence the design of the spacecraft. Although designing planetary-exploration spacecraft is a relatively young art, the practice of this art and the struggle against the requirements and constraints for 40 years and about 20 design cycles have identified some detailed technical design principles. These design principles, which are being implemented at NASA's Jet Propulsion Laboratory, originate in the need for very reliable planetary-exploration spacecraft. This section also includes design margins that have been developed to increase the probability that the spacecraft will be ready to launch (with a high degree of certainty) during the inflexible launch window imposed by solar-system celestial mechanics. In many cases, these principles have been developed in response to past failures.

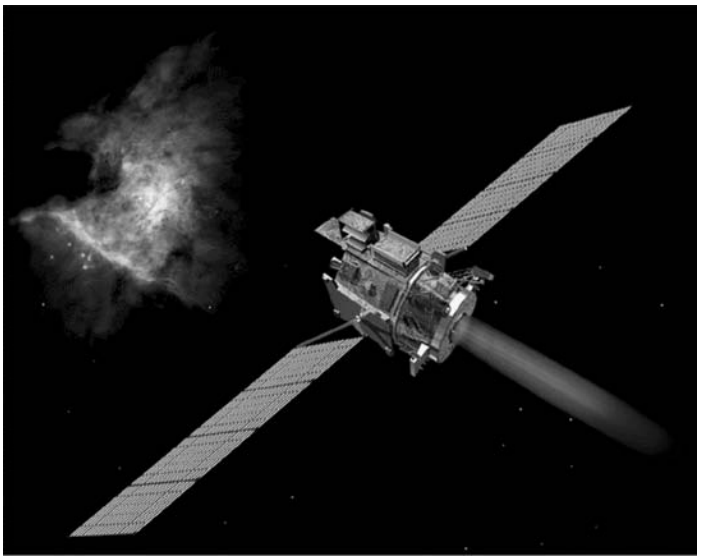

Fig. 15. Launched on October 24, 1998, Deep Space 1 was the first mission under NASA's New Millennium Program, designed to test new technologies for future space and Earth-observing missions. During the primary mission, Deep Space 1 tested 12 advanced technologies and instruments aimed at making future science spacecraft smaller, less expensive, more autonomous, and capable of more independent decision-making so that they rely less on tracking and intervention by ground controllers. In a mission extension, the spacecraft flew by Comet Borrelly in September, 2001, returning the best images and other science data ever from a comet. The mission concluded on December 18, 2001. Source: http://nmp.jpl.nasa.gov/ds1/; http://www.nasa.gov/centers/glenn/about/history/ds1.html. (*Image courtesy of NASA/JPL*).

The following principles applied during the design phase help ensure that long-lived spacecraft successfully complete very challenging missions:

- Routine, in-flight power cycling of critical hardware shall be avoided.
- Mission-critical data (flyby science, orbit insertion, etc.) shall simultaneously be recorded onboard and transmitted.
- Thermal design shall keep piece-part, silicon-junction temperatures below 110 °C (230 °F) (assuming a 70 °C (158 °F) mounting-surface temperature) for circuit design and packaging.
- Electronic hardware shall survive power on/off cycling, temperature cycling, and/or solar exposure cycling of three times the number of worst-case expected mission cycles with worst case flight-temperature excursions. Until a mission estimate is available, the equivalent of 10,000 cycles with a 15 °C ΔT (change in temperature) for new/inherited design hardware shall be used.
- The prime-power distribution hot and return lines shall be DC-isolated from the spacecraft chassis by at least 2 ohms. (This ensures a single fault so that a chassis short anywhere in the distribution system among power source, electronics, or user loads does not pose a catastrophic failure.)
- Prime-power on/off switching of electrical loads shall be done by "simultaneously" switching both hot and return sides. This ensures total load removal (no possible ground-return sneak paths) in case of power-related faults.
- Mission-critical deployable design (for example, solar arrays) shall demonstrate a margin of at least 100% under worst-case conditions, particularly cold, stiff cable bundles, vacuum versus air, and coefficient of friction effects.
- Mission-critical separation design (for example, launch vehicle, probe release) shall demonstrate a margin of at least 100% under worst-case conditions.

- Mission-critical mechanisms and actuator design shall demonstrate at least 100% margin for range-of-motion and the end-of-life stage under worst-case conditions, including restart from within any range-of-motion position.
  - All electronic-parts radiative capability shall be at least twice that of the expected end of nominal-mission environment.
  - A minimum, prelaunch power-on operating time shall be established for all electronics as follows:
  - Unit level prior to spacecraft integration: each electronic assembly, including each side of a block-redundant element, shall have at least 200 hours of operating time.
  - System level before to launch: each single-string electronic assembly shall have 1000 hours of operating time. Each side of a block-redundant element shall have at least 500 hours of operating time and a goal of 1000 hours.

Planetary-Exploration Spacecraft Operating Principles. These principles address the most common and critical issues for operating a planetary-exploration spacecraft far from Earth for many years that has only a single opportunity to perform its unique mission:

- All flight-command sequences shall be tested on a high-fidelity, flight-like system test bed, and all anomalies shall be understood and corrected before sequence-uplink transmission.
- After initiation, mission time-critical operations shall not require "ground-in-the-loop" commanding to enable successful operation/completion.
- Launch-sequence completion shall leave the spacecraft in a ground-commendable, safe state that requires no "immediate" time-critical ground commanding to assure health/safety.
- After in-flight turn on, the downlink-RF transmitter shall not be turned off during nominal flight operations but shall remain powered during the entire mission, except for momentary power cycling via system-autonomous, fault-protection responses.
- Power cycling of mission-critical hardware shall be avoided.
- Prime-selected hardware elements shall remain in use for all operations.
- Swapping to redundant hardware elements shall be limited to fault-recovery actions to ensure health/safety.
- Stored critical data (for example, launch, fly-by science, orbit insertion, entry/descent and landing) shall be protected from loss in the event of selected anomalies (for example, transient power outage) and shall be transmitted to Earth as soon as practical.
- Mission-critical events (for example, launch-vehicle separation and deployments) and verification of deployables shall be available via real-time telemetry.
- Telemetry and command capability shall be available throughout the mission in normal cruise-pointing attitude and during special cruise-phase mission/system activities (for example, long-duration, deep-space trajectory correction, maneuvers, and mission-critical propulsion pyrodevice actuations).
- During non-mission-critical cruise periods following a fault condition, the flight-protection response shall at least autonomously configure the spacecraft to a safe, quiescent, ground-commandable state, preferably transmitting engineering status, but at least an RF-carrier downlink signal.
- During critical-mission activities (for example, launch and orbit insertion), the flight fault-protection response shall autonomously reestablish the needed spacecraft functionality to permit safe, reliable, and timely completion of mission-critical activity.

Design Margins. Design margins are intended to keep the spacecraft design, build, and test program on track to meet the launch date. Design margins must be large enough to accommodate design uncertainties/unknowns and still enable design changes with minimal system wide effects:

- Spacecraft system-level mass margin shall be at least 30% at the project start; 20% at project preliminary design review (PDR), 10% at critical design review (CDR); 5% at assembly, test, and launch operations (ATLO) readiness; and 2% at launch.
- The spacecraft-system-level power margin for cruise, mission-critical, and safing modes shall be at least 30% at project start, 20% at project PDR, 15% at CDR, and 10% at ATLO start.
- At launch, there shall be at least 10% predicted power margin for mission-critical, cruise, and safing-operating modes.
- At the start of the spacecraft design, the computer throughput and memory capability shall exceed estimated requirements by at least a factor of 4.
- The nominal deep-space link margin shall be at least 3 dB.
- Deep-space links with extreme geometry conditions, surface-to-orbit links, or surface-to-surface links shall consider margins of 10 dB or more, depending on the nature, complexity and scope of design uncertainties.

NOTE The Jet Propulsion Laboratory (JPL), California Institute of Technology, carried out the research described in this article, under a contract with the National Aeronautics and Space Administration. The review and contributions of many individuals at JPL are acknowledged, especially Neil Yarnell, John Slonski, David Doody, and Matthew Landano. The efforts of Tom Wilson as editorial assistant are also gratefully acknowledged.

SPACECRAFT GUIDANCE, NAVIGATION AND CONTROL SYSTEMS. The difficulties in maneuvering a vehicle through space are not intuitively obvious to someone who has not been involved in the field. After all, we have been exposed to the television and movie concepts of space travel, wherein there seems to be almost unlimited electrical power, rocket thrust, and propellant, and the protagonist simply flies off to a distant moon or planet using visual references for navigation.

Actually, the finite limits of electrical energy, thrust, and propellant on a vehicle are the driving forces that demand efficient and accurate equipment to perform the functions of steering and navigation while keeping the vehicle attitude stabilized. Added to these restrictions are the needs for minimum volume and mass. An intricate system results that is extremely difficult to design, construct, and test and usually is one of the most expensive on the vehicle.

Terminology. As in most fields, the space industry has a set of terms and definitions peculiar to the field that, unfortunately, are not always consistent in meaning. The term "guidance system" is sometimes used interchangeably for "guidance and navigation system" or "guidance, navigation, and control system" or "guidance and control system." In this article, the terms are used as follows:

Guidance. Means the actual steering of the vehicle as it travels through space. Guidance commands may originate from a crew onboard, from an onboard computer, or from external sources via radio commands. In addition, if the thrust of a space vehicle is variable and controllable, the command for modulating the thrust is usually a guidance function.

Navigation. Is the measurement of the location of the vehicle in space and plotting the course of the vehicle. Navigational fixes may come from onboard human sightings using telescopes and sextants, from automatic onboard star or horizon sensors, or from radio/radar tracking equipment on the ground.

Control. Refers to the spatial alignment and stabilization of the vehicle while the guidance and navigation functions are being performed, and includes onboard processing and routing of commands to the devices (typically thrusters, reaction wheels, control moment gyroscopes, or aerodynamic surfaces), termed *effectors*, that produce reactive forces on the vehicle.

The combination of these three functions into one system results in the *integrated guidance, navigation, and control system*, or simply the GN&C system.

Space Guidance. As mentioned earlier, the finite limits of electrical energy, thrust, and propellant on a space vehicle are the reasons one simply cannot point the vehicle toward the target and fly it there. Further, within the Universe, the target itself is typically moving, and if the spacecraft were simply steered toward it, the spacecraft could end up chasing it. The situation is analogous to that of a shotgunner who must "lead" the target, that is, aim at a point on the flight path ahead of the target so that the shot arrives at the point where the target will be rather than the point where it was when the trigger was pulled. Other complicating factors are the effects of the gravity of Earth, the Moon, the Sun, and the planets, as well as their individual rotations if the launch points or landing sites lie on the surface.

A typical spacecraft trajectory that results from these conditions has the following characteristics:

- The launch point is on a rotating Earth (or Moon or planet).
- The gravitational pull of Earth and the Moon are significant effects.
- The flight path is curved and is likely to be nonplanar.
- The flight duration may be anywhere from minutes to years.
- The flight path is carefully plotted and optimized during mission planning.

The guidance function steers the spacecraft along the preplanned flight path while accommodating these characteristics.

To understand the guidance function better, consider the following hypothetical mission trajectory:

1. Launch occurs at Cape Canaveral, Florida, U.S.A. The flight path bends from a vertical ascent to a due easterly direction. As orbital altitude, say 200 nautical miles, is achieved, the spacecraft flies on an elliptical path in a plane at the same angle to the equator as the latitude of the launch site — in this case, 28.5°.
2. The orbital altitude is then increased to 800 nautical miles by using the Hohmann transfer. This is a minimum energy maneuver where the thrusting is done at the apogee and perigee of the orbit.
3. A plane change is accomplished to permit rendezvous with another spacecraft in a different plane.
4. After rendezvous and docking with the second spacecraft, say, to replenish propellants, our spacecraft undocks and drifts away.
5. The spacecraft then thrusts in a new direction for transplanetary injection. Escape velocity is achieved, and the spacecraft leaves Earth on a hyperbolic trajectory toward the target planet.
6. Along the way, course corrections are made using small velocity increments (*delta V's* in space parlance).
7. The spacecraft flies to the target planet or passes nearby and continues out into space. These mission segments are shown pictorially in Fig. 1.

To accomplish the guidance function during each of these mission segments, the GN&C system must have reasonably precise knowledge of the pointing direction of the vehicle and the acceleration during thrusting. Devices used to obtain this information are called *inertial sensors* and include the gyroscope and accelerometer. Further, for the rendezvous phase, it needs to know the relative position of the spacecraft to the targeted vehicle; rendezvous radar can be used for this purpose. For the docking phase, a near-in distance-measuring sensor, such as a laser, is required.

Gyroscopes. The gyroscope, or gyro as it is usually called, is a spinning wheel supported in rings called gimbals. The gyro has two properties that are useful for guidance applications — the tendency to remain fixed in alignment in space if undisturbed, and the tendency to precess predictably when a torque is applied to the gimbal 90° to the spin axis.

Suppose that a gyro were mounted in a spacecraft. Suppose further that some method is used to spin the wheel and measure angular movement of the gimbals. A gyro used in this manner is termed a *vertical gyro*. Rotational motion of the spacecraft about all axes except the gyro spin axis could be measured and used for guidance purposes. For the case of spacecraft rotation about the gyro spin axis, a second gyro whose spin axis is at 90° to the spin axis of the first gyro could be added. Some aircraft and missiles that have short flight times use gyros in this manner for attitude control during flight (see, for example, the discussion in the Rauscher Ref.). However, drift due to bearing friction and difficulties in precise

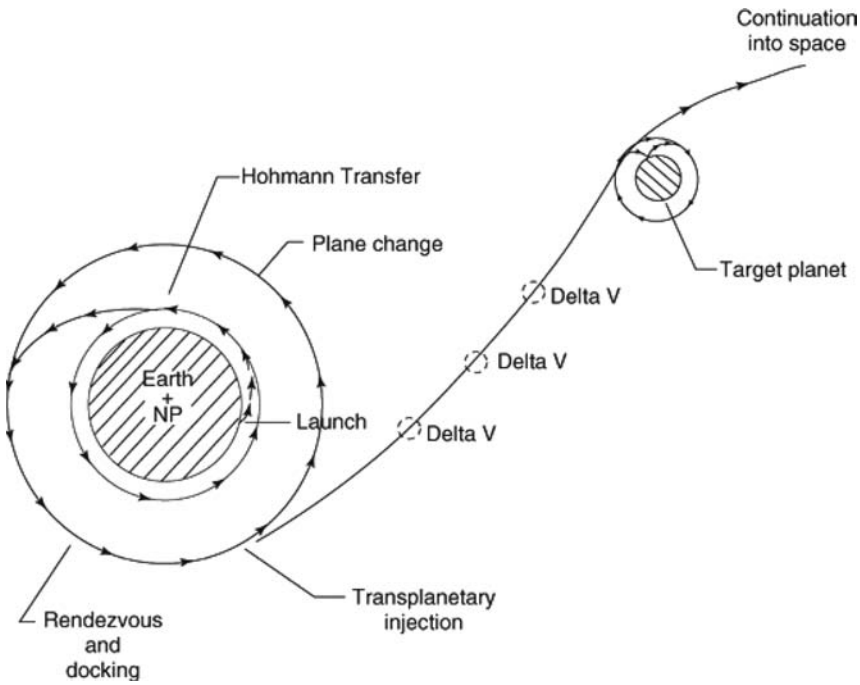

Fig. 1. Hypothetical space mission.

readout of the gimbal positions usually make this application unsuitable for spacecraft that have precise trajectory requirements and long flight durations. In practical applications for modern spacecraft, the property of *precession* is more useful.

The spinning wheel in a gyro has an angular momentum and a rate of precession given, for small disturbances, by the expressions

$$\text{Angular momentum} = I\omega \tag{1}$$

$$\text{Rate of precession} \equiv \Omega = T/I\omega \tag{2}$$

where I is the inertia of the wheel, ω is the angular velocity, and T is the torque applied at 90° to the axis of spin.

Suppose that a gyro is mounted in a vehicle, as shown in Fig. 2. In this drawing, the two gimbals on which the spinning wheel is mounted are clearly visible. As the vehicle rotates about the axis labeled *input axis* transverse to the spin axis, it exerts a torque T on the *spin axis* and there is precession about the axis labeled *output axis*. A measure of the rate of precession will be proportional to the vehicle rotation, as shown by Eq. 2. A gyro used in this manner as a rate sensor is called a *rate gyro*. To keep the displacement of the wheel within narrow limits, a restoring torque motor must be used. Further, if the rate of precession is integrated over time, a value of vehicle angular displacement is determined. A rate gyro used in this manner is termed an *integrating rate gyro*. This approach to determining vehicular attitude is usually much more accurate than the vertical gyro approach.

When the gyro is used as a sensor, a number of design considerations come into play. First, the wheel is spun using a high-efficiency electric motor. Next, in an effort to reduce volume, the wheel may be made small and the spin rate increased to retain high angular momentum, a desirable feature for measuring very small angular rates. Next, bearings inevitably cause some disturbing torques on the wheel, and in an effort to reduce this effect, the wheel may be supported on a thin film of liquid or gas in lieu of conventional bearings. An optical pickoff is preferable to inductive pickoffs to reduce reactive forces and to measure very small rates. Finally, restoring torque commands may be in the form of pulses that provide a compatible interface with a digital computer. Some design approaches for mechanical gyros used in spacecraft can be found in the Slater, and Ausman Ref.

Optical Gyros. Another type of sensor for measuring rotational displacement is the so-called *ring laser gyro* (RLG). This is not a gyro in the conventional sense in that there are no moving parts. The principle

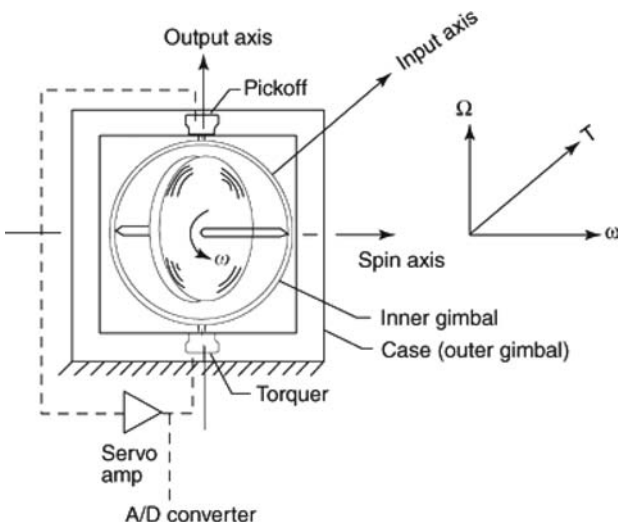

Fig. 2. Gyroscopic precession.

of operation is the Sagnac Effect discovered in 1913. The sensing element is a laser beam that is split into two beams directed clockwise and counterclockwise in a somewhat circular, closed, vacuum chamber. Three or more mirrors are arranged in a "ring" around the chamber so that the two beams are reflected back to the source where there is a detector. A conceptual design approach is shown in Fig. 3. If the chamber is rotated in either direction about an axis perpendicular to the plane of the mirrors (i.e., the *input axis*), there will be a measurable difference (phase shift) in the travel times of the two beams because one will travel a shorter distance than the other. The output of the RLG can be digitized for rotational rate output and then integrated over time for a measure of angular displacement. The disadvantages of RLGs are the difficulty and cost of achieving and maintaining the necessary mechanical alignment.

Fiber-optic gyroscopes (FOG), sometimes called *interferometric fiber-optic gyroscopes* (IFOG), operate on the same principle as the RLG in that there are two beams of light directed in opposing loops, but in this case the medium is optical fiber. A conceptual drawing of the FOG is shown in Fig. 4. In general, FOGs are easier to fabricate and align than RLGs and are more suitable for microminiaturization. One disadvantage

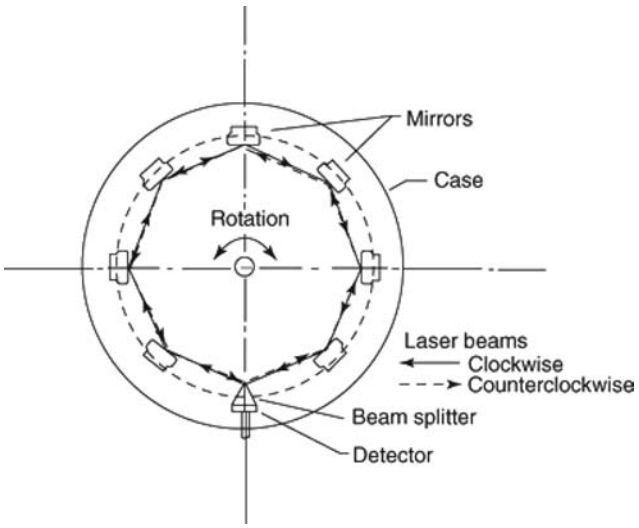

Fig. 3. Ring laser gyro.

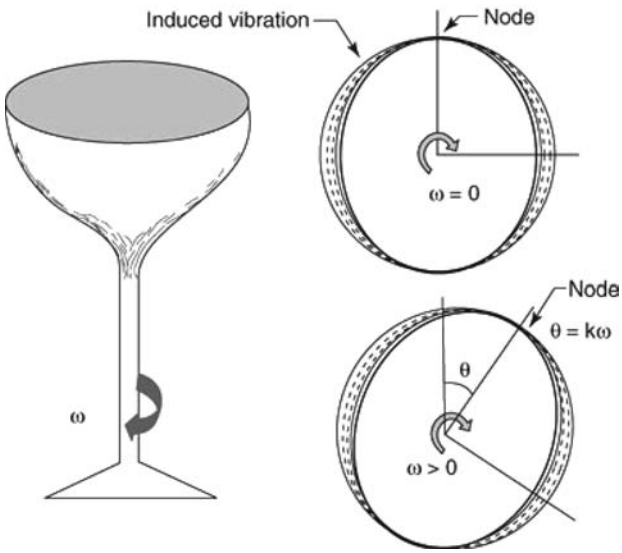

Fig. 5. Vibrating bell gyro.

is that scale factors in FOGs are usually nonlinear. Also, the fiber must be carefully chosen to avoid the potential of becoming unserviceable due to aging or radiation in space. FOGs have flown on the *Clementine* and *Technology for Autonomous Operational Survivability* (TAOS) spacecraft. An extensive discussion of the FOG may be found in.

Vibratory Gyros. The *vibratory gyro* is another type of gyro different from the classical mechanical gyro. The ancestry of this type can be traced to the experiments of G. G. Bryan, a British physicist, who studied vibrating wine glasses. He discovered that the induced vibrational pattern on a glass would move (precess) if the wine glass were rotated about its stem and that the displacement was proportional to the rotational rate. This is shown in Fig. 5. An example of this type of gyro is the *hemispherical resonator gyroscope* (HRG) discussed in Wright and Bunke Ref. In this example, the resonating element that is analogous to the wine glass is a 30-mm diameter bell made of fused silica. A surrounding housing induces vibration and also senses the nodal pattern shift through the use of capacitive pick-offs. This gyro has been used on satellites and on the Jet Propulsion Laboratory's *Cassini* spacecraft. The main advantage of the HRG is that there are no moving parts other than the resonator bell. A disadvantage is that the case must be evacuated and vacuum-sealed to prevent air damping.

The *tuning fork gyro* shown in Fig. 6 is another type of vibratory gyro. In this case, the tines are excited in the plane of the tines. As the tuning fork is rotated about an axis parallel to the tines, they tend to continue oscillating in the original plane, as shown in the vector diagram in the figure. The vector component perpendicular to the plane of the tines is proportional to the rotational rate and may be measured by capacitive or optical sensing. Materials used for the tuning fork include crystalline quartz and silicon. Crystalline quartz is a highly stable piezoelectric material suitable for micromachining. In the case of silicon, the fork may be part of an integrated circuit chip where the controlling and sensing electronics are designed into the chip. See also **Gyroscope**.

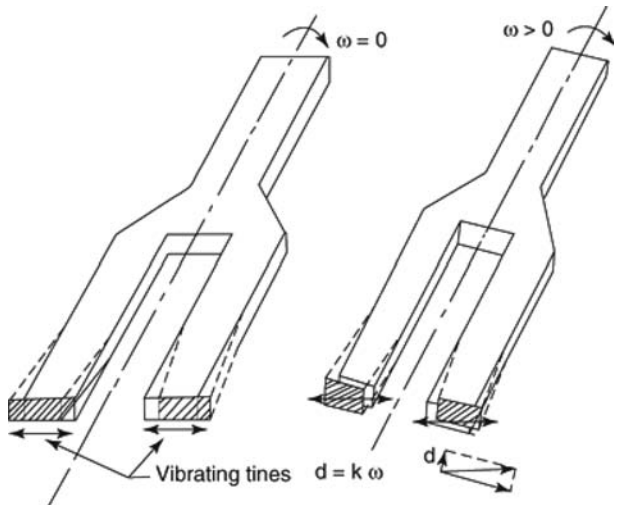

Fig. 6. Tuning fork gyro.

Accelerometers. Accelerometers are devices used to sense changes in velocity. They are made in a number of ways, but the common feature of most is a mass that moves in accordance with Newton's second law. This sensing mass, sometimes called the *proof mass*, may be suspended in a number of ways and held in the neutral position by a magnetic field. As the acceleration is sensed by the mass and it begins to move, a pickoff detects the movement and sends a restoring signal through an amplifier to the restoring coil. Rather than hold the mass in a neutral position, some designs force the mass to swing back and forth on a pendulum using a series of back and forth pulses. This restoring circuit also sends the

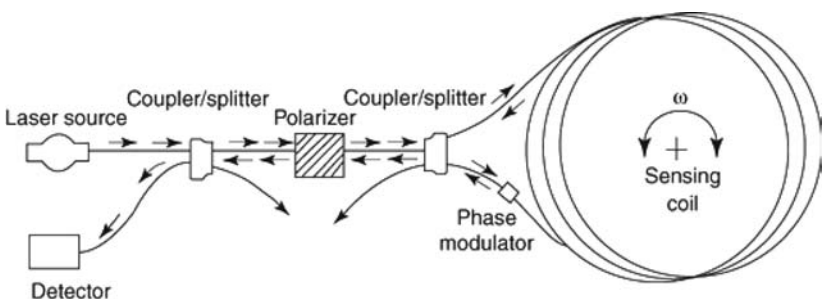

Fig. 4. Fiber-optic gyro.

restoring pulses to a counter that adds the positive and negative pulses algebraically; the sum represents the sensed acceleration. If the counter is coupled with a digital computer and integrated over time, it can keep an ongoing status of vehicle velocity. This type of accelerometer, called a *pulsed integrating pendulous accelerometer* (PIPA), was used successfully in the NASA Apollo Lunar Landing Program.

Advancements in the past decade in *microelectromechanical systems* (MEMS), also known as *microsystems technology* (MST), have produced accelerometers of continually decreasing size, mass, and power usage. Using the same principles of vibratory gyros discussed before, sensing elements now include flexing quartz seismic beams and "squeezed film." Movement may be detected by measuring changes in capacitance between the flexing mass and the adjacent fixture. *Nanotechnology*, generally defined as the next order of size reduction, will no doubt reduce the size of accelerometers further. See also **Accelerometer**.

Inertial Measurement Units. The *stable platform*, variously referred to as the *inertial platform*, *guidance platform*, or *inertial measurement unit* (IMU) is a common application of gyros and accelerometers. In a typical approach, a group of three single-axis gyros or two dual-axis gyros is mounted on a rigid platform, and their input axes are aligned orthogonally. Three single-axis accelerometers, or two dual-axis accelerometers, are also mounted orthogonally on the platform. The platform is then mounted on two or three gimbals, and the restoring torque signals from the gyros are used to command the gimbal drive motors. The result is that, after initial erection and alignment, the platform is maintained inertially fixed in space. A platform designed in this manner provides an inertial attitude reference and measures accelerations along the inertially fixed axes of the platform. This information can be used by a flight computer to calculate and maintain the status of attitude, acceleration, velocity, and position of the platform. The GN&C system then essentially flies the platform through space, and the vehicle moves around the platform in the process.

The three-gyro, three-accelerometer platform was used on the NASA Apollo Lunar Landing Program. The two-gyro, two-accelerometer IMU is currently used on the NASA Space Shuttle. The Space Shuttle IMU is shown in Fig. 7. For a further discussion of IMUs, see Thompson Ref. See also **Space Shuttle**.

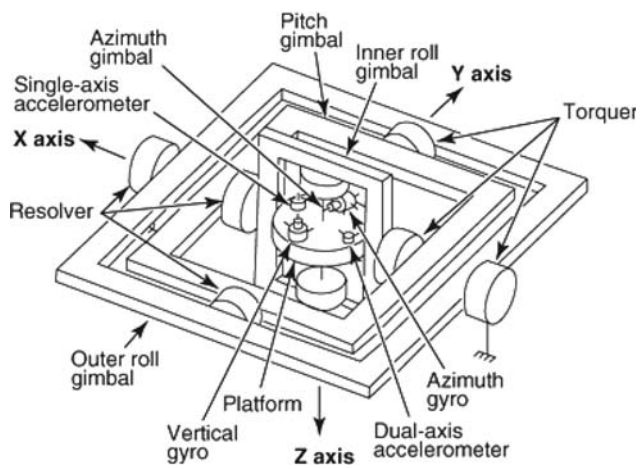

Fig. 7. Space Shuttle inertial measurement unit (courtesy NASA).

Strap-Down IMU. The limitations of early onboard flight digital computers encouraged a marriage with gimballed IMUs because of their ability to erect themselves and maintain alignment for at least short times using self-contained torquer motors and dedicated electronics. Even if the flight computer failed, the IMU alignment data could be used in these short periods of time to drive cockpit displays for manual steering. Later on, dedicated local processors within IMUs off-loaded the flight computer even more by applying scale factors, correcting biases, and encoding data words. Over the years, gimballed IMUs have earned a reputation for reliability and have become cheaper to produce.

As onboard digital computers have grown in capability there has been a trend to replace the gimballed IMU by an assembly of gyros and accelerometers rigidly mounted on the spacecraft structure. This approach is called the *strap-down IMU or strap-down guidance system*. In this approach, the flight computer must do all of the angle resolutions (body angles to inertial angles, or body angles to Euler angles) and continually maintain the inertial reference. Further, corrections must be made by the flight computer (or a dedicated local processor) to eliminate the effects of spacecraft rotation on the accelerometers. Strap-down systems are generally smaller than gimballed IMUs, require less electrical power, and are cheaper to build. A disadvantage is that they must be continually serviced by the flight computer, and if either the strap-down system or the flight computer should fail, inertial reference is instantly lost.

It is interesting to note that the Apollo Program spacecraft used a gimballed platform for the primary system and a limited form of a strap-down IMU for backup. In the latter case, body-mounted gyros were used for backup angular rate and displacement information for both the flight computer for automatic steering and displays for manual steering. But there were no body-mounted accelerometers, and if the gimballed IMU accelerometers failed, thrust duration had to be manually timed.

It seems likely that future trends in MEMS and nanotechnology will continue to reduce the size and power usage of strap-down IMUs, making them more and more attractive for spacecraft use. However, inherent time-dependent inaccuracies in both types of IMUs require realignment using noninertial sensor or manual updating.

Rendezvous and Docking Sensors. In the hypothetical mission described before, there is a phase when the spacecraft must approach and dock with another spacecraft. Assuming that the target is passive and if the spacecraft is not manned so that manual control may be employed, the maneuver must be accomplished automatically by the onboard GN&C system. Candidate sensors for the rendezvous phase would include a Doppler radar and possibly the Global Positioning System for rendezvous in Earth orbit. A laser might be suitable for docking. Both translational and rotational commands to the spacecraft attitude control rockets are required and would be generated by the guidance function of the GN&C system. The guidance algorithm must be carefully scripted so that the spacecraft is slowed down enough to prevent impact damage but still has enough kinetic energy on impact to overcome the resistance of the latching mechanism.

Space Navigation. The foundation of space navigation was laid in the seventeenth century by two major advances. Early in the century, Johann Kepler, using the observations of Tycho Brahe, empirically derived his laws of planetary motion. The first law, and the most important for celestial navigation, stated that the planets of the solar system move about the Sun in elliptical orbits and the Sun is at one focus of the ellipses. Later, Sir Isaac Newton stated his laws of motion and formulated the law of universal gravitation. His work confirmed Kepler's findings and allowed extension to celestial bodies other than planets, for example, comets, and to motions described by conics other than ellipses. These trajectories include circles (a special case of the ellipse), parabolas, and hyperbolas. A discussion of the historical background of this development can be found in Baker and Makemson Ref. See also **Earth Orbiting Satellite Theory**.

Newton's law of universal gravitation may be stated generally mathematically as

$$F = \frac{Gm_1m_2}{s^2} \tag{3}$$

where F is the magnitude of the force of attraction, m_1 and m_2 are the masses of the two bodies, s is the distance between them, and G is the gravitational constant whose numerical value depends on the system of units used. The force F points in the same direction as the line s that joins the two masses.

Equation 3 may be applied with reasonable accuracy to a spacecraft orbiting Earth if certain simplifying assumptions are made:

1. Let m_1 represent the mass of Earth; Earth is of uniform density and is spherically symmetrical, that is, the oblateness of Earth is ignored. This allows the Earth to be treated as a point mass at its center.
2. Let m_2 represent the mass of the spacecraft, so small relative to the mass of Earth that the center of mass of the system lies at the center of Earth.
3. Let m_1 be fixed in inertial space with the origin of the reference axes at its center.

4. The spacecraft is in coasting flight with only gravity acting on it, that is, other forces such as aerodynamic drag, solar winds, and electromagnetic forces are ignored.

These assumptions allow simplifying the analysis to what is generally termed the "restricted two-body problem," and the approach may be used for spacecraft operating near other relatively large bodies, for example, where m_1 represents the Sun, Moon, or one of the planets.

Following the approach of Mueller, the spacecraft equations of motion can be derived as follows. Using polar coordinates and vector notation, we show the Earth–spacecraft coordinate system in Fig. 8. Referring to Newton's second law and restating Eq. 3 in vector form in the polar coordinate system,

$$\sum \vec{F} = m_2 \frac{d^2 \vec{r}}{dt^2} \tag{4}$$

$$\sum \vec{F} = (-)\frac{Gm_1 m_2}{r^2}\hat{r} = (-)\frac{Gm_1 m_2}{r^3}\vec{r} \tag{5}$$

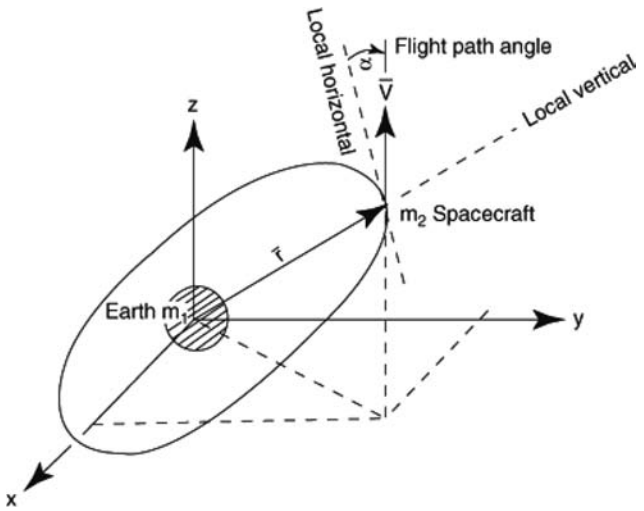

Fig. 8. Earth–spacecraft coordinate system.

where r is the distance between the masses, $\hat{r}$ is a unit vector that points along the line joining the two masses, and $\vec{r} = r\hat{r}$. Combining Eqs. 5 and simplifying produces

$$\frac{d^2 \vec{r}}{dt^2} + \frac{\mu \vec{r}}{r^3} = 0 \tag{6}$$

where μ is defined as a constant $\mu = Gm_1$. Equation 6 is the vector differential equation of motion for the restricted two-body problem. Note that it is independent of m_2.

Using the methods described elsewhere in this *Encyclopedia* and referring to Fig. 8, two equations of importance for an orbiting spacecraft can be derived from Eq. 6:

$$E = \frac{v^2}{2} - \frac{\mu}{r} \tag{7}$$

and

$$H = rv\cos\gamma \tag{8}$$

where γ is defined as the *flight path angle*.

E is a constant in Eq. 7, termed the *specific mechanical energy* of the spacecraft, implying a continual exchange of kinetic energy and potential energy throughout the orbit. H in Eq. 8 is called the *specific angular momentum* and is also constant throughout the orbit. Notice that as r increases, v decreases, as might be expected intuitively.

Finally, referring again to methods described elsewhere in this *Encyclopedia*, Eq. 6 can be solved, resulting in the following scalar equation termed *the trajectory equation*:

$$r = \frac{H^2/\mu}{1 + B/\mu\cos\nu} \tag{9}$$

where, as before, H is the specific angular momentum and B is the magnitude of a vector from the focus to that point on the trajectory nearest the focus. This point is called the *perifocus* or *periapsis*, or in the case of Earth orbits, the *perigee*. The angle ν (nu) is the angle between $\vec{B}$ and $\vec{r}$, the radius vector.

Equation 9 is in the form of the general equation for a conic section written in polar coordinates. If p is defined as $p = \mathrm{H}^2/\mu$ and e is defined as $e = B/\mu$, the equation can be written as

$$r = \frac{p}{1 + e\cos\nu} \tag{10}$$

In this form, p is called the "parameter "or "semilatus rectum" and is a measure of the size of the conic. The term e is called the "eccentricity." The solution of Eq. 10 is a circle if $e = 0$, an ellipse if $0 > e < 1$, a parabola if $e = 1$, and a hyperbola if $e > 1$.

In summary, application of these laws to a spacecraft operating in a central force field results in trajectories that are similar to those of celestial bodies. A coasting spacecraft that has sufficient energy will orbit Earth in a plane and in an elliptical fashion. With the additional thrusting it can be made to travel further out to loop around the Moon and return to Earth, or be captured in an orbit about the Moon. Even more thrusting will cause it to escape Earth's gravitational pull and proceed on a parabolic or hyperbolic path to one of the other planets or into deep space. The resulting trajectories can be divided into conical segments, whose combinations are called *patched conics*.

As mentioned earlier, limitations in onboard expendables require planning most space trajectories carefully in advance of the actual flight to achieve the most economical and efficient missions. Launch dates, orbital plane changes, midcourse velocity changes, and rendezvous points must be determined by working backward from a desired target along the way and at the end of the flight. This is usually done by using numerical integration with considerable trial and error adjustments.

Once the mission plan is determined, navigational sightings are defined in terms of times, locations, and types of sensors to be used. At each point, the sightings are made, the information is routed to the onboard flight computer, and the inertial platform is aligned. If an adjustment is required in the state vector of the vehicle, attitude alignments of the vehicle are made and midcourse delta V's are made using the thrusters on the vehicle. This is repeated as often as required to achieve mission goals.

On the launch pad, the inertial measurement unit is held in a locked position relative to the spacecraft until the last practical moment, usually a few minutes before ignition. In the minutes after IMU release to actual vehicle liftoff, the IMU is controlled by a gyrocompass program to keep it aligned relative to Earth. At liftoff, the IMU is allowed to go inertial and remain so until the next navigational update in flight.

During flight, there are several types of navigational updates. Ground radar tracking is the most common for spacecraft orbiting Earth. Optical sensors may be used to take sightings of Earth, the Sun, or the stars. These sensors include star trackers, horizon scanners, or Sun seekers for automatic navigation. For the manned NASA Apollo Lunar Landing Program, the astronauts made visual sightings using a telescope and sextant that were coupled electronically to the flight computer. All of these sensors are usually carefully mounted on a rigid navigational base that also supports the inertial measurement unit, so that angular resolution from an optical sensor to stable member axes can be made precisely.

Navigational fixes can also be made using the *Global Positioning System* (GPS) satellites. See also **Global Positioning System (GPS)**. This approach can be used to determine the vehicle attitude as well as the location in space if multiple receivers are located precisely on the spacecraft and their relative positions are differentiated.

Star Trackers. The *star tracker* is an automatic optical device used to determine the angle between the spacecraft and a luminous body typically

outside the solar system. Planets do not make good targets because they lie in a fairly narrow band (the zodiac) and their motion is erratic compared to stars many light-years away. A candidate group of stars is usually preselected and stored in the flight computer along with their general location and their brightness number. The spacecraft is oriented so that the star tracker points in the general direction of a candidate star and then searches until a match is made. Alternately, the tracker itself may be gimballed and allowed to move relative to the spacecraft axes. Two different sightings are enough to establish the spacecraft's position in space or to align the IMU stable member, but a third or more additional fixes are used for confirmation and greater accuracy. Star trackers now in production have angular accuracy of 0.1 arc seconds or less. Star trackers are sometimes used to track other spacecraft, and they may be combined with cameras for photography.

Horizon Scanners. The *horizon scanner* is used to determine the *local vertical* of a spacecraft that is orbiting Earth or other planetary bodies. The local vertical may be considered a vector from the center of mass of the vehicle to the center of Earth. Three or more sightings are taken of Earth's horizon, as shown in Fig. 9, and the angles to the local vertical relative to the spacecraft body axes or inertial axes are computed geometrically by the flight computer. Once the local vertical is determined, star sightings can be made and the latitude and longitude of the vehicle determined. Since visible light is scattered by Earth's atmosphere, the sensor is usually designed to detect infrared waves that more sharply define Earth's horizon. Another advantage of infrared is that Earth radiates heat at infrared wavelengths even when the horizon is not in the direct rays of the Sun, and, consequently, sightings can be made on the dark side of Earth.

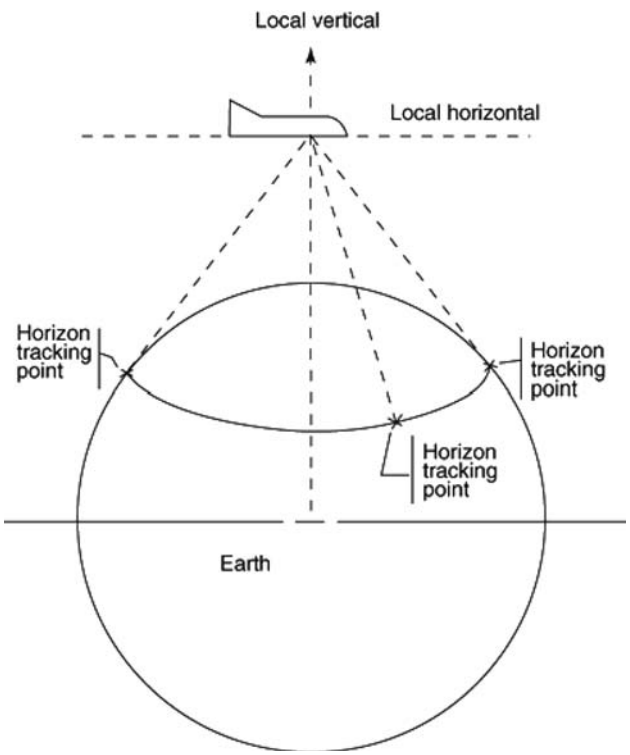

Fig. 9. Horizon scanner.

Sun–Earth Sensors. *Sun–Earth sensors*, sometimes individually referred to as *Sun seekers* or *Earth sensors*, are sometimes used as attitude determination devices for spacecraft. They are relatively simple to build, and sightings are usually reliable because the Sun and Earth are large targets and hard to miss. But for the same reasons and because of the relatively rapid movement of Earth in its orbit, they are not usually as accurate for navigation as other devices previously discussed. A principal use of Sun seekers is to orient the vehicle relative to the Sun for thermal control.

Radio Navigational Aids. For Spacecraft required to return safely to Earth and land (e.g., the NASA Space Shuttle Orbiter) or land on other bodies, one or more radio navigational aids may be required. The simplest of these is the *radar altimeter*, which allows the spacecraft to measure altitude autonomously above the surface of the landing zone. In the Space Shuttle Orbiter, the radar altimeter measures altitude from about 5000 ft down to touchdown.

Tactical Air Navigation (TACAN) units are used on the Space Shuttle Orbiter to determine the slant range and magnetic bearing of the Orbiter during landing approach. This is not an autonomous capability, and several precisely located active ground stations are required. The maximum range of TACAN is about 400 nautical miles. The Orbiter acquires bearings at a range of about 300 nautical miles and 160,000 ft altitude after entry blackout. TACAN data can be used down to an altitude of about 1500 ft.

For final approach, the Orbiter uses the *Microwave Scanning Beam Landing System* (MSBLS). This system requires active ground stations located immediately adjacent to the runway. The Orbiter acquires the MSBLS signal at a range of 8 to 12 nautical miles and at an altitude of approximately 18,000 feet. The Orbiter Commander usually takes over manually over the runway threshold at about 100 feet altitude. See also **Space Shuttle**.

Control. A number of functions must be performed during spacecraft flight that fall under the general heading of *control*:

- During navigational observations, the spacecraft must be aligned relative to an inertially fixed axis system and the attitude stabilized within a very narrow angular deadband. This is sometimes called the *attitude hold mode*.
- During periods of thrusting, the spacecraft must be pointed in the correct direction, and the thrust vector controlled. This is usually called the *delta V mode*.
- Spacecraft attitude hold relative to the Sun may be required, or perhaps the vehicle is slowly rolled (so-called "barbeque" mode) for thermal control.
- Attitude control may be required in conjunction with the deployment of certain mechanisms such as solar panels, radiators, docking mechanisms, and manipulator arms.
- If the spacecraft is to land on Earth or on one of the planets that has an atmosphere, control during atmospheric entry may be required and may necessitate blending of attitude control rockets and aerosurfaces. Landing control is likely to be required and may include control of aerosurfaces, speed brakes, parasails, drag parachutes, landing gear, wheel brakes, and steering on the ground.
- Effector command signals must be processed (scaled, mixed, prioritized, time-delayed) and routed.

Depending on the GN&C system design, attitude change commands may come from the flight computer, directly from the flight crew, or from the ground via radio links. Attitude stabilization commands may come from body-mounted gyros that are generally less accurate than those used for inertial guidance but may serve as emergency backups for the IMU. A newer technique for stabilizing spacecraft in Earth orbit uses differential Global Positioning System (GPS)-derived position data from multiple receivers located remotely from each other on the spacecraft. It has been found that attitude knowledge of the order of 0.05° is possible. Body-mounted accelerometers may be used for docking sensing or aerodynamic drag sensing during entry.

Effectors. Devices that produce intentional reactive forces on the spacecraft are termed *effectors* and may include any of the following:

- Attitude control thrusters that use cold gases or reactive chemicals as propellants. These may also be used for small translations for such maneuvers as docking.
- Major engines that produce large changes in the velocity of the spacecraft (*delta V*). Both thrust level and direction (*thrust vector control*) may be controlled.
- *Reaction wheels* where the wheel rotational rate is accelerated or decelerated to achieve reactive torquing of the spacecraft and a corresponding change in attitude.

- *Control moment gyros* that are typically mechanical gyros torqued electrically so that the resulting precession produces a desired change in spacecraft attitude.
- Aerodynamic surfaces and drag devices.
- Tethers that produce electromagnetic thrusting.

Usually the effectors themselves are not considered part of the GN&C system, but their control electronics are. Analysis of the effects on vehicle motion is usually considered a GN&C responsibility. A simplified generalized block diagram of control function is shown in Fig. 10.

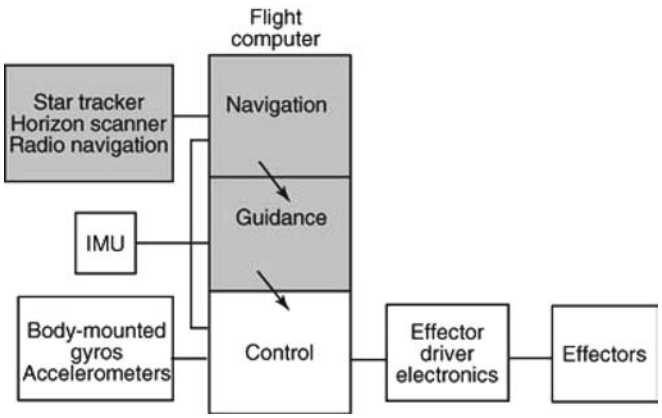

Fig. 10. Control block diagram.

Environmental Disturbances. There are several disturbances that can cause a variation in attitude and possibly tumbling or wobbling. These are usually more noticeable during quiescent periods when the spacecraft is allowed to drift:

- Gravity gradient effects, usually significant when orbiting or flying near a large body.
- Aerodynamic drag and moments when flying near a body having an atmosphere.
- Solar radiation pressure, usually significant when the spacecraft configuration includes large planar surfaces, such as solar cell panels.
- Electromagnetic induction when flying through the magnetic field of a large body.

The effects of these disturbances are difficult to calculate accurately but may be estimated using the methods of Thompson and Abzug Ref.[1] At the appropriate time, when a fixed attitude is required, these must be counteracted by the attitude control system. Often a small angular deadband is desired and is maintained by use of the reaction wheels, control moment gyros, or attitude control thrusters. In the last case, thruster propellant usage is always a consideration and sometimes leads to sophisticated electronic logic for duty cycle optimization.

Reference Axis System. Since effectors and some sensors are mounted rigidly to the spacecraft structure, it is customary for control analysis to use an axis system originating at the center of mass of the spacecraft. This is depicted in Fig. 11. Symbols are defined in Table 1, followed by a sign convention in Table 2.

Equations of Motion. Development of the equations of motion for all mission phases of a spacecraft is an arduous task and beyond the scope of this article. The usual approach to analyzing a particular phase is to make certain simplifying assumptions to reduce the number of mathematical terms significant in that phase. Later on, after achieving a basic understanding of the dynamics, correcting terms may be added for evaluation.

For example, shown below are *six-degree-of-freedom* equations of motion for the coasting (in space) attitude hold mode. Simplifying assumptions are as follows:

- The spacecraft is considered a rigid body.
- Vehicle mass and inertia remain constant during the period of interest.

[1] Another approach might be that used by the U.S. Navy to estimate aerodynamic stability derivatives in the transonic region for aircraft. Displaying remarkable initiative and refreshing candor, the Bureau of Aeronautics claims success using the method of omphaloskepsis (see BuAer Report AE-61-4, Fundamentals of Design of Piloted Aircraft Flight Control Systems, Volume II, Dynamics of the Airframe, February 1953, p. v-11.)

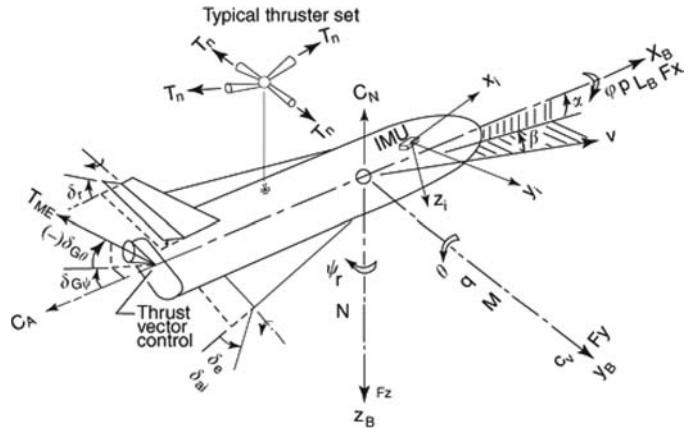

Fig. 11. Control reference system.

TABLE 1. BODY AXES COORDINATE SYSTEM

x_B, y_B, z_B	Orthogonal body axes, right-hand rule
x_i, y_i, z_i	Orthogonal inertial axes, right-hand rule
F_x, F_y, F_z	Forces along the body reference axes
L, M, N	Moments about the x_B, y_B, z_B axes, respectively, right-hand rule
φ, θ, ψ;	Angular displacement about the x, y, z axes, respectively
p, q, r	Angular velocity about the x_B, y_B, z_B axes, respectively
V	Velocity vector
α	Angle between the x axis and the projection of the velocity vector in the $x-y$ plane; angle of attack
β	Angle between the x axis and the projection of the velocity vector in the $x-z$ plane; angle of sideslip
$\delta_G\theta$	Main engine gimbal deflection (pitch)
$\delta_G\psi$	Main engine gimbal deflection (yaw)
δ_e	Elevon deflection
δ_a	Aileron deflection (produced by differential elevon deflection)
δ_r	Rudder deflection
$T_n n = 1, 2, 3 \ldots$	Attitude control thrusters; each has a unique number and may produce forces along all body axes
T_{ME}	Main engine thrust; may produce forces along all axes and moments about all axes

TABLE 2. SIGN CONVENTION

Cause	Effect
(+) angle of attack ($+\alpha$)	(−) z airload
(+) sideslip ($+\beta$)	(+) y airload
(+) rudder deflection ($+\delta_r$)	(+) y force, (−) yaw ($-N$)
(+) elevon deflection ($+\delta_e$)	(−) z force, (−) pitch ($-M$)
(+) differential elevon deflection ($+\delta_a$)	(−) roll ($-L$)
(+) gimbal deflection in pitch ($+\delta_G\theta$)	(−) z force, (−) pitch ($-M$)
(+) gimbal deflection in yaw ($+\delta_G\psi$)	(+) y force, (−) yaw ($-N$)
(+) force	(+) linear acceleration
(+) moment	(+) angular acceleration
(+) attitude control thruster force ($+T_n$)	(+ or −) moment depending on thruster location
(+) C_N normal force coefficient	(−) force along the z_B axis
(+) C_A axial force coefficient	(−) force along the x_B axis
(+) C_Y side force coefficient	(+) force along the y_B axis

- The spacecraft is symmetrical about the $x-z$ plane, causing the products of inertia J_{yz} and J_{xy} to drop out.
- Terms involving the products of inertia, pJ_{xz} and rJ_{xz}, are small and may be ignored.

$$\overline{x} = 1/m\left[\sum F_x\text{THRUSTERS} + \sum F_x\text{ENVIRONMENT}\right]$$

$$\overline{y} = 1/m\left[\sum F_y\text{THRUSTERS} + \sum F_y\text{ENVIRONMENT}\right]$$

$$\overline{z} = 1/m\left[\sum F_z\text{THRUSTERS} + \sum F_z\text{ENVIRONMENT}\right]$$

$$\overline{\phi} = 1/I_{xx}\left[\sum L_{\text{THRUSTERS}} + \sum L_{\text{ENVIRONMENT}}\right]$$

$$\overline{\theta} = 1/I_{yy}\left[\sum M_{\text{THRUSTERS}} + \sum M_{\text{ENVIRONMENT}}\right]$$

$$\overline{\psi} = 1/I_{zz}\left[\sum N_{\text{THRUSTERS}} + \sum N_{\text{ENVIRONMENT}}\right]$$

It is helpful to write the equations in this form to get an understanding of the importance of the different terms. Numerical solution on digital computers is usually more convenient after conversion to matrix form.

The Flight Computer. There is no part of GN&C technology that has evolved during the past 50 years as dramatically as the onboard digital flight computer. It started in the early 1950s as a fire control computer 4 cubic feet in volume with 250 vacuum tubes. Then came the addition of the onboard navigation function with transistor-transistor logic (TTL). Then its use was expanded to include guidance where steering signals were injected into an analog flight control system. By the time of the second-generation Apollo spacecraft, the flight control function was added, integrated electronic circuits were implemented, and the first automatic fly-by-wire flight control was realized. With the Space Shuttle came computer control of all GN&C functions for both atmospheric and spaceflight, computer-driven cockpit displays and computer processing of all manual flight control inputs, and the beginnings of distributed processing. Current flight computers are on the order of cubic inches in volume or smaller, use relatively modest amounts of electrical power, and compute at rates incomprehensible only a few years ago. Microminiaturization is being realized in current applications, and the application of nanotechnology seems likely within a few years.

Today's flight computer performs an impressive array of functions, depending on the mission of the spacecraft:

- Guidance sensor management and data processing, guidance algorithm computation, and steering signal generation.
- Navigation sensor management and data processing; course evaluation, correction, and forecasting; and trajectory calculation.
- Flight control sensor management and data processing, vehicle attitude control, command mixing and prioritization, effector selection, thrust vector control, attitude thruster control, aerosurface control, vehicle bending and longitudinal oscillation control.
- Aerobraking control, parachute and parasail deployment and steering, nose wheel steering, and wheel braking.
- Systems management for non-GN&C systems, such as electrical power generation, distribution and control; radio/radar/television communications; exploratory payload sensor management and data processing; environmental control systems; and hydraulic and pneumatic systems.
- Consumables accounting and management.
- Flight instrumentation control, data processing, and downlink control.
- Generation of cockpit displays and processing of manual commands for flight control.
- Accommodation of ground commands via radio for software updates, GN&C commands, and data downlinking.
- Redundancy management.
- Vehicle health management (an extension of onboard checkout).
- Multiplex data bus management.
- Distributed processing management.

Input/Output. Probably the most difficult problem in implementing flight computers is communication between the computer and the various devices that are commanded or generate data. The magnitude of this problem can be appreciated intuitively if one imagines the number of wire bundles and connectors required to link the devices to the computer. The problem is compounded if there are redundant computers linked to one another that share the same information. Also, put simply, the digital flight computer is an anomaly in the middle of an analog world, and the necessary conversion of signals from analog-to-digital (A/D) and digital-to-analog (D/A), plus attendant voltage scaling and device scale factor and bias accommodation, is a significant task.

The computer communications problem has been solved successfully in various ways:

- Separating the input/output function and the computation function into two boxes called the input-output processor (IOP) and the central processor unit (CPU). In this approach, the IOP handles the A/D and D/A conversions, voltage scaling, temporary data storage, data bus management (if required), and other functions.
- Doing the A/D and D/A conversion, scale factor adjustment, and voltage scaling at the devices served. In some cases, small local processors are implemented in the devices to perform these relatively simple chores, so that messages to and from the main flight computer are reduced to significant flight data. (This is the beginning of *distributed processing*.)
- Implementing a multiplex data bus distribution system for communicating with the various devices. In this approach, various devices that have unique addresses are connected to a data bus managed by the IOP. An important advantage of this approach is weight reduction in wiring.
- Sharing the computation task among several processors on the spacecraft. It could be argued that this *distributed processing* approach is more of a fundamental change in the approach to hardware and software than just a solution to the I/O problem. Certainly, it significantly affects the total software design, implementation, and verification/validation approach. In addition, it usually reflects not just a GN&C decision, but total spacecraft system engineering methodology.

Real-Time Operation. The requirement of uppermost importance for flight computers doing GN&C computations is the ability to keep up with the dynamics of the vehicle and the sensors that provide input data. Whereas batch processing computers in typical ground settings simply run longer when necessary to complete a job, such a delay can be deadly in flight computers in the loop of highly dynamic flight scenarios. The flight computer must maintain system stability, provide computational precision, service sensors, accept interrupts, cope with failures, and even monitor itself while running on control software cycle times typically of 40 milliseconds. The computation bandwidth is almost impossible to estimate accurately early in the design phase of a program, and even the most generous growth margins are usually exceeded and call for compromises to be accommodated later on in the flight software.

A key characteristic of the computer loading is the iterative nature of many calculations, particularly in navigation. There will be errors from a number of sources, including navigation sensor measurements and system mechanization. A technique for handling these errors is the Kalman filter, a stochastic analysis and estimation process used extensively in space, aircraft, and missile computers since the early 1960s. Beginning with a priori knowledge of system errors, the Kalman filter continually performs a statistical error analysis and predicts new values for system variables. The resulting product is continuing improvement in position determination.

Flight Software. In the early days of general-purpose digital computers, and especially in digital flight computers, computation times were extremely slow by today's standards, and random access memory (RAM) was bulky and expensive. The typical computer programmer was a mathematician who likely had a keen appreciation of the overall computation objectives and was driven to code austere programs in what was termed *machine language* in those days but called *assembly language* today. Major disadvantages in that software coding approach were that it was labor-intensive and only the original programmer understood the logic behind his organization of the computer program. If other programmers were brought in to modify the program, there was usually some unproductive period to learn the code already in existence. The major advantage was that the assembly code was understandable, at least to the original programmer, and was easily modified. The GN&C engineer often simply had only to speak in general terms to the programmer to have a change incorporated in a timely manner.

Since those early days, three things have happened to cause a revolution in the way flight software is produced today: computation rates have increased by orders of magnitude, random access memory has become inexpensive, and *higher order languages* (HOL) have become predominant in the development of software programs. Now, software engineers and programmers are formally educated in information systems technology rather than mathematics. The use of higher order languages such as FORTRAN, C, C++, Ada, and HAL/S makes the flight software engineer and programmer very productive in terms of assembly code generated. And once software engineers or programmers learn the rules and methods for a particular HOL, they can become productive immediately without knowing very much about the "big picture" of the flight program.

This evolution in computer hardware and software production is not without drawbacks. The very universality of a typical HOL that makes it attractive to modern diverse users also produces very inefficient assembly code. Traditionalists cringe at the squandering of RAM, and even today there never seems to be enough RAM as a spacecraft program progresses. Then, there is the assembly code itself — often virtually indecipherable and difficult to change if relatively simple modifications (called *patches*) are necessary. The alternative is to make the changes in the source code in the HOL and recompile, a time-consuming process and so prone to introducing undesirable effects that lengthy reverification is usually required. An unfortunate result of this modern approach is that the GN&C engineer usually does not have a thorough knowledge of the flight software program and has difficulty developing an intuitive "feel" for the program. He must rely almost exclusively on the formal verification/validation of the program for confidence.

Another characteristic of the modern GN&C flight software program is that it seems to "grow like Topsy" as the spacecraft design matures. This is an unfortunate product of an evangelistic-like effort in the early days of spaceflight, and still today, by enthusiasts to "sell" the digital flight computer by welcoming more and more functions into the software program as a cheap way of implementation. Software accommodation of a feature may appear initially to be a simple and seemingly inexpensive thing to do, but often the penalties in time and expense for the subsequent verification/validation are not anticipated. A vigorous GN&C system engineering program is probably the best solution for this quandary.

The cost of flight computer software is likely to be the most significant item in the GN&C budget and may exceed the cost of the rest of the GN&C system. There are several important factors involved in containing this cost:

- It is critical to document software requirements in as much detail as possible or the computer may be undersized, or the software cost driven to astronomical levels by changes later on, or both.
- The HOL must be chosen carefully while balancing its suitability, maturity, and compilation time with the availability of software engineers and programmers familiar with it.
- The executive program (operating system) must be carefully planned for real-time operation with the attendant issues discussed earlier.
- Application software must be compatible with the devices commanded, and the software engineer-to-device engineer interaction is expensive and sometimes difficult to orchestrate.
- All software must be designed recognizing the time, manpower, and equipment costs associated with the verification process.
- Configuration management is an absolute must for the duration of the spacecraft project.
- The verification and validation approach must be selected. For verification, will flight computers or computer emulators be used? For validation, will a flight computer plus simple simulator be used, or will an "iron bird" or high-fidelity avionics integration facility plus high-fidelity simulator be used? And will performance of the verification/validation be done (or repeated) by an independent organization (so-called *independent verification and validation* or IV&V)?

Current Trends. Flight computers continue to grow in capability — faster computational speeds and greater RAM — and are becoming smaller, less power hungry, and cheaper. Choices that were significant a few years ago are not issues anymore. For example, fixed-point versus floating-point arithmetic is now typically decided in favor of floating-point even though floating-point takes more computing time. Word length is now typically 32 bits, and 16-bit machines are passing from the scene. Lasers are being used for communication within the computer in place of copper wire. More and more devices in the GN&C system have embedded digital processors that take care of much of the computer overhead, thus off-loading the central flight computer. Other advancements are discussed under "Integrated GN&C" following.

Integrated GN&C. Modern spacecraft GN&C systems have their roots in the automatic pilots (*autopilots*) developed for aircraft in the middle of the last century to relieve pilots on long flights. Rapid advances were made in the 1930s and 1940s, inspired largely by World War II. Initial, relatively crude, vacuum-driven gyros plus vacuum control valves plus hydraulic actuators gave way to electrical sensors plus electronic (vacuum tube) signal processing plus electrical actuators. Throughout this period, the guidance and navigation functions were typically performed by the flight crew manual commands could be issued to the aircraft directly or via the autopilot control system. Autopilots were the means used to control bombers with steering commands coming from the famous Norden bombsight. Conceptually, then, the guidance and navigation functions were an "overlay" to the autopilot control system.

During the 1950's to early 1960's when onboard digital flight computers came on the scene to perform the G&N functions this overlay approach was followed. Flight computers provided steering commands to the vehicle via the analog control system in much the way aircraft crews had done in the past. The analog control system continued to provide three-axis stability and processed the computer-generated steering commands. This design approach was typical of aircraft and guided missiles of the period, and it was followed on the NASA Gemini spacecraft and the early NASA Block I Apollo spacecraft. It is interesting to note that toward the end of this period when manned spacecraft came on the scene mechanical control linkage gave way to electrical communications between the astronaut and effectors and the expression *fly-by-wire* originated.

In the mid-1960s, as flight computers became more powerful and compact, the entire GN&C calculation function was assigned to them, and analog channels were retained as backup. Outputs were then made directly to the driver amplifiers of the analog control system to command the attitude control thrusters and large engines for changes in translational velocity and thrust vector control during thrusting. This *integrated* GN&C System became the standard design approach used in guided missiles, satellites, the NASA Apollo lunar mission spacecraft, the NASA Space Shuttle, and is followed today in the International Space Station. This evolution is shown in Fig. 12.

The *integrated* approach has several advantages. Since the flight computer performs all the GN&C calculations, the computer program ("flight software") development can be managed more easily. Flight software design changes can be controlled and implemented with less chance of error. System internal redundancy, if desired, can be implemented more efficiently. Overall GN&C electrical power usage is less. Total system volume and mass are reduced.

This is not to say that the integrated GN&C System is necessarily less complex. Likely, it is not. Computer programs become larger, harder for nondeveloper users to understand, and almost impossible to test completely. Training of flight crew and ground support personnel is usually more tedious and lengthy. Preflight testing of the integrated system becomes more involved and expensive because of the fidelity required.

Nonetheless, the integrated GN&C System provides the capability of performing more complex missions and is more flexible for design changes needed for corrections, evolutionary development, and last minute mission changes.

Digital Data Buses. A major advancement in the design of the NASA Space Shuttle was the use of multiplex serial digital data buses for communication with the flight computer. This approach helped solve the computer input/output loading problem and also provided substantial weight saving. Some 28 data buses are used in the Shuttle design. The data bus is, physically, a twisted shielded pair of wires with transformer couplers for bus protection at each electronic "user" box. The computer uses command and data words that have unique addresses for each receiver so that although all boxes on the bus hear all communications, each responds only to words that have its address. Multiplexers/Demultiplexers convert and format serial digital commands into separate parallel discrete, digital, and analog commands for the various systems served (demultiplexing)

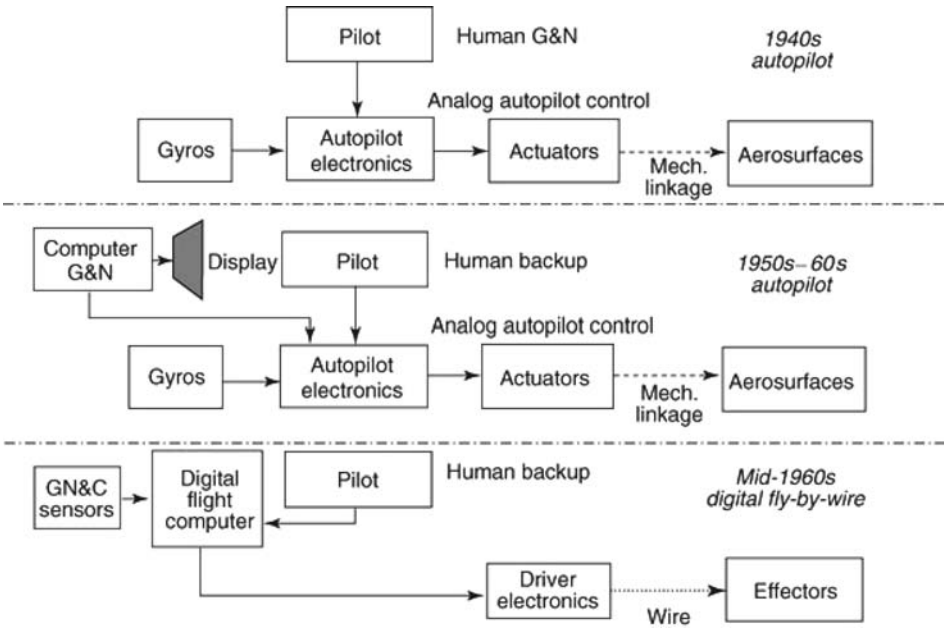

Fig. 12. Evolution of the autopilot.

and do the reverse for data collected and sent back to the computer (multiplexing). The USAF continued this development, and multiplexed data buses are now common on aircraft, spacecraft, and missiles.

An approach similar to the copper data bus discussed before is the fiber-optic bus. Fiber has the advantages of potentially higher data rates and less susceptibility to electromagnetic interference or intentional jamming. Disadvantages include larger minimum bend radius for installation and the potential to become unserviceable due to age or environmental effects.

Fiber optics is also considered part of a general class of communications called *photonics*. This is a term used for the general case in which the medium is light rather than electron flow. In GN&C, the expression *fly-by-light* is sometimes used. When direct line of sight exists between devices, the use of laser beams or infrared beams for data transfer is possible.

Fly-by-Wireless?. A promising development that could be used in lieu of the data bus is digital spread-spectrum radio frequency communication between the flight computer and devices in the GN&C system. *Spread-spectrum* is a technique used to reduce or avoid interference by taking advantage of a statistical means to send a signal between two points using different frequencies at different times. The theory is that noise tends to occur at different frequencies at different times. Therefore, even though part of a transmission might be lost due to interference, enough of the message will come through to create noticeably better output compared to fixed-frequency systems. Further, using error correction techniques, the original message can be totally restored. The promise of this approach for aircraft and spacecraft is reduction in size, weight, and power of GN&C systems while offering immunity to natural interference or jamming from man-made equipment.

INVOCON, based in Conroe, Texas, has had considerable success in developing instrumentation for the NASA Space Shuttle Orbiter and the International Space Station by linking sensors to a central controller/transponder via *spread-spectrum radio*. Using the same principle on a project sponsored by NASA Dryden Flight Research Center, INVOCON successfully replaced a data bus link from the flight computer to an elevon actuator on a NASA F-18 research airplane. This concept is shown in Fig. 13.

Redundancy. The use of backup hardware in aircraft and spacecraft to allow operation in the event of failure dates back many years. In manned vehicles, the crew normally has had the capability to choose the backup, usually degraded in performance, but may have been incapable of making the decision in dynamic situations.

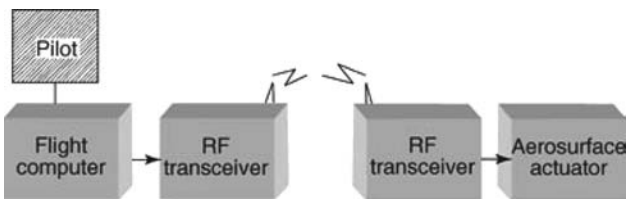

Fig. 13. Fly-by-wireless concept.

The NASA Space Shuttle, which had a design requirement to remain fully operational with one failure and to remain safe after two failures, probably reached the maximum in complexity in the approach to automatic and manual redundancy management. Basic to the design approach is the provision of four redundant primary flight computers to handle two computer hardware failures automatically and a fifth identical backup flight computer loaded with dissimilar software to be chosen in a manual switchover in case of a generic software error in the primary set. Three or more redundant channels of sensors are shared by all computers, which then command four parallel redundant channels to the effector servoelectronics. The primary flight computers automatically compare and vote by "majority rule." In addition, the aerosurface actuators, which have four channels at the secondary (pilot spool) stage, were designed to vote effectively by force fight, that is, three channels overcome the offending fourth channel by force summing three against one.

The requirement of redundancy and automatic redundancy management in spacecraft depends on the need for vehicle survivability weighed against the cost of redundancy implementation. For expendable vehicles, it may be cheaper simply to build more spacecraft than to make them internally redundant. In manned spacecraft, loss of life is so intolerable in this country that safety must be maintained, regardless of cost.

Simulation. The sheer quantity of "black boxes" in a modern day GN&C system begs the question as to whether system end-to-end mathematical analysis is possible. Further, the time-varying, cascading signal flow from the multiple sensors to the flight computer to the various driver electronics for the motion effectors makes end-to-end analysis and solutions by conventional closed form methods virtually unachievable. Moreover, if the solution were tractable for a particular time and set of physical conditions and produced acceptable results from an operational point of view, the flight conditions could change in the next few moments, and the analysis would have to be repeated. The analytical approach commonly used in these situations is known as *computer simulation*, or simply *simulation*, where time is the primary independent variable.

Simulations are used in the conceptual design phase of a program and grow in complexity and fidelity as the program matures. Mathematical models of the functions of the different pieces of hardware evolve in complexity from simple first-order equations to higher and higher levels of fidelity. Desktop computers are adequate in the early phases to define and analyze single sensors, signal amplifiers, effectors, and units as complex as inertial platforms. As the program progresses, multiple hardware units are combined, vehicle characteristics and operational environments become better known in more detail, and the simulations are forced to move to larger complexes of computers, data library devices, and resultant data readout devices.

Additional complexity accompanies increased fidelity when the simulation is required to operate in a *real-time* mode. *Real time* means that a series of events simulated is calculated on the simulator in the same period of time as the real events would occur. Real-time simulation is used any time there is flight crew involvement or flight-like hardware is substituted for simulated hardware. For GN&C system-level simulations, the flight computer is usually one of the earliest units substituted for its modeled counterpart.

If the flight vehicle is a manned spacecraft, a crew station (cockpit) is usually added. Active crew displays and controls, either flight-like or simulated, are added to allow realistic crew participation for evaluating the GN&C system. If visual cues are required for this crew participation, "out-the-window" scenes may be included. The NASA Johnson Space Center Engineering Simulator that has some two million lines of computer code is an example of these large man-in-the-loop simulations.

As the program matures, a simulator especially designed for flight crew and ground operations personnel training is usually constructed. This simulator–trainer typically has the highest fidelity of all simulations in the program. All onboard displays and controls are included, and system simulated failures may be introduced to enhance training. For manned spacecraft, out-the-window scenes are included for all phases of the intended vehicle mission, including prelaunch, launch, orbit transfers, midcourse deltaV's, rendezvous and docking with another spacecraft, deorbit, and landing.

Vital to the fidelity of simulations throughout a program are valid mathematical models for the components of the GN&C system, for effectors and other non-GN&C equipment, and for the environment in which the vehicle is supposed to be operating. Simple first-order equations are quite satisfactory early in the design phase, but as actual hardware is built, the fidelity desired increases, and the corresponding mathematical models become more complex. Similarly, equations of motion, environmental models for ambient physical conditions, aerodynamic data, ephemerides, and out-the-window scenes all become more intricate in the drive for fidelity as the program progresses and the design matures. This often results in large simulation complexes that are expensive to create and maintain, but they are indispensable for system development, anomaly investigations, and crew training.

Integration and Verification. The term *integration* is an overworked word in the aerospace business, but it is quite descriptive in GN&C systems development. Hardware piece parts and modules are *integrated* (assembled) into *line replaceable units* (LRUs) or "black boxes"[2] that are replaceable as the first level of maintenance on spacecraft. The LRUs are then *integrated* (combined) to form the whole GN&C system. A similar process is followed in developing flight computer software. As this process is followed, engineering tests are conducted, and design errors are uncovered and corrected. This successive *integration* is part of the development process and is the most demanding part of GN&C engineering.

Verification is the process of formal evaluation of the hardware and software and is done somewhat in parallel with the *integration* process. Four methods are generally used and are listed here in order of preference: *test, inspection, demonstration, and analysis*. These are defined as follows:

Test — the stimulation of the hardware and software under prescribed conditions and the responses measured and evaluated against specifications.

Inspection — the visual examination of hardware, usually in static situations.

Demonstration — operation in a test-like environment but where res ponses usually cannot be measured and performance must be evaluated subjectively.

Analysis — mathematical and logical evaluation using mathematical models, drawings, flow charts, and photographs.

Formal hardware verification testing begins with the *acceptance test* at the GN&C system vendor's plant. This test is conducted before the buyer accepts delivery to ensure that the equipment is functioning in accordance with the requirements of the contract between the vendor and the buyer.

Ideally, one or more LRUs are randomly selected from those already accepted for a subsequent *qualification test*. The qualification test is conducted at extremes in ambient conditions [pressure, temperature, vibration, input electrical power, electromagnetic interference (EMI), etc.] beyond the limits expected in normal operation. This test ensures that the hardware has comfortable operating margins.

The next level of testing is the *integrated system test*. In this test, the entire GN&C system is assembled in a flight-like configuration, and stimuli at the sensors are processed through the system to the outputs of the effector driver electronics. This is also sometimes called a *system end-to-end test*. Debate continues as to whether this test is an engineering development test or a formal verification test, but in reality it is usually both. Certainly, any design errors or generic manufacturing errors that are uncovered must be corrected. A critical part of this exercise is the testing of interfaces with non-GN&C equipment. The importance of this aspect is discussed in the Euler, et al. Ref.

The final ground verification test is the *mission verification test*. The significant addition to the integrated system test configuration is a real-time simulation computer complex. This is used to "close the loop" (i.e., close the flight control loop using simulated vehicle dynamics) and to model missing flight hardware and the vehicle flight environment so that the entire mission, or significant portions, may be "flown" as realistically as practical short of actual flight. Flight computer software is used in the flight computer and is *validated* in the process. Successful completion of the mission verification test allows *certification for flight*. This sequence is shown pictorially in Fig. 14.

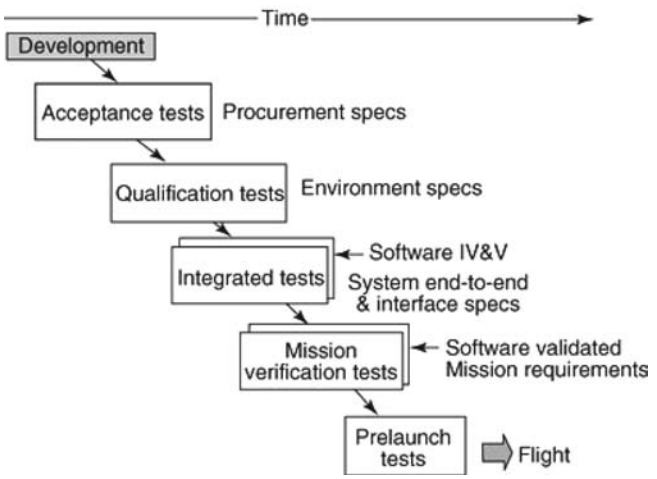

Fig. 14. Integration and verification sequence.

One of the most sophisticated facilities for the integrated system test and the mission verification test is the Shuttle Avionics Integration Laboratory at the NASA Johnson Space Center. An artist's rendering of

[2] The terms *black boxes* and *line replaceable units* (LRU's) have their heritage in the airplane world. Before the space era, most airplane electronics boxes were, and still are today, painted black. Line replaceable units are the level of replacement for maintenance on the airport *flight line* or ramp. A term that has come into use on the International Space Station program is *orbital replacement unit* (ORU), and as the name implies, the ORU is the usual replacement unit for maintenance during orbital flight around Earth.

the facility is shown in Fig. 15. The avionics are installed in a high-fidelity, three-dimensional full-scale arrangement with flight-like vehicle wire harnesses. The outline of the Orbiter is shown in dashed lines for orientation.

For manned spacecraft, one or more flight tests are usually required before the vehicle, including the GN&C system, is certified for normal operational use.

SPACECRAFT POWER SYSTEMS. Spacecraft travel millions of miles away from Earth, often encountering hostile space environments along the way. Power for these spacecraft must be efficient and reliable, providing power to the spacecraft's instruments and other subsystems (communication, navigation, etc). Roughly 300 Watts to 2500 Watts of electricity is required to power a spacecraft like *Voyager*, *Galileo*, or *Magellan*. The power supply must provide a large percentage of its power over a lifetime measured in years or decades. Choices of technology to meet these requirements are constrained largely to two: photovoltaics and radioisotope power systems.

A spacecraft's electrical power system generally consists of the primary power generating unit (solar or radioisotope) and a power management and distribution system. The electrical power system may also contain an energy storage unit (battery) for other spacecraft power needs.

This article discusses the various ways NASA provides power for spacecraft that are orbiting Earth as well as traveling to distant planets.

Battery Power. A battery, which is actually an electric cell, is a device that produces electricity from a chemical reaction. Strictly speaking, a battery consists of two or more cells connected in series or parallel, but the term is generally used for a single cell. A cell consists of a negative electrode; an electrolyte, which conducts ions; a separator, also an ion conductor; and a positive electrode. The electrolyte may be aqueous (composed of water) or nonaqueous (not composed of water), in liquid, paste, or solid form. When the cell is connected to an external load, or device to be powered, the negative electrode supplies a current of electrons that flow through the load and are accepted by the positive electrode. When the external load is removed the reaction ceases.

A primary battery is one that can convert its chemicals into electricity only once and then must be discarded. A secondary battery has electrodes that can be reconstituted by passing electricity back through it; also called a storage or *rechargeable battery*, it can be reused many times.

One of the first space batteries was the silver–zinc battery, which dominated the industry in the 1960s. This is a premium system with very high specific power and energy, but is quite expensive due to the use of silver. They are still used in selected applications, such as launch vehicles (rockets) and torpedoes. The Mars *Pathfinder* also used a silver–zinc battery, but it was designed to be rechargeable. They have a relatively short cycle life, and are not used for multiyear missions. This type of battery is used commonly in the commercial market for hearing aids.

Batteries come in several styles; the most familiar are single-use alkaline batteries. NASA spacecraft usually use rechargeable nickel–cadmium or nickel–hydride batteries like those found in laptop computers or cellular phones. Engineers think of batteries as a place to store electricity in a chemical form.

Battery technology is part of the power system, storing and discharging energy on each orbit of the spacecraft. The batteries help provide a constant source of power to the spacecraft by storing energy when excess is provided by the solar cells and discharging stored energy when the solar cells are not providing any during periods of eclipse.

Nickel-Cadmium Batteries. Nickel–cadmium has been the most common space battery since the 1970s. They were used in all commercial communications satellites, in most earth orbiters, and in some space probes. They are generally a prismatic (resembling, or being a prism) design, and packaged very efficiently. This means that the batteries can be stored on the spacecraft in a very compact form, eliminating the need for extraneous space. They have been known to last for ten to twenty years in space. They are still in use in selected space applications, including small satellites and for missions that encounter very severe radiation environments.

This battery uses nickel oxide in its positive electrode (cathode), a cadmium compound in its negative electrode (anode), and potassium hydroxide solution as its electrolyte. The nickel–cadmium battery is rechargeable, so it can cycle repeatedly. A nickel–cadmium battery converts chemical energy to electrical energy upon discharge and converts electrical energy back to chemical energy upon recharge. In a fully discharged NiCd battery, the cathode contains nickel hydroxide, $Ni(OH)_2$, and cadmium hydroxide, $Cd(OH)_2$ in the anode. When the battery is charged, the chemical composition of the cathode is transformed and the nickel hydroxide changes to nickel oxyhydroxide, NiOOH. In the anode, cadmium hydroxide is transformed to cadmium. As the battery is discharged, the process is reversed, as shown in the following formula.

$$Cd + 2H_2O + 2NiOOH \longrightarrow 2Ni(OH)_2 + Cd(OH)_2$$

Nickel–cadmium is the most commonly used battery for Low Earth Orbit (LEO) missions. A spacecraft battery consists of series-connected cells, the number of which depends upon bus voltage requirements and output voltage of the individual cells. See also **Battery**.

Nickel–Hydrogen Batteries. The nickel–hydrogen battery is currently the most popular space battery. It can be considered a hybrid between the nickel–cadmium battery and the fuel cell. The cadmium electrode was replaced with a hydrogen gas electrode. This battery is visually much different from the nickel–cadmium battery, because the cell is a pressure vessel, which must contain over one thousand pounds per square inch (psi) of hydrogen gas. It is significantly lighter than nickel–cadmium, but is more difficult to package, much like a crate of eggs. It is the longest-lived space battery yet built, with 10 to 20 year lifetimes being common. This battery is too expensive for commercial applications, and few terrestrial examples have been built.

Nickel–hydrogen batteries are sometimes confused with nickel–metal hydride batteries, the batteries commonly found in cell phones and laptops. The nickel–metal hydride system is rarely used in space due to its limited life. Nickel–hydrogen, as well as nickel–cadmium batteries use the same electrolyte, a solution of potassium hydroxide, which is commonly called *lye*.

Incentives for developing nickel–metal hydride (Ni-MH) batteries comes from pressing health and environmental concerns to find replacements for the nickel–cadmium rechargeable batteries. Due to worker's safety requirements, processing of cadmium for batteries in the U.S. is already in the process of being phased out. Furthermore, environmental legislation for the 1990s and the 21st century will most likely make it imperative to curtail the use of cadmium in batteries for consumer use. In spite of these pressures, next to the lead–acid battery, the nickel–cadmium battery still has the largest share of the rechargeable battery market. Further incentives for researching hydrogen-based batteries comes from the general belief that hydrogen and electricity will displace and eventually replace a significant fraction of the energy-carrying contributions of fossil-fuel resources, becoming the foundation for a sustainable energy system based on renewable sources. Finally, there is considerable interest in the development of Ni–MH batteries for electric vehicles and hybrid vehicles.

The nickel–metal hydride battery operates in concentrated KOH (potassium hydroxide) electrolyte. The electrode reactions in a nickel–metal hydride battery are as follows:

$$\text{Cathode } (+) : NiOOH + H_2O + e^- Ni(OH)_2 + OH^- \quad (1)$$

$$\text{Anode } (-) : (1/x)MH_x + OH^- (1/x)M + H_2O + e^- \quad (2)$$

$$\text{Overall} : (1/x)MH_x + NiOOH(1/x)M + Ni(OH)_2 \quad (3)$$

The KOH electrolyte can only transport the OH-ions and, to balance the charge transport, electrons must circulate through the external load. The nickel oxy–hydroxide electrode (equation 1) has been extensively researched and characterized, and its application has been widely demonstrated for both terrestrial and aerospace applications. Most of the current research in Ni–metal hydride batteries has involved improving the performance of the metal hydride anode. Specifically, this requires the development of a hydride electrode with the following characteristics: (1) long cycle life, (2) high capacity, (3) high rate of charge and discharge at constant voltage, and (4) retention capacity.

Lithium Batteries. These systems are different from all of the previously mentioned batteries, in that no water is used in the electrolyte. They use a nonaqueous electrolyte instead, which is composed of organic liquids and salts of lithium to provide ionic conductivity. This system has much higher cell voltages than the aqueous electrolyte systems. Without water, the evolution of hydrogen and oxygen gases is eliminated and cells can operate with much wider potentials. They also require a more complex assembly, as it must be done in a nearly perfectly dry atmosphere.

A number of nonrechargeable batteries were first developed with lithium metal as the anode. Commercial coin cells used for today's watch batteries are mostly a lithium chemistry. These systems use a variety of cathode systems that are safe enough for consumer use. The cathodes are made of various materials, such as carbon monofluoride, copper oxide, or vanadium pentoxide. All solid cathode systems are limited in the discharge rate they will support.

To obtain a higher discharge rate, liquid cathode systems were developed. The electrolyte is reactive in these designs and reacts at the porous cathode, which provides catalytic sites and electrical current collection. Several examples of these systems include lithium–thionyl chloride and lithium–sulfur dioxide. These batteries are used in space and for military applications, as well as for emergency beacons on the ground. They are generally not available to the public because they are less safe than the solid cathode systems.

The rechargeable lithium battery field is a growing area for space, and the latest technology for space is the lithium ion battery. The high voltage lithium-ion cells are moving into space for short to moderate length missions. They are easy to package, and very light. In this system, the lithium metal anode is replaced with a carbon electrode, which inserts lithium ions from the electrolyte, storing them in a solid solution phase. This configuration has improved safety over previous lithium rechargeable, and yet gives good rate capability.

The next step in lithium ion battery technology is believed to be the lithium polymer battery. This battery replaces the liquid electrolyte with either a gelled electrolyte or a true solid electrolyte. These batteries are supposed to be even lighter than lithium ion batteries, but there are currently no plans to fly this technology in space. It is also not commonly available in the commercial market, although it may be just around the corner.

In retrospect, we have come a long way since the leaky flashlight batteries of the sixties, when space flight was born. There is a wide range of solutions available to meet the many demands of space flight, 80 below zero to the high temperatures of a solar fly by. It is possible to handle massive radiation, decades of service, and loads reaching tens of kilowatts. There will be a continued evolution of this technology and a constant striving toward improved batteries.

Radioisotope Power. Radioisotope power systems convert the heat (thermal energy) generated from the decay of radioisotopes to electricity. The heat may be used to produce electrical power either by a static or a dynamic conversion process. See **Radioisotope Power System Technology (RPS)**. Static processes use nonmoving energy conversion devices such as a thermocouple or a thermionic converter to convert the heat into useful electrical energy.

Radioisotope Heater Units (RHUs) provide proven and reliable continuous heat to sensitive spacecraft components and instruments, enabling their successful operation throughout a mission. RHUs generate heat from the radioactive decay of a small pellet of plutonium. This heat is transferred to spacecraft structures, systems, and instruments directly without moving parts or intervening electronic components.

Radioisotope Power System Technology (RPS). The traditional means to satisfy electrical power requirements for planetary space probes that cannot rely on solar or battery power alone is through Radioisotope Power Systems (RPS). Advanced RPSs, using higher efficiency thermal conversion, are under study to reduce the quantity of radioisotope material necessary to accomplish a mission and to provide a smaller, more efficient radioisotope power system.

The basic method of radioisotope power energy conversion is based upon thermoelectrics. The thermoelectric conversion concept is based on the principle that when two dissimilar metals are joined in a closed circuit and two junctions are kept at different temperatures, an electrical voltage, and subsequent electrical current, is produced. An RPS is based on the thermoelectric concept consisting of two parts: a source of heat and a system for converting the heat to electricity. The heat source contains a radioisotope, such as plutonium dioxide, that becomes physically hot from its own radioactive decay. This heat is converted to electricity by a thermoelectric converter, which uses the Seebeck effect. All of the U.S. radioisotopic power generators launched to date have employed thermoelectric converters.

Radioisotope Heater Unit (RHU). Most spacecraft can use solar energy to provide heat to keep their structure, systems, and instruments warm enough to operate effectively. However, when solar or other heat source technologies are not feasible, an alternative heat source is required for the spacecraft.

By using Radioisotope Heater Units (RHUs), the spacecraft designer can allocate scarce spacecraft electrical power to operate the spacecraft systems and instruments. RHUs also provide the added benefit of reducing the potential for electromagnetic interference generated by electrical heating systems.

Characteristics of RHUs include:

- Highly reliable, continuous and predictable output of heat.
- No moving parts.
- Compact structure.
- Resistance to radiation and meteorite damage.
- Heat produced is independent of distance from the sun.

RHUs provide proven and reliable continuous heat to sensitive spacecraft instruments and scientific experiments enabling their successful operation throughout the mission.

RHUs generate heat from the natural radioactive decay of a small pellet of plutonium dioxide (mostly plutonium-238). This heat is transferred to spacecraft structures, systems, and instruments directly without moving parts or intervening electronic components.

RHUs are very compact, 3.2 centimeters (1.3 inches) long and 2.6 centimeters (1 inch) in diameter. The fuel pellet is about the size and shape of a pencil eraser weighing approximately 2.7 grams (0.1 ounces). All together each RHU weighs about 40 grams (1.4 ounces).

RHUs have a very rugged containment system to prevent or minimize the release of plutonium dioxide fuel even when subjected to severe accident conditions. Containment is achieved through multiple layers, which are resistant to the heat and impact that might be encountered during a spacecraft accident. An external graphite aeroshell (a reentry shield) and a graphite insulator protect the fuel from impacts, fires and atmospheric reentry conditions. Internally, the fuel is encapsulated in a high-strength, platinum–rhodium metal shell (or "clad") which further contains and protects the fuel during potential accidents. See Fig. 1.

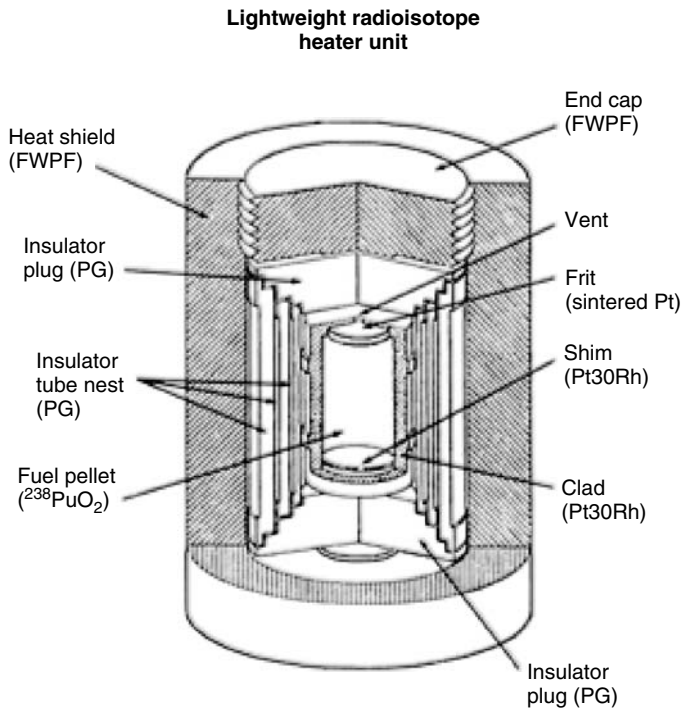

Fig. 1. Lightweight radioisotope heater unit. (*NASA/JPL.*)

In addition to this containment, the plutonium dioxide fuel is used in a ceramic form of which tends to break into large pieces rather than dispersing as fine particles. This minimizes interaction of the fuel with the environment and the potential for human exposure in the extremely unlikely event the multiple fuel containment barriers are breached. Since each RHU fuel pellet is individually encapsulated in its own aeroshell and fuel clad, the potential for a single event to affect more than one pellet is reduced.

RHUs have been subjected to a rigorous series of laboratory and field tests. This testing has demonstrated that the RHUs are extremely rugged and reliable devices that safely provide fuel containment in a wide range of accident scenarios. No releases occurred for those events, which were within the limits of anticipated accident scenarios. In summary, the RHUs are extremely dependable devices that have been designed and tested to contain their fuel in a wide range of mission accidents.

Radioisotope Thermoelectric Generators (RTGs). RTGs are a compact space power system, which convert thermal energy from the decay of radioisotope materials to electrical current through the use of solid-state thermoelectric converters. These power systems are reliable even when used in the harsh environment of outer space. RTGs are not nuclear reactors and have no moving parts. They use neither fission nor fusion processes to produce energy. Instead, they provide power through the radioactive decay of plutonium. The heat generated by this process is changed into electricity by solid-state thermoelectric converters.

For about three decades, the United States has used RTGs to meet the thermal and electrical energy requirements for some spacecraft. These power requirements include operation of the on-board scientific experiments, spacecraft maintenance and monitoring, temperature control, and data transmission.

Radioisotope power systems convert the heat (thermal energy) generated from the decay of radioisotopes to electricity. The heat may be used to produce electrical power either by a static or a dynamic conversion process. See **Radioisotope Power System Technology (RPS)**. Static processes use nonmoving energy conversion devices such as a thermocouple or a thermionic converter to convert the heat into useful electrical energy. The thermocouple (thermoelectric conversion) is based on the principle that when two dissimilar metals are joined in a closed circuit and the two junctions are kept at different temperatures, an electrical voltage, and subsequent electrical current, is produced. This conversion technology is used in RTGs. Thermionic converters produce electricity by boiling off electrons from a heated surface or cathode. A collector or anode then captures the electrons. The cathode and the anode are enclosed in a tube with conductive vapors that enhances current flows created by the directional movement of the electrons. All of the U.S. radioisotopic power generators launched to date have employed thermoelectric converters, i.e., have been RTGs.

One beneficial contribution of RTGs is their simplicity: because there are no moving parts and no moving fluids to contain, they are highly reliable. RTGs are long-lasting and relatively insensitive to the chilling cold of space and virtually invulnerable to high radiation fields, such as Earth's Van Allen belts and Jupiter's magnetosphere. However, one unfortunate attribute is that they are relatively inefficient in producing electricity.

RTGs as currently designed for space missions contain several kilograms of an isotopic mixture of the radioactive element plutonium in the form of an oxide, (i.e., plutonium dioxide) pressed into a ceramic pellet. The primary constituent of these fuel pellets is the isotope 238 (Pu-238). The pellets are arranged in a converter housing and function as a heat source. The radioactive decay of the plutonium dioxide produces heat, some of which is converted into electricity by an array of thermocouples made of silicon-germanium. Waste heat is radiated into space from the external housing surface and the attached array of metal fins. Each 56-kg (123.3-pound) General Purpose Heat Source (GPHS) RTG contains approximately 11 kg (24 pounds) of plutonium dioxide fuel. See Fig. 2.

The Department of Energy (DOE) has demonstrated that RTGs will minimize the possibility of fuel release during the generators' lifetime, particularly in the event of an accident. The very low probability of a plutonium release results from the protective-layering design of a spacecraft's RTGs. The radioisotope energy source for the GPHS-RTG is a stacked column of 18 individual GPHS modules. Each module consists of a graphite aeroshell, two-carbon-bonded carbon fiber (CBCF) insulator sleeves, two graphite impact shells (GISs), and four fueled clads. The graphite (carbon-carbon composite) aeroshell serves as the module's primary heat shield to protect the internal components from direct exposure to a reentry's thermal and aerodynamic environment. The two GISs contained in each GPHS module provide the primary resistance to impact or mechanical loads. Each GIS assembly is thermally insulated from the aeroshell by a low thermal-conducting CBCF insulator sleeve. Each fueled clad, separated by a graphite floating membrane, consists of one fuel pellet of ceramic (or solid) plutonium dioxide encased in an iridium shell. The iridium shell protects and immobilizes the fuel. The iridium alloy is compatible with the plutonium dioxide fuel material, resists oxidation to air and has a high melting temperature. Each clad also contains a vent designed to release the helium generated by the alpha particle decay of the fuel. The protective layers are specifically designed to safeguard the plutonium from fires, explosions, fragment impacts and the heat of atmospheric re-entry.

The DOE has designed the GPHS to assure that the plutonium dioxide fuel is contained or immobilized to the maximum extent practical during all mission phases, including ground handling, transportation, launch, and unplanned events, such as atmospheric reentry from Earth orbit, Earth impact, and post-impact situations. The design features for the GPHS-RTG assembly incorporate many safety-related considerations. The graphitic (carbon–carbon composite) materials (i.e., the aeroshell, CBCFs, and GISs) contained in the GPHS modules perform several safety functions. As stated previously, the primary function of the aeroshell is to protect the fueled clads against the hostile environment of atmospheric heating. The GISs protect the fueled clads from ground or debris impact in the event of an accident. Each GIS also serves as a redundant heat shield in the event of a GPHS failure. In addition, the GIS also serves as a redundant reentry aeroshell. Assembly of the graphitic materials used for the aeroshell is started with a three dimensional weave of high-strength graphite fibers. The fibers upon impregnation with a carbonaceous resin and graphitization of the matrix, form a material which has outstanding high temperature strength capabilities required to accommodate heat shield mechanical and thermal stresses that occur during reentry. This material is one of the best available for reentry applications.

More than 30 years have been invested in the engineering, safety analysis and testing of RTGs. The Safety features listed below are incorporated into the RTG design and extensive testing has demonstrated that they are expected to contain or limit the releases during most launch or reentry accident scenarios.

First, the plutonium dioxide fuel is used in its heat-resistant, ceramic form, which reduces its chance of vaporizing in fire or reentry environments. This ceramic-form fuel is also highly insoluble, has a low chemical reactivity, and if fractured, tends to break into large, non-respirable particles and chunks. These characteristics help to mitigate the potential health effects from accidents involving the release of this fuel.

Second, the fuel is divided among 18 small, independent modular units, each with its own heat shield and impact shell. This design reduces the

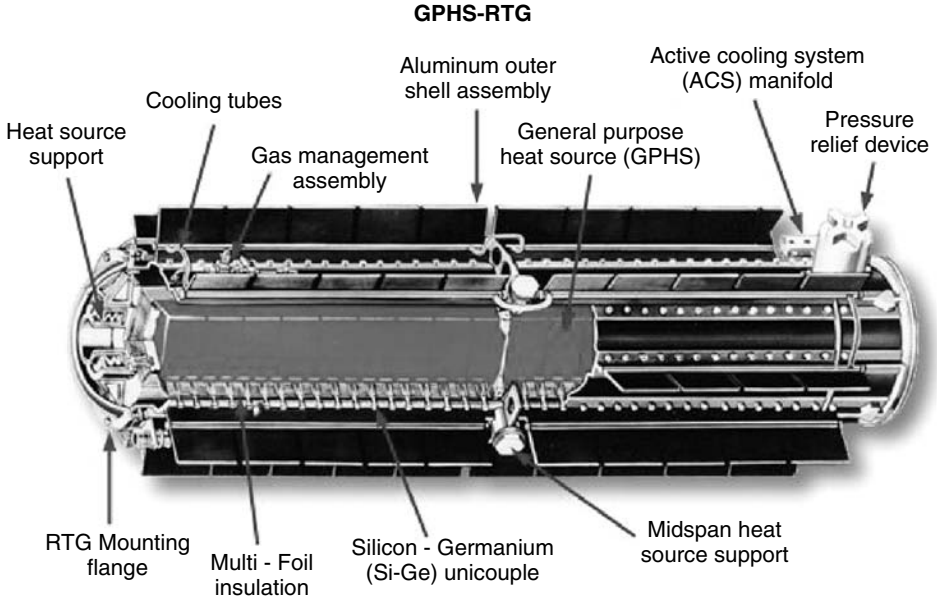

Fig. 2. Radioisotope thermoelectric generator. (*NASA/JPL.*)

chances of fuel release in an accident because all modules would not be equally impacted in an accident.

Third, multiple layers of protective materials, are used to protect the fuel and prevent its accidental release. Iridium is a metal that has a very high melting point and is strong, corrosion-resistant and chemically compatible with plutonium dioxide. These characteristics make iridium useful for protecting and containing each fuel pellet. Graphite is used because it is lightweight and highly heat-resistant.

In the United States, the current RTG design philosophy is fuel containment; that is, if a mission must be aborted the RTGs are designed to retain the plutonium dioxide when the GPHS modules re-enter the Earth's atmosphere. The success of this design philosophy has been tested twice during the course of the U.S. space program. In both cases, the RTGs performed as designed and no fuel was released.

Overall, the DOE has spent more than twelve years in engineering, fabrication, safety testing, and evaluation of the GPHS modules. Testing of the present design has demonstrated the ability of the GPHS modules to retain the fuel in a range of accident conditions. In addition, DOE is constantly striving to improve upon their research and improve the safety of the GPHS design, including the use of alternative materials.

Stirling Power Systems Technology. NASA Glenn Research Center (GRC) and the Department of Energy (DOE) are researching a Stirling convertor for an advanced radioisotope power system that could provide more efficient spacecraft power for NASA missions. NASA GRC is also analyzing systems using Stirling convertors for other space applications including solar dynamic power systems for space-based radar and as a potential alternative to radioisotope thermoelectric generators (RTGs) for space applications. The Stirling engine converts the heat from radioisotope decay to a reciprocating mechanical motion and in turn, that mechanical motion is converted to an electrical current for use by the spacecraft. These systems use the heat generated from the radioactive decay of radioisotopes to warm a gas or a liquid to rotate a turbine or move a piston in a cylinder. The turbine or piston in turn drives a generator or linear alternator that produces electricity. The free-piston design was introduced to eliminate seals and lubrication in the power linkage, thus making it useful for space applications.

Stirling efforts that have focused on a 55 watt free-piston Stirling convertor, are known as the *Technology Demonstration Convertor* (TDC). The TDC has successfully tested the free-piston design in a configuration relevant to space applications. Further work would be required to demonstrate a feasible Stirling system design.

In a Stirling Conversion system, heat from some source (i.e., radioisotopes) is used to power a Stirling engine. The engine has a working gas contained within it that absorbs the source heat through conduction, convection, or radiation. Attaching an alternator to the drive shaft can then produce electricity. The alternator produces single phase, alternating current (AC) power typically between 50 and 70 Vrms (volts root mean square). Most Stirling power systems would include power electronics to convert the AC into the usable direct current (DC) for the spacecraft.

The GRC technology effort is complemented by a DOE Stirling Radioisotope Power System (SRPS) integration activity. It is expected that many of the configuration, operational and reliability issues associated with Stirling will be addressed through these efforts.

Solar Power. Solar panels are devices that convert light into electricity. They are called solar after the sun or "Sol" because the sun is the most powerful source of the light to use. They are sometimes called *photovoltaics*, which means "light-electricity". Solar cells or PV cells rely on the photovoltaic effect to absorb the energy of the sun and cause current to flow between two oppositely charge layers. Most NASA spacecraft are powered by solar panels (collections of solar cells), including all NASA spacecraft that orbit the Earth and Mars and spacecraft that are going to nearby comets or asteroids.

Crystalline silicon and gallium arsenide are typical choices of materials for solar panels for deep-space missions. Gallium arsenide crystals are grown especially for photovoltaic use, but silicon crystals are available in less-expensive standard ingots, which are produced mainly for consumption in the microelectronics industry.

When exposed to direct sunlight at 1 AU, a 6-centimeter (2.4-inch) diameter silicon cell can produce a current of about 0.5 ampere at 0.5 volt. Gallium arsenide is more efficient. Crystalline ingots are sliced into wafer-thin disks, polished to remove slicing damage, dopants are introduced into the wafers, and metallic conductors are deposited onto each surface: a thin grid on the sun-facing side and usually a flat sheet on the other. Spacecraft solar panels are constructed of these cells cut into appropriate shapes, protected from radiation and handling damage on the front surface by bonding on a cover glass, and cemented onto a substrate (either a rigid panel or a flexible blanket), and electrical connections are made in series-parallel to determine total output voltage. The cement and the substrate must be thermally conductive, because in flight the cells tend to heat up from absorbing infrared energy that is not converted to electricity. Since cell heating reduces the operating efficiency it is desirable to minimize the heating. The substrate is supported on a deployable structural framework. The resulting assemblies are called *solar panels* or *solar arrays*.

A solar panel is a collection of solar cells. Although each solar cell provides a relatively small amount of power, many solar cells spread over a large area can provide enough power to be useful. To get the most power, solar panels have to be pointed directly at the Sun. Spacecraft are built so that the solar panels can be pivoted as the spacecraft moves. Thus, they can always stay in the direct path of the light rays no matter how the spacecraft is pointed. Spacecraft are usually designed with solar panels that can always be pointed at the Sun, even as the rest of the body of the spacecraft moves around, much as a tank turret can be aimed independently of where the tank is going. A tracking mechanism is often incorporated into the solar arrays to keep the array pointed towards the sun.

Solar panels need to have a lot of surface area that can be pointed towards the Sun as the spacecraft moves. More exposed surface area means more electricity can be converted from light energy from the Sun. Sometimes, satellite scientists purposefully orient the solar panels to "off point," or out of direct alignment from the Sun. This happens if the batteries are completely charged and the amount of electricity needed is lower than the amount of electricity made. The extra power will just be vented by a shunt into space as heat.

Solar panels are very hardy. Compared to alternative power sources, they wear out very slowly. The principal factor affecting the loss in power with time is the Space radiation environment. For low radiation environments, such as low Earth orbiting, their effectiveness decreases around 1 to 2 percent a year. This means after a five year mission the solar panels will still be making more than 90% of what they made at the beginning of the mission (as long as they have not gotten farther away from the Sun). In contrast, for missions in higher radiation environments, such as mid altitude Earth orbit 1,240 to 6,210 miles (2,000 to 10,000 kilometers), arrays can lose half their power within 1 year. That is one reason few missions fly in this orbital range.

To date, solar power has been practical for spacecraft operating no farther from the sun than the orbit of Mars. For example, *Magellan, Mars Global Surveyor*, and *Mars Observer* used solar power as did the Earth-orbiting, Hubble Space Telescope. For future missions, it is desirable to reduce solar array mass, and to increase the power generated per unit area. This will reduce overall spacecraft mass, and may make the operation of solar-powered spacecraft feasible at larger distances from the sun.

Solar array mass could be reduced with thin-film photovoltaic cells, flexible blanket substrates, and composite support structures. Solar array efficiency could be improved by using new photovoltaic cell materials and solar concentrators that intensify the incident sunlight.

Photovoltaic concentrator solar arrays for primary spacecraft power are devices, which intensify the sunlight on the photovoltaics. This design uses lenses, called *Fresnel lenses*, which take a large area of sunlight and direct it towards a specific spot by bending the rays of light and focusing them. Some people use the same principle when they use a magnifying lens to focus the Sun's rays on a pile of kindling or paper to start fires.

Solar concentrators put one of these lenses over every solar cell. This focuses light from the large concentrator area down to the smaller cell area. This allows the quantity of expensive solar cells to be reduced by the amount of concentration. Concentrators work best when there is a single source of light and the concentrator can be pointed right at it. This is ideal

in space, where the Sun is a single light source. Solar cells are the most expensive part of solar arrays, and arrays are often a very expensive part of the spacecraft. This technology allows costs to be cut significantly due to the utilization of less material.

Fresnel lenses have been around since Augustin Jean Fresnel invented them in 1822. Theaters use them for spotlights and lighthouses use them to make their lights visible at greater distances. See also **Fresnel Mirror**.
Degradation of Solar Arrays

- Solar flares, which are unpredictable severe bouts of radiation that can degrade solar cell output.
- Micrometeorites, which are tiny, gravel-sized bits of rock and other space junk floating in space can pit or penetrate solar cells. The solar concentrator as well as a thick layer of glass can provide some protection to the solar panels from these.
- If a satellite's mission path takes it away from the Sun (farther out into the solar system) solar panels will become less and less useful.
- Conversely, when used nearer to the sun, the solar array mechanical integrity and solar cell output can be reduced by severe heating. Most long lifetime solar arrays have generally been limited to the orbit of Venus.

Development Projects for Solar Arrays

- AEC-Able, manufacturer of the SCARLET array is developing a higher efficiency, lower mass, solar array with linear solar concentrators for use in the New Millennium program.
- The Mir Cooperative Solar Array is a joint U.S. / Russian flight demonstration of the solar array technology to be used on the International Space Station.
- The AstroEdge Concentrator Solar Array is a flight demonstration of reflective solar concentrators and lightweight rigid panel array structures on the SSTI

Clark spacecraft.

- The Hughes (now Boeing) HS702 commercial communications satellite solar array uses a low ratio reflective concentrator and has been operational since 1999.
- AEC-Able Engineering challenged the Solar Array industry by lowering the achievable limits on weight and stowage volume. Approximately 1/4 of the weight of conventional designs, UltraFlex enables spacecraft to maximize payload or reduce launch costs especially for interplanetary missions.
- Sharp is developing higher efficiency silicon solar cells for space applications.

SPACEFLIGHT: U.S. MANNED (MERCURY, GEMINI, APOLLO, SKYLAB, APOLLO-SOYUZ PROJECT AND SPACE SHUTTLE PROGRAM). There are many publications relating to Mercury, Gemini, Apollo, Skylab, Apollo-Soyuz Test Project, and the Space Shuttle. This article presents an objective review of some of the technical considerations of the design, development, and operation of these spacecraft. Although there were many triumphs, a number of surprises, and not a few setbacks during the 39-year period covered, such incidents will be mentioned only in the context of technical significance. A little more than 19 years elapsed between 20 February 1962, when John Glenn first rode Mercury into orbit, and 12 April 1981, when John Young and Robert Crippen inaugurated orbital flight for the Space Transportation System, or the Space Shuttle as it is commonly called. A comparison of the Mercury capsule and the spaceship Columbia reviews the extent of progress made during these first years of manned flight.

During the early 1920s after approximately 19 years of development, the aviation industry was also entering the transportation phase. But there is a significant difference between the development of airplanes and the development of manned spacecraft. Early airplanes were relatively cheap and easy to build. Often, only one person and at most just a handful would be sufficient to do the entire design job. Consequently, a great number of airplanes was built and flown. This led to a rapid evolutionary process for both the design and the operation of aircraft, and a number of accidents and fatalities provided a strong cooperative influence on any misdirection. The philosophical basis for the design and operation of spacecraft has had to progress without this impartial and unerring guidance of "survival of the fittest." As a substitute, we have had to rely on intensive analysis, extensive testing, imperfect simulations, and the judgment and experience of the hundreds of key people working on these programs.

American manned spacecraft by type together with a number of weights, dimensions, and features that characterize them are listed in Table 1. Mercury was a first of a kind design, and the Gemini and Apollo command and service module (CSM) followed in an evolutionary trend. The Apollo lunar module (LM) and the Space Shuttle, on the other hand, represent new and distinctive designs and have unique features for which no prior art existed.

Project Mercury

The National Aeronautics and Space Administration (NASA) was established in October 1958, and within a few weeks, the first manned spacecraft program, Project Mercury, was initiated. To execute the program as quickly as possible, it was deemed desirable to choose an existing rocket for the launch vehicle. The Atlas, considered the most powerful that would be available during the desired time period, was chosen. Conservative estimates indicated that the Atlas could orbit approximately 900 kg (2000 lbm) of payload. The spacecraft grew almost 50% during its development period. When finally developed, the entry weight of the Mercury spacecraft was in excess of 1180 kg (2600 lbm). Fortunately, the Atlas performance also grew sufficiently during this period.

The basic purpose of Project Mercury was to expose several test pilots to orbital flight and to have them evaluate the experience so that future and more substantive programs could be planned (Table 2). To move the program rapidly and because of severe weight constraints, the design of all systems was as simple as possible and provided only the basic necessities of launch, a short orbital flight, and safe descent and landing. A simple ballistic configuration designed to minimize reentry heating was chosen. Although kept as simple as possible, each active system had at least one level of redundancy. Descent was initiated by firing three solid retrorockets; however, a safe reentry was ensured if only two of these rockets fired. A parachute system that was backed up by a reserve system of identical design provided a safe landing. Redundant sets of hydrogen peroxide monopropellant reaction control jets were used. To guard against electrical failure, one set of jets had its electrically actuated valves backed up by a set of mechanical valves directly linked to the astronaut's rotational hand controller. Life support was provided by a pure-oxygen cabin atmosphere at one-third sea-level pressure. This was backed up by a pressure suit that would automatically inflate if the cabin atmosphere dropped to less than one-fourth sea-level pressure. Redundant voice, telemetry, and command signals could be sent and received on a number of communication channels. The Mercury capsule also carried both C-band and S-band radar beacons

to assist the radars at the various ground stations that tracked the flight. Finally, power was supplied by redundant battery sets that had independent buses. Heat was dissipated from the Mercury crew compartment by a water evaporator. Figure 1 shows the Mercury spacecraft and its components.

The concept for flight control was very simple. Basically, the Mercury spacecraft was inserted into a low Earth orbit using the launch vehicle guidance system. Once in orbit, no further velocity change maneuvers were required until it was time for descent. Return to Earth was accomplished by maneuvering the spacecraft to a retrorocket firing attitude where the heat shield was forward and then firing a cluster of three solid rockets strapped to the heat shield. This deflected the flight path to one that entered Earth's atmosphere. The spacecraft was not designed to produce lift, so it followed a highly predictable ballistic entry trajectory. Consequently, the time when the retrorockets were fired determined the location of splashdown in the ocean. It was recognized that there would be a fairly large dispersion about the planned landing location. However, consideration of emergency descent or aborts during launch that could result in a landing anywhere along the flight track made survival for a period of time on the water after landing and extensive use of location aids a basic design requirement anyway.

Flight control equipment on board the spacecraft was needed only for attitude control, particularly when firing the retrorockets. These functions could be done both manually and automatically. When in automatic flight, an autopilot and two horizon scanners were set up to maintain the vehicle in a fixed attitude with respect to local vertical. An onboard timer also initiated the retrofiring sequence after commanding the optimum attitude for the maneuver. This timer, which was started at liftoff, could be corrected during flight by command signals from the ground. The astronaut could also control attitude with a hand controller either by using an attitude indicator on the instrument panel or by looking through the window. He could also override automatic initiation of the retrorocket sequence. The astronaut could crudely determine his position in orbit by comparing his view of Earth using a clock-driven replica of Earth's globe.

The mission was crontrolled from the ground. Communications with the spacecraft and tracking data were obtained from a network of stations

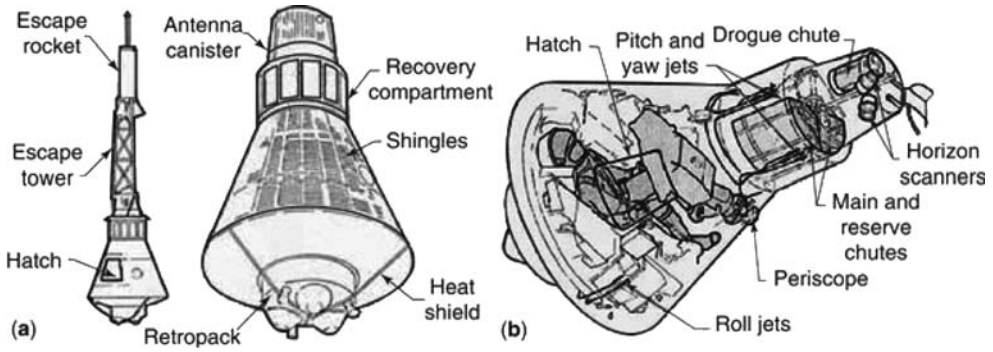

Fig. 1. The Mercury Spacecraft and some of its component parts. The escape tower and rocket is shown in picture **(a)**, the heat shield and the retrorocket pack is shown in **(b)** and the position of the astronaut in the space capsule.(*NASA*).

TABLE 2. PROJECT MERCURY MANNED SPACEFLIGHTS

Spacecraft	Launch Date	Crew	Flight time, hr:min:sec	Comments

along the path of the first orbits. There were 16 different stations located to allow a maximum of 10 minutes without communication contact. The data from these stations were sent to the Mercury Control Center at the launch site in Florida. On the basis of these processed tracking data, the orbital ephemeris was determined. The location of intended splashdown was predetermined to accommodate postretrofiring tracking and thereby to enhance final location for recovery.

During Project Mercury, six tests were made, two suborbital on a Redstone launch vehicle and four orbital on the Atlas. In preparing for these tests, 17 unmanned flight tests were made; four were made with primates aboard the spacecraft. Only 10 of these 17 tests were successful. In addition to the biomedical studies, these tests provided engineering studies of all of the modes of flight such as escape system operation, entry flight, and performance of the various onboard systems. Of the four manned orbital tests, each was of increasing duration starting with the three orbits made by John Glenn and ending with the 22-orbital flight made by Gordon Cooper.

Gemini Program

Based on the success of Mercury and undisputed evidence confirmed by the Russian program that people could function comfortably and effectively in space, it became obvious that the next step would be to develop the role of people in space. Consequently, two new programs were established during 1961 to this end: Gemini, to explore the possibilities and limitations of manned operation in space, and Apollo, a bold program committed to exploration of the Moon and sending people there. In Gemini, the approach was, quickly and, where possible, directly, to capitalize on what was learned in the Project Mercury. However, vastly improved capability was desired to explore the feasibility of the following operations: maneuvering in orbit, rendezvous and docking with another vehicle, extravehicular activity (EVA) by the astronauts in pressure suits, guided flight during entry to precisely designated target areas, and establishing and refining flight operation methods. All of these objectives were met with highly positive results that were applied extensively in the Apollo Program and contributed greatly to the success of that program.

The Gemini Program employed the new Titan II launch vehicle. This booster had roughly twice the capability of the Atlas and made it possible for the Gemini spacecraft to carry a crew of two and to incorporate a great number of design features requisite to the program requirements. The Gemini configuration was basically a scaled-up version of the Mercury vehicle. However, the center of mass of the Gemini spacecraft was offset from its centerline. This configuration caused the spacecraft to trim at a slight angle of attack, which produced a small aerodynamic force (lift) normal to the drag force. Although the lift-to-drag ratio (L/D) was only slightly greater than 0.1, it was more than sufficient to steer the entry path to a desired touchdown point. Steering was done by controlling the roll attitude of the spacecraft and thereby the lift vector to deflect the reentry path (up, down, right, left) in the desired manner.

Gemini carried its adapter into orbit. This was the conical structure that connected the Gemini spacecraft to the booster. In this adapter section, which was jettisoned before entry, a great number of systems that were used during orbit were carried. A set of bipropellant rocket motors provided for both translational and rotational maneuvers. Fuel cells and their hydrogen and oxygen supply tanks were installed in the adapter as were radiators that provided for heat dissipation. The fuel cells and radiator made mission durations as long as 2 weeks possible. The Gemini spacecraft was equipped with an inertial platform and digital computer to aid in orbital navigation and to provide for reentry navigation and guidance. Rendezvous radar and docking equipment were installed in the nose of the Gemini capsule. The hypergolic propellants used in the Titan II launch vehicle produced a low-yield explosion in the event of a launch vehicle breakup, so ejection seats could be used instead of an escape rocket. Finally, to accommodate extravehicular activity, a hatch operable while in orbit was provided over each astronaut's position.

In contrast to the great number of unmanned flights that preceded manned operations in Project Mercury, there were only two unmanned flights in the Gemini Program. The purpose of these flights was primarily to check out system operations and the compatibility between spacecraft and launch vehicle.

The Gemini Program also included a target vehicle to accommodate rendezvous operations. This target vehicle was a converted Agena propulsion stage that was launched into a rendezvous-compatible orbit by an Atlas launch vehicle. The procedure was to launch the target vehicle shortly before the Gemini was launched and then to maneuver the Gemini through a series of rendezvous maneuvers until the Gemini was brought within a few feet of the target vehicle. After inspection, the Gemini was maneuvered into a docking position, and the docking maneuver was made. After docking was completed, the Agena propulsion system could then be controlled by the crew on board the Gemini. The Agena propulsion stage could be used to make several maneuvers while the Gemini was attached, for instance, raising the orbit's apogee to much higher altitudes than could otherwise be achieved. There were 10 manned flights of Gemini during

a 20-month period (Table 3). All of these flights were successfully completed, and a great deal was learned during the Gemini Program that was later used in the Apollo Program, particularly for extravehicular activity, rendezvous techniques, mission control procedures, reentry control, and postlanding recovery operations. Figure 2 shows a picture of the Gemini spacecraft along with the adapter.

Apollo Program

Although Project Mercury was still in the early developmental phase, NASA started considering more advanced manned missions during the spring and summer of 1959. The most obvious and appealing prospect was for some type of lunar mission. Three types of manned missions were considered. They were, in order of increasing difficulty, circumlunar flight, lunar orbit, and lunar landing. Regardless of the ultimate goal, it was generally felt that the first flight would be circumlunar, and the spacecraft would pass within several hundred kilometers of the lunar far side. After this, orbital flights would be made using the same outbound and homeward navigational techniques proven in the circumlunar missions. Finally, a lunar landing would be made by descending from lunar orbit. By this scheme, each mission would be an extension of the previous one; thus the overall difficulty of achieving the final goal would be divided into a number of incremental steps; each would have greatly reduced exposure to the unknown. Nevertheless, the first time a plan to make a manned landing by descending from lunar orbit was outlined to NASA management, several in the audience severely questioned the wisdom of not taking advantage of the experience that would be obtained from Surveyor, which was designed to go directly from Earth straight down to lunar surface. Clearly, they had not considered the excitement of the crew during a landing that started at hyperbolic velocity in a near-vertical approach and that would be fully committed before they knew whether the landing rocket would fire. This incident is mentioned to illustrate that at the same time a manned lunar landing was seriously being debated, the basic understanding of the venture was quite primitive.

Because it required the least amount of propulsion and the least sophistication in navigational and guidance equipment on board the spacecraft and it clearly seemed the least hazardous, the first mission seriously considered was circumlunar navigation and return. This was a modest extension of orbital flight; in fact, circumlunar flight is achievable by a highly eccentric Earth orbit of the proper parameters. However, the gravity field of the Moon creates a major influence on such orbits. Consequently, even the smallest error in the state vector at the time of translunar injection could not go uncorrected for safe entry into Earth's atmosphere at the end of the mission. The question was how to determine the error and how accurately the corrections could be made. There was real concern that a safe entry into Earth's atmosphere at lunar-return velocity might be beyond the guidance and navigational "state-of-the-art" technology. At these velocities, the spacecraft must pull negative lift to skim along a very narrow corridor of the upper layer of Earth's atmosphere during the initial stages of entry. If the upper boundary of this corridor were exceeded, the spacecraft would skip out of the atmosphere back into

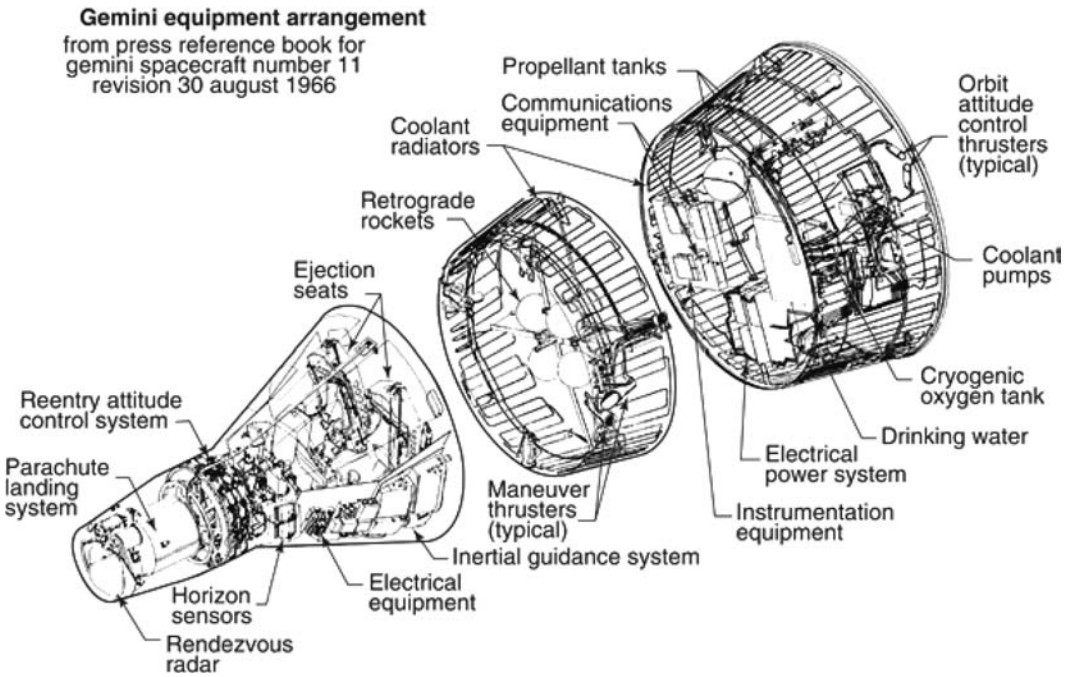

Fig. 2. A cutaway picture of the Gemini spacecraft with the adapter section that attaches the spacecraft to the Titan launch vehicle. The position of the two astronauts in the spacecraft is also shown. (*NASA*).

a highly eccentric orbit and perhaps expend its supplies before entering the atmosphere a second time. On the other hand, if the corridor boundary were missed on the lower side, the spacecraft would exceed the heating or load limitations of its structure. An associated concern was entry and landing point location. Because the mission was not very well understood, it was conjectured that the time of return might vary greatly from the planned time and, because of Earth's rotation, the geographical position of the entry might have a large dispersion. For these reasons, configurations with a fairly high lift-to-drag ratio appeared desirable. In summary, the thinking in 1959 was that from the standpoint of flight control, the circumlunar mission would be flown using ground-based navigation obtained from tracking data. Guidance instructions would be transmitted to the crew for the necessary midcourse corrections. A budget for velocity changes of 152 m/s (500 ft/s), it was initially estimated, needed a lift-to-drag ratio of more than 1 to provide a large maneuvering footprint while safely staying within the entry corridors.

During the 1960s, enough studies had been performed by NASA and industry to understand fairly well the implications of various manned lunar mission models. Missions that involved putting a spacecraft in orbit around the Moon for a total flight duration of about 2 weeks received a great deal of interest. Such missions did not appear to be a great deal more difficult than circumlunar flight but would provide much more scientific data. Furthermore, these missions would provide the means for gaining significant flight operational experience and reconnaissance data that would support a future lunar landing. At this point, the most important roadblock to executing of a lunar mission was that an enormous new space launch vehicle would be required. Another consideration was that features of the lunar surface were not well enough known to make detailed planning of a lunar landing possible. Both the United States and the Soviet Union were conducting robotic orbiting missions that would yield high-resolution photographs to make landing site selection possible. Also, hard landers (Ranger) and soft landers (Surveyor), both U.S. missions, would reveal the properties of the lunar surface in structure and hardness.

On 25 May 1961, President Kennedy, in an address to the U.S. Congress, said, ". . . I believe that this Nation should commit itself to achieving the goal, before this decade is out, of landing a man on the Moon and returning him safely to Earth". This commitment initiated the Apollo Program and precipitated some firm decisions. First and foremost, the return to Earth had to be determined because the safety of the crew ultimately depended upon this. The guidance and control precision of entry into the atmosphere at lunar-return velocity was sufficiently well established to commit to an entry configuration that would have a lift-to-drag ratio of 0.5 instead of the value of 1 previously mentioned. The selected value was compatible with the use of a semiballistic entry configuration design. Such configurations could achieve the relatively low entry heating of high-drag ballistic designs with a modest amount of lift. Furthermore, these features could be embodied in an axisymmetric shape, which simplified a number of design, manufacturing, and test considerations. The design chosen for Apollo was a derivative of the Mercury shape. By offsetting the center of mass by a distance of 19 cm (7.5 in) from the centerline, the Apollo spacecraft would trim at about a 33° angle of attack, which was sufficient to produce the desired L/D of 0.5. Using this much lift, the spacecraft could be confidently guided to land 9360 km (5000 nautical miles) downrange from the entry point. As various equipment items were designed for the entry capsule, the center of mass inexorably moved toward the center of volume. Consequently, the center of mass ended up displaced only a little more than 12.7 cm (5 in) from the centerline and the resulting lift-to-drag ratio was lowered to 0.35. However, this turned out to be more than sufficient. Planned splashdown for all missions actually flown was set for 2593 km (1400 nautical miles) downrange, and the never used capability either decreased it to 1482 km (800 nautical miles) or increased it to 4074 km (2200 nautical miles). It should be mentioned that only once in all of the returns from the Moon was it deemed desirable to move the preplanned landing point. It was moved 926 km (500 nautical miles) further downrange to avoid the possibility of predicted bad weather at the previously chosen landing point. However, the decision to relocate was made early, and the change was accomplished by a propulsion maneuver during trans-Earth coast a day before entry. Thus, the actual entry was standard at a nominal downrange distance.

About a year after President Kennedy gave the go-ahead for the Apollo Program, a decision was reached on which launch vehicle to use. Originally, a very large launch vehicle called Nova was in the plan; Nova was substantially larger than the Saturn V rocket system that was actually employed. Nova was necessary because, originally, the entire spacecraft would be put down on the Moon. The judgment was made that the development of Nova would be too costly and would take long enough that President Kennedy's deadline for the lunar landing could not be met. Using the less capable Saturn launch vehicle, two spacecraft would be necessary because a rendezvous maneuver would be employed to reduce the weight of the system that would have to be lifted to the Moon (Fig. 3).

A debate ensued in 1962 whether the rendezvous between the two spacecraft should take place in Earth orbit or in an orbit around the Moon. The advantage of the former was that a spacecraft would remain in Earth orbit following the Apollo missions as a legacy, and many thought that was important. The principal advocate of the lunar orbit rendezvous was Dr. John Houbolt of the NASA-Langley Research Center. Eventually he made a compelling argument that only by adopting the lunar orbit rendezvous method would it be possible to meet President Kennedy's deadline of 1970 for the landing on the Moon. From the standpoints of mission planning and guidance and navigation, lunar orbit rendezvous was completely compatible with all of the work that had been done by the time the decision was taken. The requirement of the rendezvous in lunar orbit did have a major impact on the equipment and the operational techniques that would be necessary for rendezvous navigation. The experience gained during the Gemini Program was extremely valuable in that connection. Furthermore, the general rules of the interplay between the mission control center in Houston and the astronauts were also developed during the Gemini Program.

The two spacecraft required for the lunar orbit rendezvous were the command and service module (CSM) for flight to lunar orbit and return and the lunar module (LM) for descent to the lunar surface and return to lunar orbit (Fig. 4). Recognizing that the duration of the Apollo mission would necessarily be extended, a crew size of three was chosen, partly to accommodate the 4-hour-on, 8-hour-off duty cycle wherein one crew member would be on duty at all times. However, based on Gemini experience, the crew stated a decided preference to sleep, eat, and be on duty at the same time. Accommodating this preference to the mission was not considered unsafe. Ground controllers could easily monitor the condition of the spacecraft systems during the crew off-duty periods. Nevertheless, the choice of a three-man crew was well suited to the purposes of the program, and, as a matter of fact, it would have been extremely difficult to have performed the necessary tasks with less than three. Based on this number, one crewman was left in lunar orbit aboard the CSM while the other two members descended to the lunar surface in the LM. It was deemed highly desirable to have two crewmen on the lunar surface, particularly during the extravehicular activity, because this accommodated the buddy system, which materially added to the safety of that operation.

The arrangement of the CSM was quite similar to that of the Gemini spacecraft. The command module (CM) housed the crew and was the only vehicle designed to reenter the atmosphere. Like Mercury, it was equipped with a launch escape rocket to be used in case of a mishap. Although the configuration was similar to that of Mercury, the conical afterbody was blunter to minimize heating on this portion at the 33° design angle of attack. A docking mechanism and tunnel were located at the apex of the cone to accommodate docking with the LM and crew transfer. The command module was much roomier and considerably more comfortable than the Gemini vehicle. (During other periods of flight, the center couch was removed to increase room for crew activity.) There was sufficient room under the remaining couches for two crew members to sleep.

The service module, like the Gemini adapter, provided for propulsion and electric power during the mission. It was equipped with 16 reaction control thrusters arranged in four identical modules. These provided the thrust for rotational and minor translational maneuvers. The service propulsion system was equivalent to a propulsion stage. It was used during the mission for several minor maneuvers and two major ones: insertion into lunar orbit and departure from lunar orbit into trans-Earth flight. The service module also contained a thermal radiator and a high grain S-band dish antenna (Fig. 5).

The LM (Fig. 6) was really a two-stage vehicle. The descent stage was equipped with a throttleable descent engine, a landing radar, and a four-legged landing gear. The legs had an extra large spread to accommodate

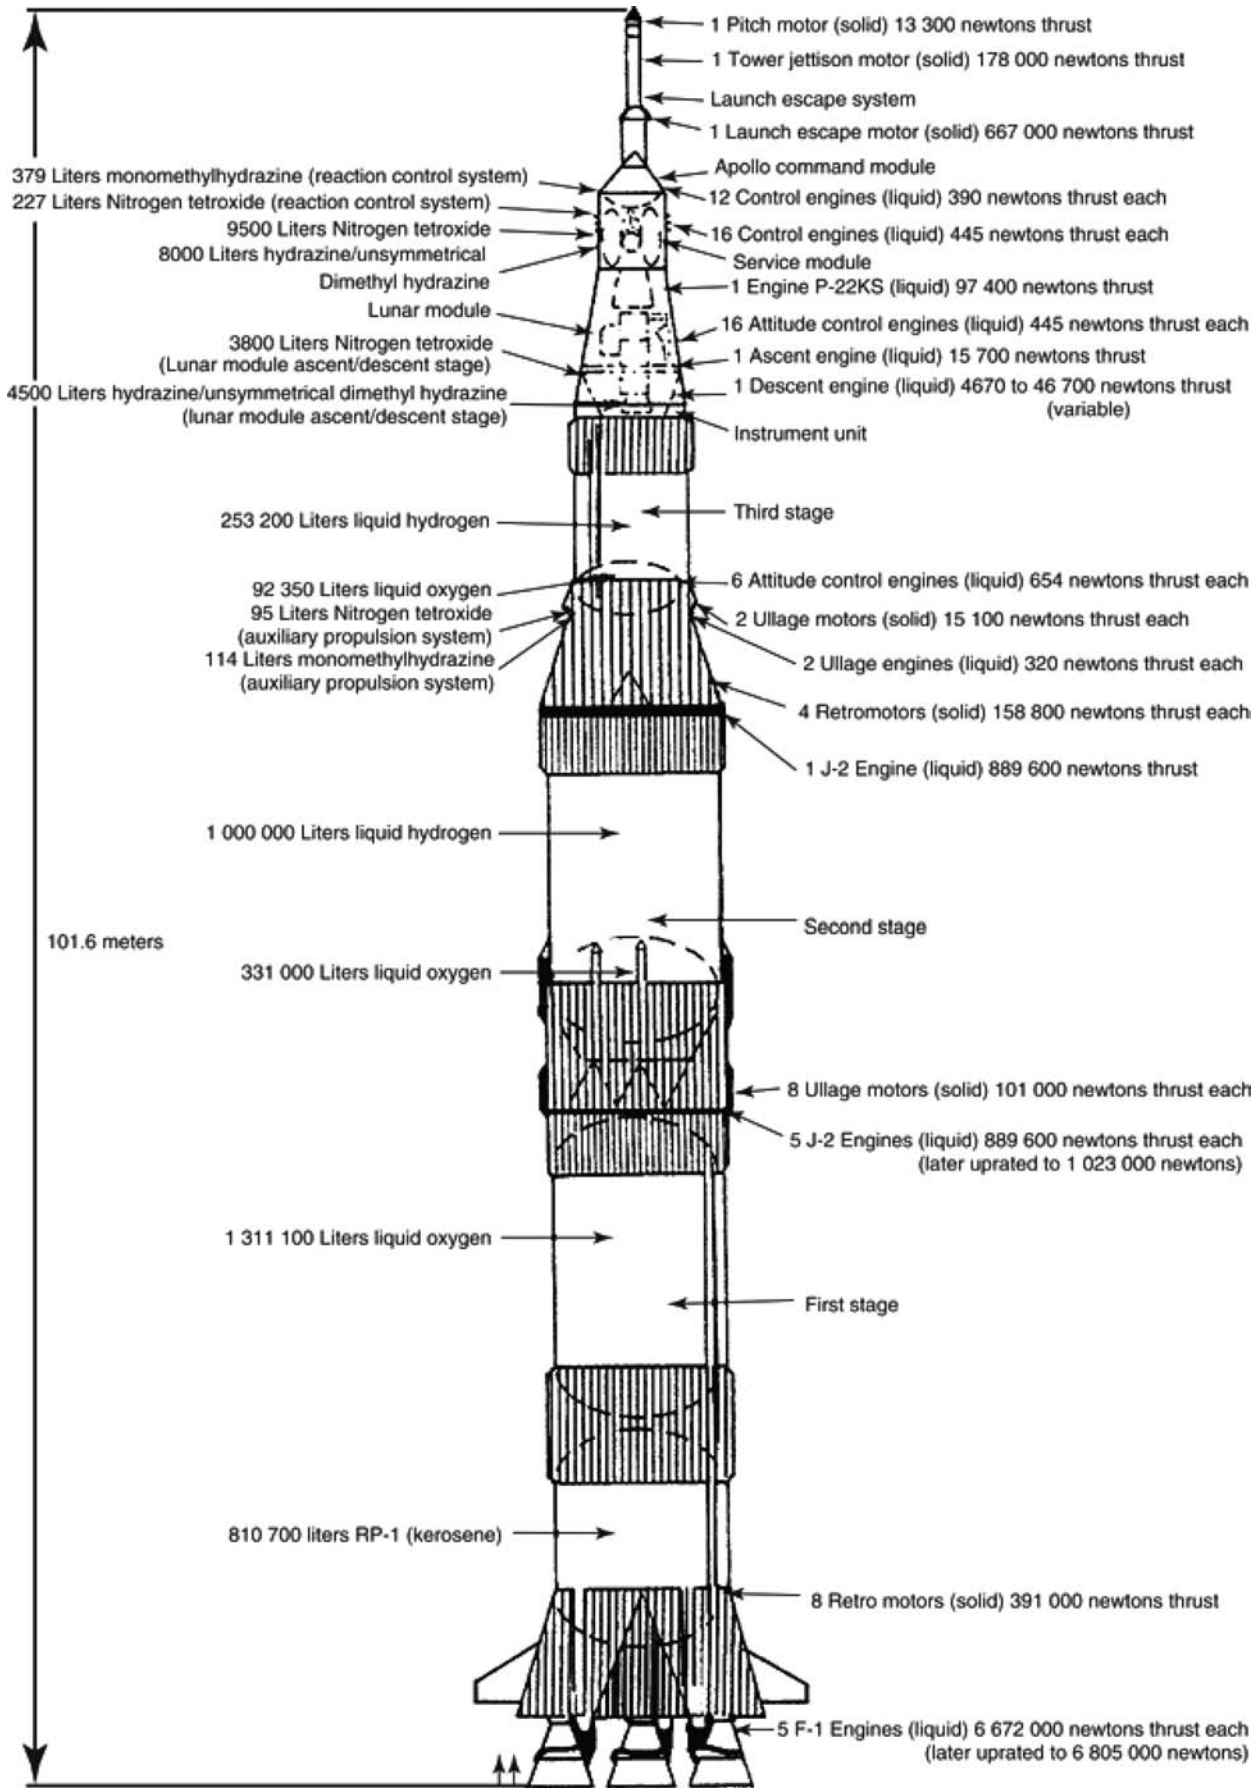

Fig. 3. The Saturn V launch vehicle that was used during the Apollo program to take people to the Moon. There were two stages to take the spacecraft that would go to the Moon into near Earth orbit. A third stage, the Saturn IV B, propelled the spacecraft, consisting of the command module, the service module, and the lunar module, into a lunar trajectory. The Saturn IV B was jettisoned following the trajectory insertion, and it eventually crashed into the Moon. (*NASA*).

the low impact stability associated with the very low gravity of the Moon. Each leg was tipped with a large dish-shaped pad, which was designed to accommodate the unknown bearing pressure of the lunar soil. The pad was socket-mounted to allow skidding at touchdown in any direction with little chance of tripping. The descent stage was designed to act as the launch platform for the ascent stage at the time of departure from the lunar surface.

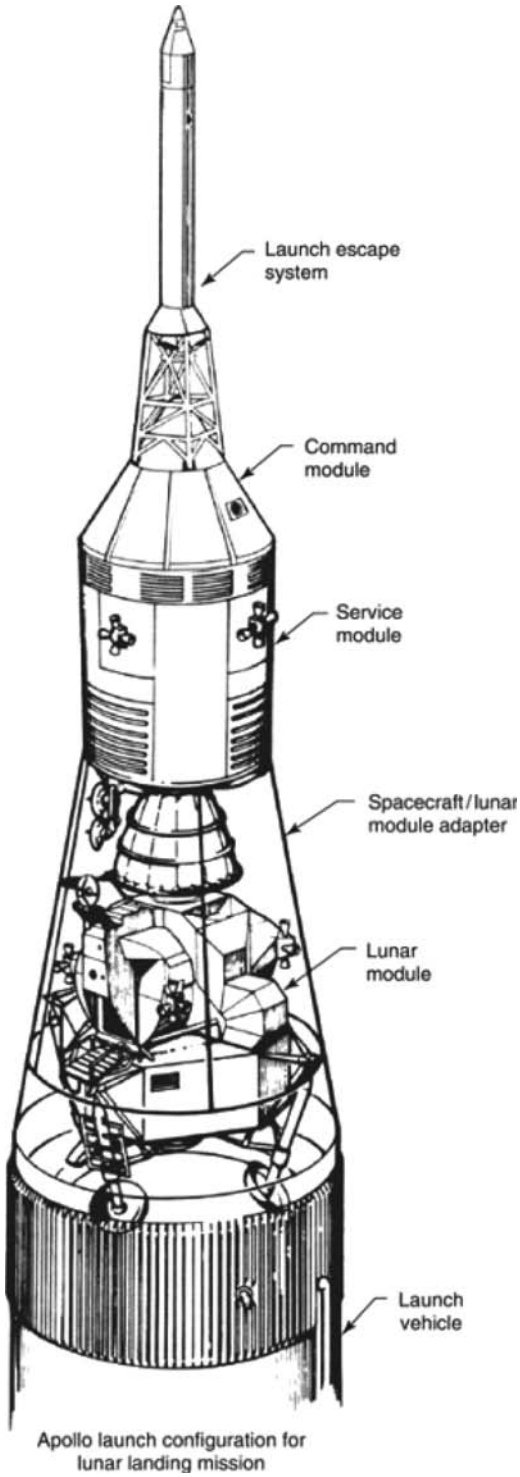

Fig. 4. A picture of the Apollo spacecraft in the launch configuration. The Command Module, the Service Module and the Lunar Module are clearly illustrated. The legs of the Lunar Module folded so that the vehicle fit into the conical shroud on top of the Saturn V spacecraft. The escape tower is also shown. (*NASA*).

The ascent stage housed the ascent propulsion system and the LM cabin. There were accommodations for two crewmen, who were positioned at their flight stations in the standing position to maximize downward visibility during the landing maneuver. The crewmen slept in hammocks while on the lunar surface. Like the Mercury and Gemini spacecraft, the CSM and the LM had a pure-oxygen atmosphere at a pressure of one-third sea-level pressure. The ascent stage was equipped with a rendezvous radar, 16 reaction control thrusters, and a high-grain S-band dish antenna. The LM was battery-powered and water-cooled. Ascent propulsion was used to launch the ascent stage from the lunar surface into a rendezvous orbit. It was also available to abort the landing maneuver into a rendezvous orbit if the landing could not have been made.

After the CSM had established the desired orbit about the Moon, the LM pilot and the commander transferred to the LM and powered it up. The LM was then separated and the CM pilot was left alone in the CSM until the other crewmen returned from the lunar surface. The LM then made a phasing maneuver, by which its orbit relative to the CSM was lowered. This maneuver placed the LM sufficiently ahead of the CSM so that an aborted powered descent would terminate into a rendezvous-compatible orbit. At the proper time, powered descent was initiated with the descent propulsion system at nearly full throttle. Slight throttle adjustments were made during descent to keep the descent trajectory on target. As the targeted landing area was approached, the LM was pitched over while, at the same time, the engine was throttled back. This allowed the crew to achieve visual contact with the landing area several minutes before touchdown. At this time, the commander could determine the touchdown point that was being targeted by the onboard guidance system. He did this by looking through a scale painted on his window, called the landing point designator. He could then override the guidance system until the landing point designator indicated a desirable landing location. During this period, altitude and descent rate were sensed by the landing radar, and control by the guidance system was continued. Hovering flight was achieved several hundred feet above the lunar surface. The final descent and touchdown were then made under control of the commander. As the LM approached the surface, a considerable amount of dust was blown up, but some visibility remained, and good landings were made in all cases. It should be mentioned that several turbofan-powered hovering vehicles designed to mimic the landing characteristics of the LM were built. The crew used the lunar landing training vehicles extensively to sharpen their proficiency before each lunar landing mission.

While on the surface of the Moon, the crew used extravehicular mobility units (EMUs) to move about. The EMUs each consisted of a space suit pressurized to 25 kPa (0.25 atm) and a battery-powered backpack. In many ways, the EMUs functioned like miniature manned spacecraft. They provided a cooled, revitalized atmosphere for the astronaut to breathe. The astronaut was kept at a comfortable temperature level by an actively cooled garment through which water was circulated at a regulated temperature. The EMU was equipped with redundant two-way communication links that provided voice communication between the two astronauts and, using the LM communication equipment as a relay station, communication with the Mission Control Center on Earth. Ground controllers could also monitor the physical condition of the astronauts and the performance of the equipment by telemetry from the EMU.

The suits provided sufficient mobility to accommodate a range of activity on the lunar surface such as setting up science stations, taking photographs, and performing short geological traverses for sample selection. On later missions, lunar surface exploration was greatly enhanced by the Rover, an electric-powered four-wheel vehicle that could carry the astronauts and a considerable amount of equipment. The Rover carried two-way communications equipment and a high-gain antenna that provided sufficient bandwidth for a direct link to Earth carrying color or television transmissions as well as relaying the communications from the astronauts to Earth.

It was recognized that both the CSM must be made considerably more reliable than previous spacecraft for several reasons. Compared to an orbital flight, a journey to the Moon implied a much greater exposure to the hazards of space. As a consequence of the complexity and the time required to abort a lunar mission, both the LM and the CSM had backup navigational and guidance systems, adequate reserve propellant, and levels of redundancy that were carefully determined to be sufficient. All possible failure modes were analyzed so that single-point failures were identified and eliminated when possible or safely accommodated.

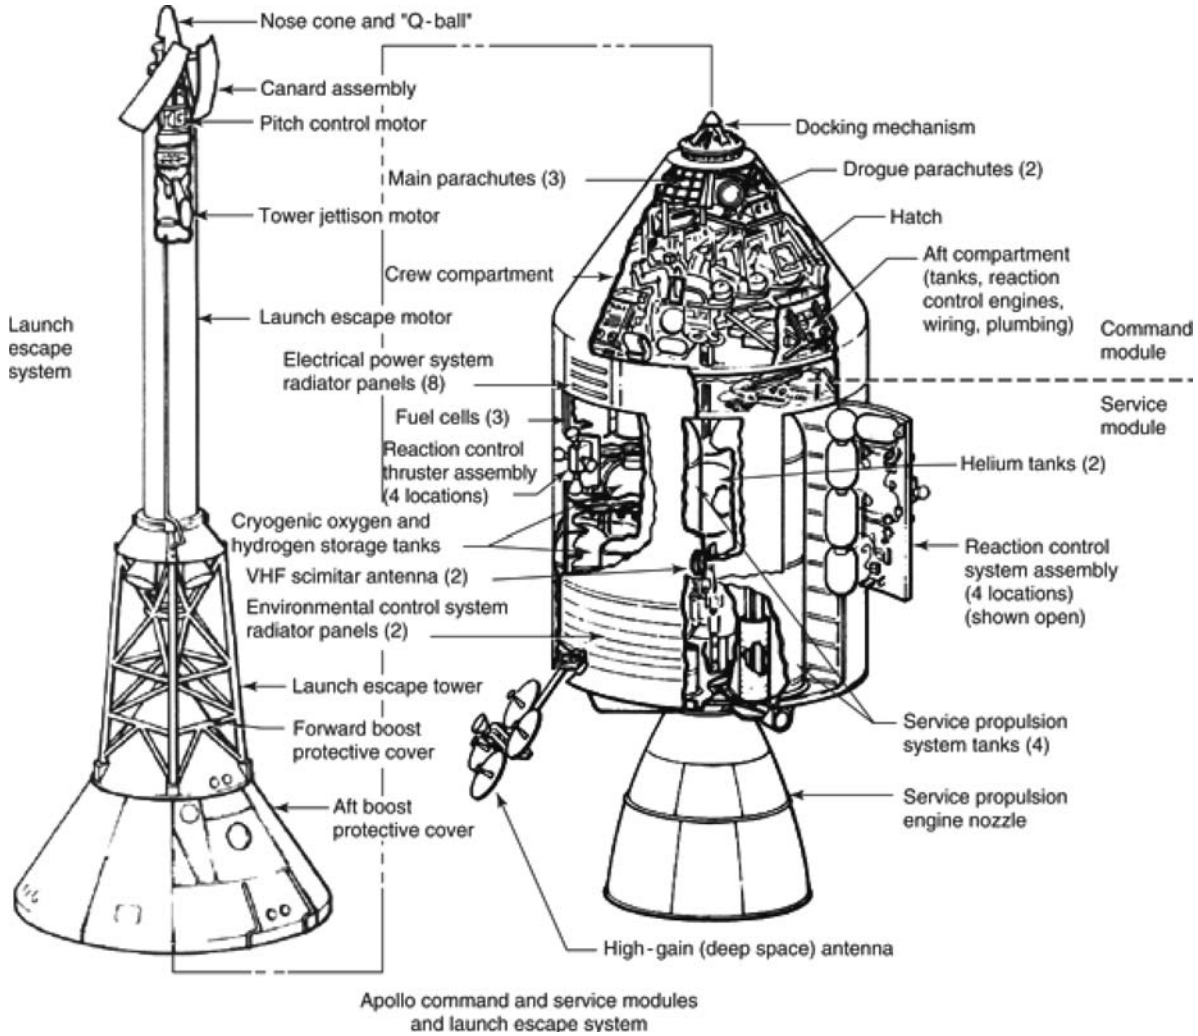

Fig. 5. A detailed cut-away drawing of the Apollo Command and Service Modules. The positions of the three astronauts in the Command Module are indicated. The launch escape system is also shown. (*NASA*).

Furthermore, operational methods were worked out to circumvent failures or to ameliorate the conditions that might be brought about by failures.

Although tracking from the ground was chosen as a primary method of navigation during the mission, it was decided that the spacecraft should be capable of autonomous navigation and guidance to return safely if all communication links were lost. The onboard navigation and guidance system was also used in verifying the accuracy of various maneuvers. Navigation in space, as on the ocean, requires precise determination of position. For this purpose, the Apollo command module was equipped with a sextant to measure the angle between a number of preselected landmarks on both Earth and the Moon and certain cataloged celestial bodies. Sightings and the time of sightings were fed into the onboard computer, which was preprogrammed to solve the navigational problem. The spacecraft was also equipped with inertial measurement units, which, together with the computer, performed the automatic guidance function.

In addition to the launch vehicle and LM and CSM, there were two other vital elements in successful execution of the lunar missions. These were the Manned Space Flight Network (MSFN) and the Mission Control Center, including all of the mission procedures and time lines that were worked out by Mission Control Center personnel. The MSFN was modeled after the Deep Space Information Facility (DSIF) developed by the Jet Propulsion Laboratory. The MSFN consisted of three 25.9-m (85-ft) diameter antennas located at approximately 120° intervals of longitude around Earth to provide coverage of the mission.

Both the MSFN and the hardware onboard Apollo were capable of producing highly accurate navigational data. Data from both sources were compared before making any velocity change maneuver. Also, immediately after the maneuver was made, data were again cross-checked. Navigation done on the ground had the benefit of a large complex of powerful

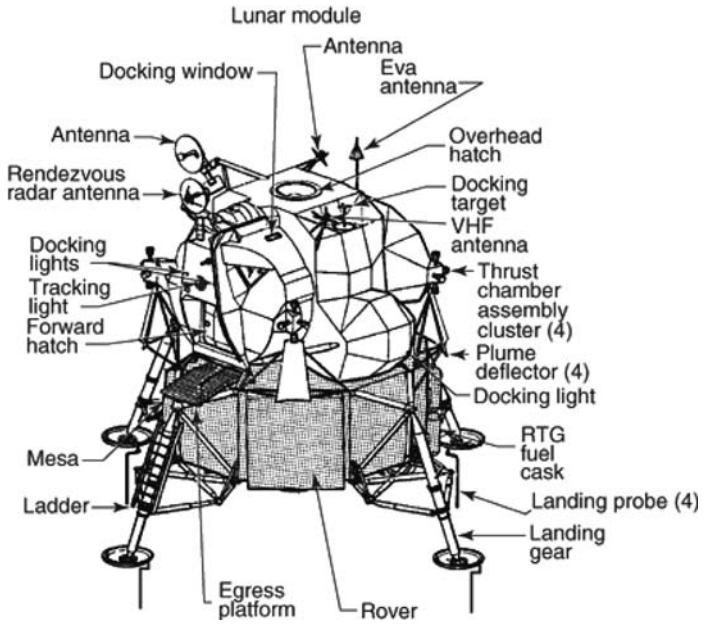

Fig. 6. A drawing of the Lunar Module in the landing configuration. The shaded portion is the descent stage which contains the rocket motor used for the landing. This portion of the spacecraft is left on the lunar surface following the completion of the extravehicular activity (EVA). The ascent stage also has a propulsion system that moves this vehicle back to lunar orbit where it then mates with the Command and Service Module. (*NASA*).

computers. Furthermore, at least two S-band trackers were always available as data sources. The data from the S-band tracker were extremely accurate. In addition to providing a Doppler count for velocity, the carrier signal was also phase-modulated with a pseudorandom noise (RN) code for range measurement. This digital signal, which was nonrepetitive for 5.5 s, was turned around and retransmitted on another carrier by a transponder on the spacecraft. Distance measurements as accurate as about 10 m could be obtained. Velocity measurements were much more useful. High-powered data processing techniques could produce an accuracy better than a millimeter per second by smoothing Doppler data across a period of 1 min. Using such data, extremely accurate state vectors could be obtained not only on translunar and trans-Earth flight but also while Apollo was in lunar orbit. This capability was important because lunar gravitational anomalies and venting from the spacecraft continually perturbed the orbit. Computational techniques were developed to the point at which tracking data obtained from the lunar module during its landing descent burn could be processed to serve as a sufficiently accurate "tie-breaker" if onboard primary and backup computations produced unexplainable differences.

The general approach to mission planning was to break the mission down into a number of discrete events and periods. Each of these was analyzed in great detail, and a complete model of the mission at great precision was constructed before flight. When flown, the missions would usually duplicate the plan in exact detail. A feature of the planning was the inclusion of time allowances for unexpected events so that the preplanned schedule could be maintained. The advantage was that almost every event or phase of the basic mission was extremely well understood and exercised. In addition to the basic mission plan, a great number of contingency plans was available to cover every rational problem.

All missions were planned to accommodate midcourse corrections both outbound and on return. Specific times were set aside for these maneuvers: four translunar midcourse correction events were allowed and three trans-Earth. However, if the error to be corrected was sufficiently small, the maneuver would not be made, and, as a matter of fact, many missions needed only one corrective maneuver each way. When first considering translunar flight in 1959, the budget of 142.4 m/s (500 ft/s) for midcourse corrections was established. The estimate was down to 91.4 m/s (300 ft/s) when the program was initiated several years later. When actual flight began, the "three sigma" estimate was 23.8 m/s (78 ft/s). Actually, most flights required less than 6.1 m/s (2.1 ft/s). For example, on the last flight, Apollo 17 executed only one correction maneuver each way: translunar, it was 3.2 m/s (10.6 ft/s); for trans-Earth, only 0.6 m/s (2.1 ft/s) was needed, which shows the great improvement in navigational systems.

The robotic missions that preceded the Apollo landings, Rover, Surveyor, and Lunar Orbiter have already been mentioned. The Ranger spacecraft was a probe that transmitted a few close-up images of the lunar surface just before colliding with the Moon at high velocity. The Surveyor was a soft lander that made five successful landings on the lunar surface. After landing, the Surveyor transmitted pictures of the surrounding features of the moonscape that provided extremely useful information on surface roughness as well as the quantity and size of rocks. Just as important, engineering data obtained from the Surveyor landings were extremely valuable in verifying the firmness of the lunar surface for landing the lunar module. The unmanned Lunar Orbiter flights, however, were every bit as valuable to the Apollo Program. They provided high-resolution photographs of the lunar surface that were extremely useful in selecting landing sites. The cartographic quality of the photographs was more than sufficient to make accurate maps of the lunar surface that could be used for orbital navigation and for visual recognition by the astronauts in the terminal phase of their descent. Just as important, analysis of orbital tracking data greatly improved the accuracy of the lunar gravitational constant and provided valuable data on lunar gravitational anomalies; all of them facilitated translunar and lunar-orbit navigation on the Apollo missions. The accuracy of navigational techniques that were ultimately developed made it possible for Apollo 12, the second landing mission, to come to rest within a short walking distance of Surveyor II, which had landed on the Moon $2\frac{1}{2}$ years previously. The Surveyor's location had been identified on a Lunar Orbiter photograph by patient and meticulous study.

Twelve unmanned test flights were made in the Apollo development program. All but one was successful. Six of these were devoted to qualifying the launch escape and parachute deployment system for the command module. The others were concerned with systems tests of the spacecraft and with compatibility of the launch vehicle and the launch environment. In one of these tests, the service propulsion system was used to drive the command module back into the atmosphere at the velocity and in the flight path expected during lunar return.

Eleven manned flights were made in the Apollo lunar program. Nine of them were journeys to the Moon, and six were lunar landing missions. These flights are summarized in Table 4.

On 27 January 1967, the program underwent a critical setback during a countdown rehearsal for what was planned to the first manned Apollo flight. The interior of the command module suddenly burst into flames, and trapped the crew. Astronauts Gus Grissom, Ed White, and Roger Chaffee were killed, and the spacecraft was destroyed. Although the immediate source of the fire was never determined, the general cause was associated with the use of many materials in the cabin interior that were flammable in the pure-oxygen cabin atmosphere, which, during prelaunch conditions, was at sea-level pressure. It took the program more than a year to recover from the fire.

Extensive changes in materials were made, and in cases for which suitable replacement materials could not be found, fireproof coatings and

TABLE 4. APOLLO MANNED SPACEFLIGHTS

coverings were used. Special test programs were made to certify the fireproofing program. It was found that, although good fire protection was achieved for an oxygen atmosphere at the reduced pressure of orbital flight, there were no practical solutions for the prelaunch conditions when the cabin would be at sea-level pressure. Therefore, the oxygen in the cabin was diluted with 40% nitrogen during prelaunch activities. After the cabin pressure dropped to one-third of sea-level pressure during ascent, there was still sufficient oxygen for breathing. Later, when the astronauts were ready to depressurize further to spacesuit pressure, the nitrogen content of the atmosphere had been sufficiently purged to preclude a bends problem.

When astronauts James Lovell, Jack Swigert, and Fred Haise were on board Apollo 13, which was to have been the third lunar landing mission, another accident occurred. During translunar flight as the Moon was being approached, one of the two tanks used to store cryogenic oxygen in the service module failed. The failure was sufficiently violent to cause the oxygen in the other bottle to begin leaking, most probably through an external line. Except for gaseous oxygen stored in the command module for life support during the short period of reentry flight, there was no other oxygen supply for the CSM. The lost oxygen was to be used both for life support and to power the fuel cells. The failure was eventually traced to a thermostat switch that had been frozen shut because of an overcurrent applied during the preflight checkout on the launch pad. As a result, the heater wire inside the oxygen tank became too hot, and the fluorocarbon insulation melted causing a spark. This ignited the insulation which readily burned in the pressurized oxygen tank, and the resulting pressure rise caused the tank to fail.

This desperate situation was countered by moving the crew to the LM cabin and powering down the CSM. Because the LM was battery-powered for only a planned 3-day period, it was configured for minimum power consumption. After getting everything in order, the crew made a velocity change maneuver to correct the flight path to a "free-return" trajectory by which the spacecraft would swing around the Moon and head back to Earth on a path consistent with reentry targeting. Another major propulsive maneuver was made after the spacecraft was in trans-Earth flight. That maneuver changed the trajectory to shorten the return time. Although there was sufficient oxygen for the return flight, an improvised method for adapting the command module's lithium hydroxide canisters used to remove carbon dioxide for use in the LM environmental control system had to be devised. This was done by experimenting on the ground and then communicating instructions to the crew. Fortunately, the crippled spacecraft returned safely with an unharmed but disappointed crew. The Apollo program continued for four additional and successful lunar landings. Total funding for the Apollo program was approximately $20,443,600,000. See also **Lunar Exploration**; and **Moon (Earth's)**.

The Skylab Program

After the completion of Apollo 17, the Apollo CSM and the Saturn launch vehicles were used for the Skylab Program (Fig. 7). The third-stage structure of the Saturn V was converted to a space laboratory. The hydrogen tank of the Saturn IV B stage was divided into laboratory, sleeping, eating, recreation, and hygiene compartments. Storage lockers, an environmental control system, and other equipment were added for the comfort and physical well-being of the crew. The oxygen tank was converted to an oversize trash container. A deployable micrometeoroid shield and passive thermal control coatings were added to the skin of the tank. A battery of telescopes designed to study the Sun were mounted on a high-precision pointing platform. There was also an airlock to accommodate EVA and a docking module to which the CSM could dock. In addition to the solar telescopes, a great variety of experimental equipment was carried, including a number of Earth-pointed remote-sensing instruments and cameras.

The Skylab orbital workshop was stabilized using three control moment gyros. These could be desaturated from time to time by reaction control jets using nitrogen as a propellant. Electric power for the Skylab was provided by two photovoltaic solar-powered systems. One system consisting of four folding arrays was attached to the solar telescope mount. The other system consisted of two wing arrays extending from the converted fuel tank.

The Skylab orbital workshop was launched on 14 May 1973 into a 50° inclination orbit. The nearly circular orbit ranged in altitude from 496 to 498 km (268 to 269 nautical miles). During launch, one of the wing solar cell arrays and the micrometeoroid shield were carried away. The other wing was jammed so that it could be only partly deployed. The micrometeoroid shield also was important in the passive thermal control system; its absence left the tank skin exposed. This was coated with a highly reflective coating which happened to be biased hot. The result was that the laboratory quickly became overheated and reached internal temperatures higher than 50 °C (122 °F).

The launch of the first crew was delayed while special repair equipment was designed, constructed, and tested on the ground. Eleven days following the launch of the Skylab orbital workshop, astronauts Charles Conrad, Joe Kerwin, and Paul Weitz were launched on Skylab 2. They deployed a parasol-like sunshield over the exposed skin which reduced the interior temperature to 24 °C (75 °F). They also freed the jammed wing of the solar cell array. Although the missing wing reduced the power available from that expected, there was sufficient power to perform the planned activity.

The Skylab orbital workshop was occupied by three different crews (Table 5). Each successive crew stayed a longer period of time. A great number of experiments and science investigations was performed before

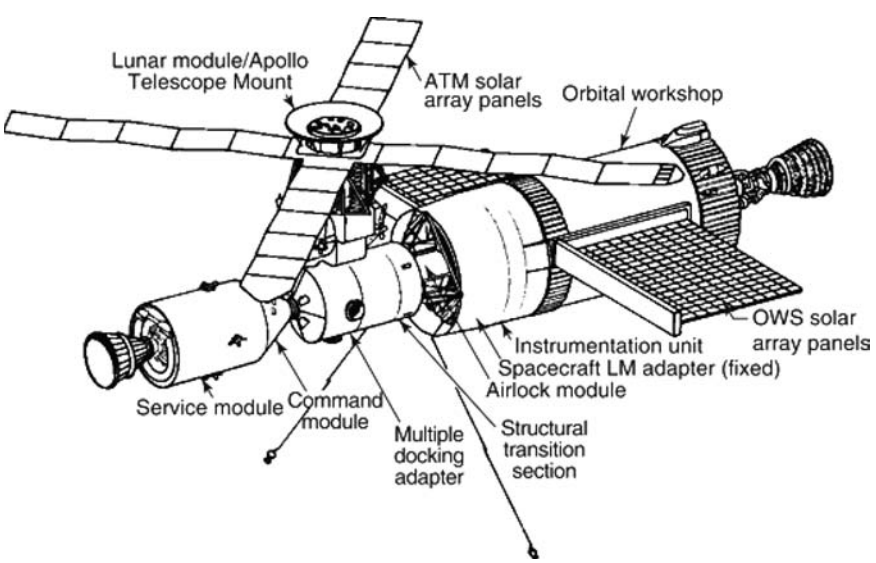

Fig. 7. The Skylab orbital workshop configuration. The Apollo Command and Service Module is on the left, the center section is the Apollo Solar Telescope Mount, and the left-hand section shows the Modified Saturn IV B that became the living space for the three astronauts during the three missions when they worked in this temporary space station. (*NASA*).

TABLE 5. SKYLAB MANNED SPACEFLIGHTS

Spacecraft	Launch Date	Crew	Flight time, hr:min:sec	Comments
Skylab 2	25 May 1973	Charles C. Conrad, Jr. Paul J. Weitz Joseph Kerwin	672:49:49	First manned mission. The crew rendezvoused with Skylab on the fifth orbit. After making substantial repairs, including deployment of a parasol sunshade which cooled the inside temperatures to 23.8 °C (75 °F), by June 4 the workshop was in full operation.
Skylab 3	28 July 1973	Alan L. Bean Jack R. Lousma Owen K Garriott	1427:09:04	Continued maintenance of the space station and extensive scientific and medical experiments. Completed 858 Earth orbits and 1,081 hours of solar and Earth experiments; three EVAs totalled 13 hours, 43 minutes.
Skylab 4	16 Nov. 1973	Gerald P. Carr William R. Pogue Edward G. Gibson	2017:15:31	Last of the Skylab missions; included observation of the Comet Kohoutek among numerous experiments. Completed 1,214 Earth orbits and four EVAs totaling 22 hours, 13 minutes.

the Skylab orbital workshop was abandoned on 8 February 1974. It was left in a condition that would allow partial reactivation in a possible visit from the Space Shuttle. Unfortunately, its orbit decayed before that was possible. Skylab reentered the atmosphere on 11 July 1979, and came to Earth mostly in the Indian Ocean, with some pieces landed in western Australia. See also **Space Stations**.

Apollo-Soyuz Test Project

After a series of meetings in 1971 and 1972, the United States and the Soviet Union agreed to a joint manned space mission as part of the "détente" policy pursued by the Nixon administration. This mission became known as the Apollo-Soyuz Test Project (ASTP) (Fig. 8). Its basic purpose was to produce hardware and operational procedures that would provide the means for one country to work with the other in future manned space missions. Particular emphasis was placed on assistance and rescue missions. Rather than merely trade design and mission control information, it was agreed that the only way to be sure assistance and rescue missions would really be feasible would be to execute an actual joint mission.

It was agreed that the American Apollo and the Russian Soyuz would rendezvous and dock during a cooperative mission. To accomplish this objective, a number of technical problems had to be addressed. The primary problems were compatible communications both in space and on the ground, compatible mission control procedures, compatible docking hardware, and accommodations for the different atmospheric constituents in the two spacecraft. The Soyuz cabin was maintained at sea-level pressure with the same 80%/20% mix of nitrogen and oxygen found in air. The Apollo cabin was at one-third sea-level pressure using an atmosphere of 100% oxygen. This incompatibility was solved by using a docking module that would be carried with the CSM during launch. It was carried in the adapter in a manner similar to that used to carry the LM during lunar missions. On one end of the docking module was the international docking system, which had been agreed on with the Soviet Union. The other end, like the LM, had the portion of the Apollo probe and drogue docking system. The docking module had an interval volume sufficient for as many as three people at the same time. It was also equipped with bottled supplies of both nitrogen and oxygen. Consequently, it could serve as an airlock between the two spacecraft.

The ATSP mission was successfully completed in July 1975 by the launch of cosmonauts Alexei Leonov and Valery Kubasov in Soyuz followed by astronauts John Stafford, Vance Brand, and Deke Slayton in Apollo. After rendezvous, both the American and the Russian mechanisms performed successful dockings. After the final undocking, both crews spent additional time in space performing individual experiments.

The Space Shuttle Program

The Space Shuttle system had been developed to improve accessibility greatly to space and thereby to facilitate many opportunities for space applications that would not be possible otherwise. Through improved operational capability and flexibility, the Shuttle would bring about a wide variety of missions and activity in space that previously had not been considered. The Shuttle missions primarily fall into three general categories:

1. Missions lasting from one to several weeks and employing one or more of the Spacelab modules developed by the European Space Agency. These missions consist of a variety of experiments and observations requiring extensive participation by the crew.
2. Missions employing one or more additional propulsion stages to carry spacecraft to orbits beyond the performance capabilities of the Shuttle alone. Most of these missions are aimed at geosynchronous orbit; some planetary exploration and military missions were also launched by the Shuttle.
3. Missions in which the Shuttle deploys satellites directly into orbit. The Shuttle can retrieve or service some of these satellites, thereby adding a new dimension of utility. In some cases, the satellites will be equipped with modest propulsive capability allowing them to move back and forth to orbits beyond the operating altitude of the Shuttle. The first example of this capability was the retrieval and repair of the "Solar Max" satellite in 1984 and later, the spectacular success of the in-orbit repair of the Hubble Space Telescope's optics in 1993, repair and refurbishment of the Hubble Space Telescope in 2002.

Most Shuttle missions probably have been a combination of these general types to enable more comprehensive use of the cargo load of each flight.

When launched from Cape Kennedy, orbits with inclinations from 28.5° (the latitude of the launch site) to 56° will be achievable. The Shuttle was initially capable of carrying as much as 29,000 kg (32 tons) of payload into low-inclination, low-altitude orbits. It was capable of returning as much as 14,500 kg (16 tons) from orbit. However, various restrictions have been placed on the payload capability of the Space Shuttle since operations of the vehicle were initiated in 1981.

The Space Shuttle in the launch configuration consists of four major elements: an Orbiter, an external tank, and two solid-rocket boosters (Fig. 9). The boosters provide the majority of the thrust for the first 2 minutes of flight. Each booster weighs about 567,000 kg (1,250,000 lbm) and produces a peak thrust in excess of 11.1 MN (2,500,000 lbf). The boosters are jettisoned after burnout and are recovered for reuse after descending by parachute into the ocean near the launch site.

The external tank contains 530 cubic meters (140,000 gal) of liquid oxygen and 1438 cubic meters (380,000 gal) of liquid hydrogen. These propellants, with a combined weight in excess of 680,000 kg (1,500,000 lbm), feed the three main engines in the Orbiter. Eight minutes after liftoff, when main propulsion burnout occurs, the Shuttle is just short of attaining orbital velocity. The tank is then jettisoned and follows a long, shallow trajectory that ends in a remote portion of the Indian Ocean. The tank is destroyed during reentry. After the tank is jettisoned, the Orbiter employs the two orbital maneuvering engines to propel itself into orbit. The orbital maneuvering engines (OMES) are also used for other maneuvers in space during the remainder of the mission.

The Orbiter is the most complex part of the Shuttle and provides control of the boosters and the external tank during launch. The Orbiter is designed to be reusable; only a minimum amount of refurbishment and maintenance are required between flights. Almost all of its systems should function reliably after a hundred or more flights. Insofar as practical, development of new systems or technology was avoided in designing of the Orbiter. The Orbiter's electric power is produced from hydrogen and oxygen in fuel cells that are an improved version of those used during the Apollo

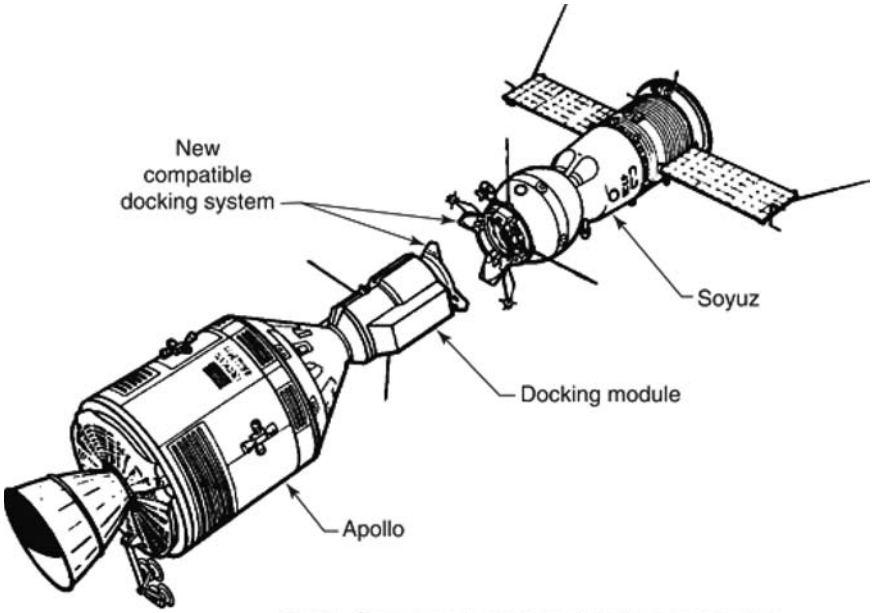

Fig. 8. The Apollo-Soyuz spacecraft. The Apollo Command and Service Module, the Docking Module, and the Soyuz capsule are all clearly shown. Two Soviet cosmonauts and three American astronauts performed the docking maneuver that led to the first meeting in space of people from each nation. Experiments and tests performed by the crew led to naming this effort the Apollo-Soyuz Test Program. (*NASA*).

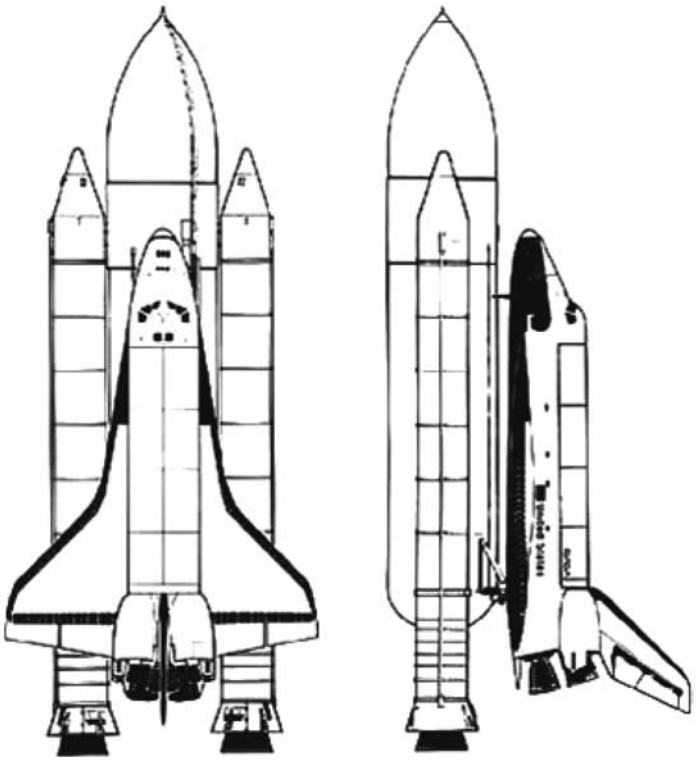

Fig. 9. The configuration of the Space Shuttle system with the Orbiter, the two solid rocket motors, and the external tank for the fuel and the oxidizers for the Space Shuttle main engines mounted in the Orbiter. (*NASA*).

Program. The basic structure of the vehicle is primarily aluminum; skins, stringers, frames, and ribs are in an arrangement typical of that of an airplane. The landing gear and the cockpit arrangement are also quite similar to those found on conventional aircraft. Hydraulic power is used to move flight control surfaces and for ground steering and braking.

The Orbiter is a key element of a highly complex launch vehicle. It is a unique and highly versatile spaceship that has astronauts on board to operate the vehicle and to perform experiments. It is the combination of these functions — launch vehicle, spacecraft, and airplane — that make the Orbiter a most complex machine. Consequently, major advancements in the state of the art were necessary in several areas. These advances were most pronounced in flight control, thermal protection, and liquid-rocket propulsion technology. See also **Space Shuttle**.

The external tank is 45.7 m (150 ft) long and 8.5 m (28 ft) in diameter. The structure of this huge tank weighs only slightly more than 31,750 kg (70,000 lbm). Nevertheless, the tank is the central element of the launch configuration, which has a combined weight of nearly 2,000,000 kg (4,500,000 lbm). The consequence is the creation of a number of easily excited low-frequency structural modes. Therefore, the flight control system employs sophisticated mode-suppression techniques in gimbaling the rocket engines as the vehicle is steered during launch.

Flight control during entry is even more complex. Unlike previous manned spacecraft such as Apollo, the Orbiter actually is flying during atmosphere entry and depends on active aerodynamic control surfaces to maintain a stable attitude and control of its flight path. When aerodynamic flight begins, it is flying four times faster than the X-15, the previous speed record holder.

The Orbiter's configuration features a double delta wing, a single, high, vertical fin, a huge cargo compartment, and a large aft end containing an assembly of rocket engines. This configuration is based on a compromise satisfying a large number of requirements. The cargo bay size was derived from a survey of potential traffic that clearly indicated that space cargo would in general consist of low-density objects. Large main propulsion engines were desirable to minimize the size of the boosters, which represent a major part of the cost per flight. The result was a center of mass that is unusually far aft. Depending on mass and location or cargo, the Orbiter occasionally encounters neutral to slightly negative static stability about the pitch axis at low speeds. For control during aerodynamic flight, the Orbiter is equipped with very large elevons on the wing trailing edge. A large flap extends from the rear of the fuselage to trim the vehicle. A combination rudder and speed brake on the trailing edge of the vertical fin is used for directional and speed control.

Return from orbit is initiated by making the typical retrograde propulsion maneuver using the OMES engines. The Orbiter then loses altitude and gradually enters the atmosphere. Initial control, similar to that of Apollo, is by rolling about the velocity vector at a very high angle of attack using the reaction control system. As aerodynamic forces gradually increase,

the control of the vehicle becomes manageable using aerodynamic control surfaces, and, except for those controlling yaw, the reaction control jets are deactivated. The rudder, which might be expected to control yaw, is ineffective as a control surface on the Orbiter because of the high angle of attack. Both yaw jets and the rudder were active for yaw control from Mach 3.5 to Mach 1.0. Below that speed regime at a lower angle of attack, the yaw jets were deactivated, and only aerodynamic control surfaces were employed in the flight control system.

Reentry at the end of the flight is made using a preselected angle-of-attack (α) profile. An angle of attack of 40° is maintained until the Orbiter decelerates to $M = 11$. From that point on, α is decreased continually and passes through $M = 1$ at $\alpha = 8°$. The approach and landing maneuvers in the subsonic flight regime ranged in α from 4° to 10°. The acceptable reentry altitude corridor is approximately plus or minus 1500 m (5000 ft) of the nominal flight path. The Orbiter is guided to stay within this corridor, while flying on the preselected α profile, by varying the bank angle. The nominal angle at the start of reentry is 80°. This value gradually diminished to about 45°. During the first flight, the landing site was essentially straight downrange. Consequently, some portions of reentry were flown banked left and others banked right. In this case, bank-reversal maneuvers were made near numbers of 18, 9, 5, and 2.5. In future flights, longer $M = 8$, 9, 5 and 2.5 portions of reentry may be spent banked in one direction or the other to accommodate landing at sites which may be displaced as much as 2037 km (1100 nautical miles) on either side of the straight downrange track. Downrange navigation is achieved by flying nearer to the lower or upper bound of the corridor. This can be accomplished by using a slightly greater or less than nominal bank angle, as the case may require. During the first Shuttle flight, John Young went to control-stick steering during the last two bank-reversal maneuvers. This allowed him to enter the bank-reversal maneuver more gradually than possible when the maneuver was programmed in the autopilot. Recent simulations had shown that the stability margins could be increased by decreasing the roll-rate acceleration during this flight regime. The decision to have the crew make this maneuver avoided modifying mature software. The entry is flown by computer until subsonic flight when the pilot uses control-stick steering and makes the approach and landing.

The Orbiter configuration was subjected to more hours of wind tunnel testing than any other flying machine. This was necessary because the Orbiter flies across a greater range of Mach numbers, Reynolds numbers, dynamic pressures, and angles of attack than previous machines. More importantly, during its first flight, it was totally committed to successfully negotiating this wide and diverse range of flight conditions before it could land. This was a unique situation not previously encountered in modern aviation flight-testing. High-performance airplanes and in fact virtually all newly designed airplanes are extensively flight-tested before maximum performance is approached. Each flight test is a cautious extension of previously encountered conditions and is followed by thorough analysis of test results from which the next safe increment in the flight-test program can be defined.

As a substitute for testing in actual flight, the Orbiter's flight control system had been extensively tested in computer-driven simulation facilities. Mathematical models resident in the facility software mimic the atmospheric conditions of flight, including gusts and crosswinds. Other models represent the wind-tunnel-derived aerodynamic responses to the simulated flight environment. However, wind-tunnel data have limited precision. Results obtained in different facilities sometimes were significantly different. Furthermore, experience has shown that data obtained in flight often exceed the bounds of data scatter of wind-tunnel data. Extensive statistical analyses of these effects on the stability and the control surface effectiveness were made to determine possible worst case aerodynamic qualities. The Orbiter's flight control system successfully "flew" simulated entries in which such worst case conditions were modeled.

The heart of the Orbiter's flight control system is a set of five identical general-purpose computers. Each computer in the set has the capacity to control the entire flight, including the guidance and navigation functions, without assistance from the others. Under control of the central computers are a great number of subordinate data processors that have specialized functions. The central computers formulate steering commands for the gimbal actuators during launch, the reaction control jets during space flight, and the yaw jets and aerodynamic surfaces during aerodynamic flight. These steering commands can originate in response to stick inputs from the crew or be generated within the central computers in the fully automated flight mode. Redundant sets of rate gyros, accelerometers, inertial measurement units, star trackers, radio navigational aids, radar altimeters, and dynamic and static pressure sensors all feed data to the central computers. The more critical sensors are quadruply redundant and allow at least two and possibly three sensors in a particular set to fail without degrading the performance of the flight control system.

The five centralized computers are divided into a redundant set of four and the fifth computer is held in reserve as an independent backup. Normally the redundant set will control the flight. Each of the four computers in this set is loaded with identical software, and all work in parallel with each other processing data from the sensors and transmitting commands to the controls. If one of the sensors should fail, each computer will detect it, and the sensor will be deactivated. Upon completion of every computation cycle, the redundant computers make a simple arithmetic comparison of their output. Any computer that fails to agree with its colleagues for two successive cycles is considered to have faulted and is deactivated. The computers also have built-in fault-detection features which should cause them to self-deactivate in most failure cases. Simple logic would indicate that this system with its depth of redundancy and its fault-detection and deactivation features should prove extremely reliable. Nevertheless, there is concern that despite all precautions, an inherent weakness could exist in the software that would ripple through the computers and deactivate them one after another. Such should an event occur, the crew would switch control to the backup computer, which is loaded with software that, although coded differently, can replace all of the functions of the redundant set.

The use of digital computers in the Orbiter for flight control provides a major improvement in versatility and precision over other systems. The digital system facilitates redundancy management, fault detection, and fault isolation and, when proven, should provide a major improvement in flight safety. Although the inherent complexity of the Shuttle flight control task forced the development of an unusually elaborate flight control system, this pioneering effort proved to be a major step toward the production of more economical and safer aircraft.

The propellant combination of liquid hydrogen and oxygen is the most energetic considered practical for use. The Shuttle, like the Saturn launch vehicle upper stages, employs these propellants for its main propulsion. However, a new high-performance engine was developed for the Shuttle (Fig. 9). It features a combustion chamber pressure of 22,409 kPa (3250 psi) at full power, or about four times higher than that of the Saturn engines. It also incorporates a new cycle that circumvents the wasteful use of some of the propellant just to power the turbine-driven propellant pumps. It might be mentioned that the total horsepower required to pump propellant to the Orbiter at full power is greater than the total propulsive power of a Forrestal-class carrier. The Shuttle rocket engines produce 7% more propulsive energy per pound of propellant than the hydrogen-fueled rocket engines used on Saturn. They also have a higher thrust-to-weight ratio. A consequence of these factors is a net gain of 18,144 kg (40,000 lbm) of payload compared to what could have been obtained using Saturn-type engines. The penalty for this performance is a considerably more complex engine that was difficult to develop and test.

The Orbiter is easily the largest man-made object to be recovered from space. Seventeen times heavier and with 50 times the surface area, it greatly exceeds the size of the Apollo command module, which previously held this distinction. Not surprisingly, the creation of a thermal protection system suitable for reuse after multiple reentries required a new material technology. Fundamentally, the choice lay between insulating the inner structure from a hot external skin or using external insulation that would keep the metallic skin cool enough to be part of the primary structure, as in conventional aircraft. The second approach was chosen as both lighter and less costly to produce. The cost savings were primarily associated with the straightforward use of conventional structural materials and manufacturing techniques commonly used in modern large airplanes. An equally important benefit was the large database from which the cost and weight of the major structural assemblies could be estimated. It also allowed additional time to analyze the thermal input because of the isolation of the structural and thermal protection system.

Except for a few regions in which the surface temperature will not exceed 644 K (700 °F), the majority of the Orbiter's external surface is

covered with lightweight tiles. There are more than 32,000 tiles, most of which are 15.2- or 20.3-cm (6 or 8 in) squares. The basic material of the tiles consists of a random matrix of fine quartz fibers. The compaction of the fibers and therefore the density is closely controlled during manufacture. Each tile is coated with a pigmented glaze that provides waterproofing, abrasion resistance, and high heat radiation. The density of most of the tiles is comparable to that of balsa wood, although some tiles of a higher density are located in regions where expected physical loads or abuse may be greater. Because the tiles have a lower coefficient of expansion than the aluminum skin to which they are bonded, a felt pad is inserted between the tile and the skin to isolate strains due to the relative motion between skin and tile. The tiles should be suitable for 100-mission reuse if they never exceed a surface temperature of 1533 K (2300 °F). If heating rates are higher, fewer reuses will be possible. One of the very good properties of the tile material is its capability of withstanding heating rates almost double its design value and still survive one flight. This was particularly reassuring during the first flight, for which heating rates could only be predicted based on a combination of theoretical analysis and wind-tunnel data. The worst case heating predictions fell well below the one-time capability of the material.

On 28 January 1986, the space shuttle, "Challenger," was destroyed by a failure of the seal on one of the solid rocket motors (SRM) that is intended to boost the vehicle into Earth orbit. Six astronauts and a schoolteacher acting as a "payload specialist" were on board "Challenger." All were killed. There is no doubt that this accident was the single most traumatic event in the effort to put people in space. The failure of the SRM occurred when the joint between the lowest and the next-to-lowest segment of the rocket stack failed and released the hot gases inside the rocket (the location of this joint — called a "field joint" because it is made up in the field — is shown in Fig. 10). These hot gases rapidly melted the fixtures that attached the SRM to the fuel/oxidizer tank and caused the SRM to deflect and puncture the tank. The release of the hydrogen and oxygen quickly created a flammable mixture that ignited and destroyed the Orbiter.

A commission to investigate the accident chaired by former Secretary of State William P. Rogers was established. The commission found that the proximate cause of the accident was that the O-ring seal of the joint opened when subjected to the pressure of the gases inside the rocket. This was attributed to a design flaw in the O-ring seal that was exacerbated by the cold temperature on the day of the launch, which embrittled the O-ring material of the seal. The report of the commission also listed as possible contributing causes the problems encountered in the assembly of the rocket stack and the very high wind shear experienced at approximately the same time as the joint failed. The commission recommended that space shuttle flights be suspended until the seal of the joint was redesigned, manufactured, and tested so that failures of this kind would not be possible. It took more than 2 years to implement this recommendation, and Shuttle flight operations resumed in September 1988.

The "Challenger" was replaced by a new space shuttle, "Endeavor," which flew for the first time in May 1992. Since September 1998 to February 1, 2003, space shuttle missions over one hundred have been successfully executed. During these flights, many important in-orbit capabilities have been demonstrated, including the repair and retrieval of satellites by astronauts working outside the Space Shuttle cabin [extravehicular activities (EVA)], the execution of many onboard experiments using the European Spacelab modules that were built for the Shuttle by the German space agency, docking with the Russian MIR space station, and launching important scientific satellites. The Space Shuttle fleet is currently providing the principal means for lifting many of the component parts of the International Space Station and all of the people who will assemble the station into Earth orbit. The Shuttles "Atlantis," "Discovery," and "Endeavor" have been uprated to deliver payloads to the higher inclination orbits of the International Space Station. The main engine is being modified and provisions such as docking hardware are being added. The external tank has also been redesigned primarily using a lithium aluminum material to increase payload capability. When the International Space Station is completed, the Space Shuttle will, for the first time, actually become what it has been called for so many years: the vehicle that will "shuttle" people and supplies back and forth to the International Space Station. See also **Space Stations**.

Upon reentering the atmosphere on February 1, 2003, the *Columbia* orbiter suffered a catastrophic failure due to a breach that occurred during launch when falling foam from the External Tank struck the Reinforced Carbon Carbon panels on the underside of the left wing. The orbiter and its seven crewmembers (Rick D. Husband, William C. McCool, David Brown, Laurel Blair Salton Clark, Michael P. Anderson, Ilan Ramon, and Kalpana Chawla) were lost approximately 15 minutes before *Columbia* was scheduled to touch down at Kennedy Space Center. This site presents information about the STS-107 flight, as well as information related to the accident and subsequent investigation by the formal Columbia Accident Investigation Board. http://history.nasa.gov/columbia/CAIB.html

The Space Shuttle represents a bold major development in the technology of human spaceflight. It has made possible activities and achievements in space that would not have been done otherwise. It has been and will continue to be the major new stepping-stone to a new era in space-operations.

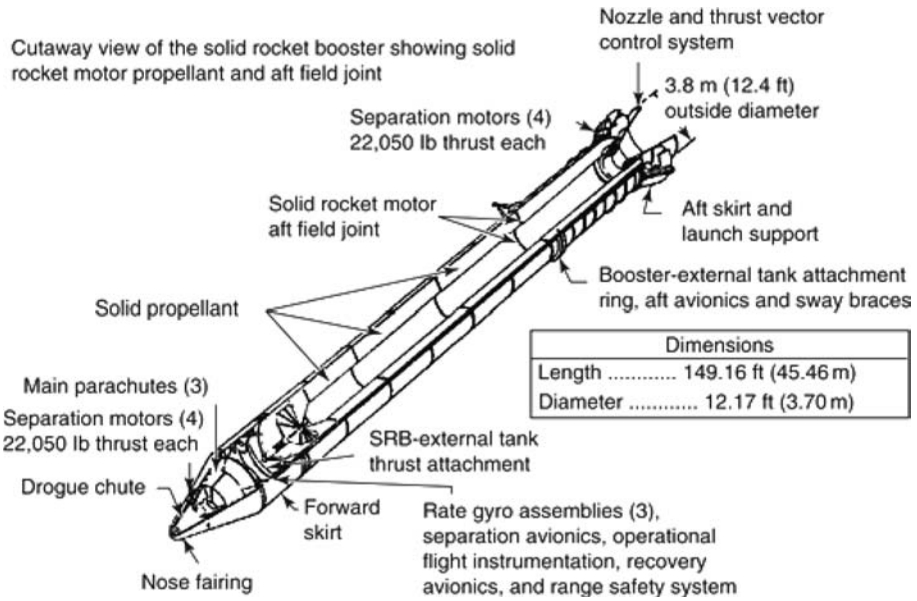

Fig. 10. A cutaway drawing of the solid rocket motor of the Space Shuttle system. The joint that failed during the launch of "Challenger" is the "aft field joint" labeled on this drawing. The picture also shows the configuration of the rocket with the nozzle, the four segments of the solid fuel grain, the separation motors, and the location of the control system in the nose section of the rocket. (*NASA*).

Conclusions

The enterprise of putting humans is space has been controversial from the very beginning. Shortly after the Mercury project was initiated in 1959, President Kennedy's science advisor, Dr. Jerome B. Wiesner, recommended giving serious consideration to canceling the program. In a report he submitted to President Kennedy shortly before his inauguration in January 1961, Dr. Wiesner argued that human spaceflight was very dangerous and could damage the new administration's prestige if some people were killed by accidents in space. Furthermore, he said that putting people in space is an expensive proposition and that the new administration's scientific and military objectives could best be achieved using robotic spacecraft. There is a kernel of truth in this argument, which is why it is still being heard now even after four decades of successful human spaceflight. What the people who make this argument either forget or ignore is the public impact of human spaceflight. The world craves heroes, and there is no doubt at all that our astronauts are modern heroes. John Glenn is a recent example. He was the first American to orbit the Earth in 1962 and flew again on the Space Shuttle, "Discovery," in 1999 when he was 77 years old. Successive administrations have been advised by very prestigious people to abandon the program to put people in space. Fortunately, this advice has been roundly ignored, and successive Presidents since John Kennedy have strongly supported the program to put people in space.

A good case can be made that 500 years from now, the only thing that will be remembered about the twentieth century is that on 20 July 1969, human beings first set foot on another body in our solar system. The lunar landing in 1969 is likely to be remembered just the way 1492 is the only year in the fifteenth century that the vast majority of people around the world remember. Christopher Columbus' landing on an island in the Bahamas has had the same impact as Neil Armstrong's landing on the Moon. Both of these events opened new horizons for human beings to aim at, and this is why they are both historically significant.

SPACE FRAME (or Space Structure). A three-dimensional framed structure. It may be composed of triangles, rectangles or a combination of these forms. Space frames are statically determinate or indeterminate depending on the number of members, support conditions and the rigidity of the joints. Bridges, framed domes, transmission towers, radio towers and building frames are all space structures.

If the space frame is statically determinate it may be analyzed by means of the equations for three-dimensional statics. These equations state that the summation of all forces parallel to three axes, usually taken as mutually perpendicular, must equal zero and the moments of all forces about these axes must also equal zero.

Indeterminate space frames may be analyzed by methods which are applicable to indeterminate planar structures. In recent years numerical methods have been developed for the analysis of rigid space frames. Bridges and building frames are highly indeterminate when considered as space frames because the joints have a certain amount of rigidity even though they may not have been designed to resist moment. Thus, all parts do participate to some extent in distributing the loads to the foundation. Due to this action some members may be subjected to torsional stress as well as direct and bending stresses.

SPACE INFRARED TELESCOPE FACILITY (SIRTF). The Space InfraRed Telescope Facility (SIRTF) is a space-borne, cryogenically-cooled infrared observatory capable of studying objects ranging from our Solar System to the distant reaches of the Universe. SIRTF is the final element in **NASA's Great Observatories Program**, and an important scientific and technical cornerstone of the new **Astronomical Search for Origins Program**. See also **Origins Program**.

To grasp the wonders of the cosmos, and understand its infinite variety and splendor, we must collect and analyze radiation emitted by phenomena throughout the entire electromagnetic (EM) spectrum. Towards that end, NASA proposed the concept of Great Observatories, a series of four space-borne observatories designed to conduct astronomical studies over many different wavelengths. An important aspect of the Great Observatory program was to overlap the operations phases of the missions to enable astronomers to make contemporaneous observations of an object at different spectral wavelengths.

The first element of the program, and the best known, is the Hubble Space Telescope (HST). The Hubble telescope was deployed by the Space Shuttle *Discovery* on April 24, 1990. A subsequent Shuttle mission in 1993 serviced HST and recovered its full capability. A second successful servicing mission took place in 1997. Subsequent servicing missions have added additional capabilities to HST, which observes the Universe at ultraviolet, visual, and near-infrared wavelengths. See also **Hubble Space Telescope (HST)**.

The second Great Observatory was launched and deployed by the Space Shuttle *Atlantis* on April 5, 1991: the Compton Gamma-Ray Observatory (CGRO). This mission collected data on some of the most violent physical processes in the Universe, characterized by their extremely high energies. The CGRO was safely de-orbited and re-entered the Earth's atmosphere on June 4, 2000 after nine years in service. See also **Gamma-Ray Astronomy**; and **Compton Gamma-Ray Observatory (CGRO)**.

The third member of the Great Observatory family, the Chandra X-Ray Observatory (CXO), was deployed from the Space Shuttle *Columbia* and boosted into a high-Earth orbit, on July 23, 1999. This observatory is observing such objects as black holes, quasars, and high-temperature gases throughout the x-ray portion of the EM spectrum. See also **X-Ray Astronomy**; and **Chandra X-Ray Observatory**.

The Space InfraRed Telescope Facility (SIRTF) represents the fourth and final element in NASA's Great Observatory program. The observatory is scheduled for launched July 2002 and will have a cryogenic lifetime of at least 2.5 years. SIRTF will fill in an important gap in wavelength coverage not available from the ground–the thermal infrared.

Mission Overview

SIRTF will explore the birth and evolution of the universe and the objects within it with unprecedented sensitivity, viewing phenomena not seen through other astronomical techniques. The SIRTF mission is managed for NASA by the Jet Propulsion Laboratory (JPL), a division of the California Institute of Technology. Infrared wavelengths, redder than the human eye can see, can be thought of as heat radiation. The colder infrared detectors are, the better they can "see" objects in the sky that glow in the infrared. In space, infrared telescopes are above the warmth of Earth's atmosphere, and can be cooled to very low temperatures, enabling studies of objects that range from far below room temperature to many thousands of degrees.

SIRTF will be the first space observatory to combine such a highly sensitive cryogenically cooled telescope with the imaging and spectroscopic power of a new generation of infrared detector arrays. SIRTF will see through clouds of dust and gas that obscure much of the universe from view. It will sense the infrared radiation, or heat, emitted by objects from the oldest galaxies to forming stars and emerging planetary systems. Scientists expect the observatory to help them discover the answers to important questions about the origin and evolution of the universe, its galaxies and stars, and to seek out stars like the Sun that may hold planets like Earth orbiting about them.

SIRTF's specially designed orbit will completely remove the spacecraft from the heat of the Earth and from the obscuring atmosphere that blocks our view of most of the infrared light from celestial sources. The observatory will see wavelengths of light critical to NASA's quest for an understanding of our origins, allowing astronomers to discover the basic processes underlying the formation of planets and the birth of stars and galaxies.

Data received through NASA's Deep Space Network from SIRTF will be processed and disseminated to the science community at the JPL/Caltech Infared Processing and Analysis Center located at the Caltech campus.

The National Academy of Sciences designated SIRTF the highest priority major mission for all of U.S. astronomy in the 1990s. With U.S. technology developments, innovative engineering and streamlined mission planning, SIRTF has undergone radical redesign to be consistent with the new NASA paradigm of faster/better/cheaper. The result is an affordable yet enormously powerful observatory.

SIRTF's Telescope and Spacecraft Overview

Cryogenic Telescope Assembly. SIRTF's Cryogenic Telescope Assembly (CTA) consists of four main parts: a superfluid helium cryostat, a light-weight 85centimeter (33.5 inch) Ritchey-Chretien telescope, an Outer Shell Group, and a Multiple Instrument Chamber which houses the Science Instruments. Everything that is cold is part of the CTA. The CTA is mechanically mounted to, but thermally isolated from, the spacecraft by means of low conductivity struts and thermal radiation shields. The solar array and spacecraft shields block the CTA from the sun and spacecraft components at all times, helping to keep the CTA as cold as possible.

Telescope. The SIRTF telescope fabricated by Hughes Danbury Optical Systems is a lightweight reflector of Ritchey-Chrétien design. It weighs less than 50 kilograms (110 pounds) and is designed to operate at an extremely low temperature. The telescope has an 85 centimeter (33.5 inch) diameter aperture. All of its parts, except for the mirror supports, are made of light-weight beryllium. Beryllium is a very strong material, which works well in the construction of infrared space telescopes because it has a low heat capacity at very low temperatures. The telescope is attached to the top of the vapor-cooled cryostat vacuum shell, which keeps the science instruments very cold.

The design philosophy of the telescope assembly is based on the following guidelines:

- Maximize the use of materials with a very high stiffness/density ratio, high thermal conductivity, and low cryogenic specific heat.
- Build the entire telescope of the same material to prevent thermal expansion mismatch complications, and to make the telescope assembly, as dimensionally stable as possible.
- Select a configuration that minimizes the size of the major elements of the telescope assembly.
- Strive for the simplest possible design to minimize the number of parts, thereby reducing the time and cost for design, fabrication, and integration.

Multiple Instrument Chamber. SIRTF's Multiple Instrument Chamber contains the cold parts of SIRTF's three science instruments as well as the pointing calibration reference sensor which is part of the pointing control system. The Multiple Instrument Chamber is built to be so tight that no light can get through it except that which is allowed to be detected directly by the instruments. The chamber is 84 centimeters (33.1 inches) in diameter by 20 centimeters (7.9 inches) high. It has an aluminum baseplate and cover and is mounted directly to the helium tank.

Infrared Array Camera (IRAC). The Infrared Array Camera (IRAC) is one of SIRTF's three science instruments, and provides imaging capabilities at near- and mid-infrared wavelengths. It is a general-purpose camera that will be used by observers on SIRTF for a wide variety of astronomical research programs.

IRAC is a four-channel camera that provides simultaneous 5.12×5.12 arcmin images at 3.6, 4.5, 5.8, and 8 microns. Each of the four detector arrays in the camera are 256×256 pixels in size. IRAC uses two sets of detector arrays. The two short-wavelength channels are imaged by composite detectors made from indium and antimony. The long-wavelength channels use silicon detectors that have been specially treated with arsenic. The only moving part in IRAC is the camera shutter.

Infrared Spectrograph (IRS). The Infrared Spectrograph(IRS) is one of the three instruments onboard SIRTF and provides both high- and low-resolution spectroscopy at mid-infrared wavelengths. Spectrometers are instruments, which spread light out into its constituent wavelengths creating a spectra. Within this spectra astronomers can study emission and absorption lines: which are the fingerprints of atoms and molecules.

The IRS has four separate modules: a low-resolution, short-wavelength mode covering the 5.3-14 micron interval; a high-resolution, short-wavelength mode covering 10-19.5 microns; a low-resolution, long-wavelength mode for observations at 14-40 microns; and a high resolution, long-wavelength mode for 19-37 microns. Each module has its own entrance slit to let infrared light in. The detectors are 128×128 arrays. The shorter-wavelength silicon detectors are treated with arsenic; the longer-wavelength silicon detectors are treated with antimony.

The IRS instrument consists of two physically separated parts, the cold assemblies which are located within the SIRTF multiple instrument chamber and the warm electronics, which are located in the SIRTF spacecraft bus. The IRS has no moving parts!

Multiband Imaging Photometer (MIPS). The Multiband Imaging Photometer for SIRTF (MIPS) is one of the three science instruments that will fly on the Observatory and will provide imaging and limited spectroscopic data at far-infrared wavelengths. It has three detector arrays. A 128×128 array for imaging at 24 microns is composed of silicon, specially treated with arsenic. A 32×32 array for imaging at 70 microns, and a 2×20 array for imaging at 160 microns both use germanium, treated with gallium. The 32×32 array will also take spectra from 50–100 microns. The MIPS field of view varies from about 5×5 arcmin at the shortest wavelength to about 0.5×5 arcmin at the longest wavelength.

The three arrays, calibrators, scan mirror, and optics compose the cryogenic part of the MIPS. This assembly is mounted in the SIRTF cold instrument chamber. In addition, the MIPS and the IRS share warm electronics that controls their operation. The only moving part in MIPS is a scan mirror used to efficiently map large areas of the sky.

Cryostat. In general, SIRTF's science payload needs to be kept very cold to work properly. This is because it uses infrared detectors that are very sensitive to heat. If the instruments are not very cold, the heat from the instruments themselves will interfere with the study of the faint infrared radiation from objects in space. SIRTF's cryostat will keep the science instruments at temperatures as low as 1.4 degrees Kelvin ($-272\,^{\circ}$C or $-457\,^{\circ}$F) for up to 5 years.

SIRTF's cryostat will keep the instruments cold by venting helium vapor from a liquid helium tank. The cryostat consists of the vacuum shell, inner and middle vapor cooled shields, helium tank, and the fluid management system. The tank holds about 360 liters of superfluid helium.

The telescope is attached to the top of the vapor-cooled cryostat. The telescope and cryostat shell is launched warm, and cool down to about 35 degrees Kelvin ($-238\,^{\circ}$C or $397\,^{\circ}$F) once in orbit. The cryostat vacuum shell must be sealed during ground operations and launch. Once the cryostat is cooled and in the vacuum of space, a cryostat door on the top of the shell is opened to allow light into the Multiple Instrument Chamber.

Outer Shell. SIRTF's outer shell is made up of a dust cover, outer shield (cooled by helium vapor), thermal shields (which block radiation from space), and the solar panels. The telescope and cryostat are surrounded by the outer shell. The shell keeps exterior heat from reaching the telescope and instuments by radiating it out into cold space.

The outer shell is made of lightweight, aluminum honeycomb sandwich construction. It is painted black on the anti-sun side, for efficient thermal radiation to cold space, and is shiny on the sun-facing side, for efficient rejection of heat from the sun and solar panels. To maximize the helium lifetime, the outer shell temperature must be as low as possible. The sources of heat to the outer shell are the spacecraft bus, solar panel, and star trackers.

The outer shell is closed at the top by an ejectable cover, which lets out unwanted dry nitrogen which, if left in, could contaminate the telescope's mirrors and other surfaces. The thermal shields are sized and shaped such that the observatory is shaded at all times when pointed properly.

Spacecraft. SIRTF's spacecraft refers to the warm portion of the Observatory, including the solar panel, the bus structure, and the components mounted in the bus that provide the Observatory engineering functions.

These components include: the solar arrays, the command and data handling unit, the reaction control subsystem, the telecommunications subsystem, the power generation and distribution subsystem, the pointing control subsystem, and the flight software.

The spacecraft consists of an octagonal bus structure in which the avionics and the science instrument's warm electronics are housed, and a solar panel that provides electrical power to the vehicle and serves to shade the cryo-telescope assembly from direct exposure to the sun. The spacecraft provides electrical power to the science instruments, orients and stabilizes the boresight of the telescope, collects and compressed data from the science instruments for later transmission to the ground, executes stored commands to direct science instrument activities, and communicates with the ground system. All communications with SIRTF will be conducted through NASA's Deep Space Network. The spacecraft is responsible for the safe operation of the Observatory.

Solar Panel Assembly. SIRTF's Solar Panel Assembly is designed to provide the electrical power needed to operate SIRTF for up to 5 years. The Solar Panel Assembly is made up of two solar panels each of which has 392 solar cells. Each solar cell is 5.5 centimeters (2.2 inches) by 6.5 centimeters (2.6 inches) in area. Together, these cells will convert radiation from the Sun into a total of 427 Watts of electrical energy. SIRTF cannot point more than 120 degrees away from the sun. If it does, sunlight will not hit the solar panels properly.

The solar panel has 50 percent of its area covered with solar cells and 50 percent covered with optical solar reflectors. These reflectors reduce the solar panel temperature to about 330 K. The wedge shaped solar panel shield is angled away from the outer shell in order to improve its view factor to space and to improve the thermal isolation between it and the outer shell.

Spacecraft Bus. SIRTF's Spacecraft Bus is an octagonal structure in which the avionics and the science instrument warm electronics are housed. The Spacecraft Bus provides electrical power to the science instruments, orients and stabilizes the boresight of the telescope, collects and compresses data from the science instruments for later transmission to the ground, executes stored commands to direct science instrument activities, and communicates with the ground system.

The bus structure makes up the nine bays within which the bus equipment is housed. Four side modules, four corner modules, two heatpipe equipment panels, and six equipment panels make up the nine bays. The equipment panels are sandwiched between the modules and are bolted and bonded together for maximum stiffness and structural integrity. On the outside of the bays, panels are bolted to the modules. These panels are removable and provide access to the outer bays during integration and test. The center bay is accessible from the top.

Science Overview

SIRTF will study a wide variety of astronomical phenomena, extending from our Solar System to the distant reaches of the early Universe. Providing coverage at infrared wavelength between 3 and 180 microns, SIRTF provides an important scientific complement to the Hubble Space Telescope and the Chandra X-Ray Observatory. The shortest IR wavelengths will pierce through the heavy obscuration of dust and allow astronomers to study newly formed stars. The longer IR wavelengths are well suited to studying the distribution of dust, an important ingredient of future planet and star formation, throughout the Milky Way Galaxy.

Nearly 80 percent of the observing time on SIRTF will be available to the scientific community-at-large through competitive proposals solicited by the SIRTF Science Center. To date, about one-fifth of the SIRTF mission (assuming a 5-year mission) has been defined through the Legacy Science Program, the First-Look Survey and the Guaranteed Time Observations. Solicitations for the balance of the science program will be issued on an annual basis, starting shortly before launch.

One consequence of the re-designs of SIRTF in the early 1990s was the decision to design SIRTF such that it would make important and lasting contributions in these four science themes:

- **The Search for Brown Dwarfs and Super-Planets:** These objects have too little mass to ignite the fusion reactions which power stars, but are larger and warmer than planets found in our Solar System. Astronomers are now starting to detect these long-sought objects and want to know the extent to which they might account for the elusive dark matter that is thought to permeate the Universe. SIRTF will provide invaluable information about their population and physical characteristics.
- **The Study of Ultraluminous Infrared Galaxies and Active Galactic Nuclei:** Many galaxies emit more radiation at infrared wavelengths than in all other regions of the electromagnetic spectrum combined. These ultraluminous IR galaxies could be triggered by intense bursts of star formation stimulated by colliding galaxies, or by dust-enshrouded active galactic nuclei (including quasars) powered by black holes. SIRTF will trace the origins and evolution of these objects to cosmological distances.
- **The Study of the Early Universe:** Cosmological redshifts result from the expansion of the Universe, shifting the observed light from astronomical phenomena to longer wavelengths. Objects at high redshifts are seen as they existed long ago. Most of the optical and ultraviolet radiation emitted from stars and galaxies since the beginning of time is now shifted into the infrared. SIRTF will provide important insights into when and how the first stars and galaxies formed.

Apart from being scientifically interesting in their own right, these themes are directly relevant to NASA's Origins Program, which seeks to understand the origins of the Universe, galaxies, stars, and planets.

While these themes drove the budget-mandated re-design of the Observatory, it should be emphasized that SIRTF's powerful capabilities will be applied to a wide range of other astronomical topics. Moreover, SIRTF offers unparalleled capabilities in a space-borne infrared telescope. History has repeatedly demonstrated that such huge advances lead to serendipitous discoveries of unanticipated phenomena. With SIRTF, astronomers expect the unexpected!

More information on the SIRTF mission is available from the project's home page at http://sirtf.caltech.edu/index.html

Pasadena, CA

SPACE INTERFEROMETRY MISSION (SIM). See **Origins Program**; and **Space Science Missions: Universe**.

SPACE LIFE SCIENCES. The term space life sciences refers to the set of sciences that study the biology of living things under conditions of spaceflight. The synonymous term, space biology, coined in 1920 by K. Tsiolkovsky, is more common in Russia (USSR). The origin and development of space life sciences as a discipline are the result of certain advancements in modern science and technology and are associated with the development of jet propelled flight vehicles that can overcome the force of gravity to ascend beyond the bounds of Earth's atmosphere.

Space biology arose at the intersection of many scientific disciplines: various branches of biology and medicine, physics, chemistry, astronomy, astrophysics, geology, geophysics, geochemistry, radiology, and mathematics. It is indissolubly bound up with cosmonautics and space medicine.

Space medicine is the area of general medicine that studies what happens to human physiological processes under the unique conditions of space flight to develop means and methods for maintaining the health and performance capacity of crews of spacecraft and space station pre-, in- and postflight. As one of the branches of occupational medicine, space medicine attempts to provide the answers to a number of questions confronting humanity as a result of scientific and technological progress. These answers are derived from a very large medical knowledge base relating to various areas of theoretical and clinical medicine such as space physiology and psychophysiology, space hygiene, space radiobiology, and medical expertise.

The mission of space physiology is to find out how much it is possible to decrease comfort and stress human physiological functions, still induce only physiological changes that are merely adaptive rather than pathological and leave performance capacity and job efficiency undiminished. In the light of the high cost of flight time in space, the constant time deficit and the serious potential consequences of human error, it is critical that cosmonauts' performance capacity be maintained at a high level.

TABLE 1. OBJECTIVES AND GOALS OF SPACE LIFE SCIENCES

Space biology	
To conduct fundamental biological research devoted to comprehensive study of space and celestial bodies as a unique living environment and of the effects of factors of the space environment, including spaceflight factors, on various forms of life	1. Study of the biological effects of various spaceflight factors on terrestrial life forms 2. Investigation of the possibilities for life to exist under extraterrestrial conditions, including other planets (exobiology) 3. Study of the mechanisms governing changes in the physiological functioning of humans and animals under exposure to spaceflight factors (space physiology) 4. Development of life support systems (LSS) for use by terrestrial life forms under spaceflight conditions
Space medicine	
To support maximum possible physical and psychological well-being, high performance capacity, job efficiency, and increased reliability of human performance under the unique conditions of spaceflight and after its completion	1. Creation of the requisite conditions to optimize human vital functions during space flight 2. Monitoring, predicting, and correcting physiological changes that occur as a result of the impossibility of fully or partially replicating terrestrial conditions 3. Maintaining human health during all phases of preparation for flight, flight itself, and after flight completion (selection, observation, diagnosis, treatment, and prevention of pathologies) 4. Ensuring the safety and increasing the efficiency of spaceflights; providing medical and ergonomic measures to increase the reliability of human–machine interactions.

Goals and Objectives

The goals and objectives of the principal space life sciences are presented in Table 1.

SPACE MEDICINE. A branch of aerospace medicine concerned specifically with the health of persons who make, or expect to make, flights into space beyond the sensible atmosphere.

SPACE MICROELECTRONICS TECHNOLOGY. Future space travel means small spacecraft. In today's constrained budget environment, large space missions can no longer be afforded. At the Jet Propulsion Laboratory (JPL), planners have adjusted the size of missions and spacecraft to be more moderate, primarily by taking more risks and asking the spacecraft to do less. In the future, they will be using very advanced technology in order to reduce the spacecraft size even more, while retaining the functionality of today's spacecraft. The spacecraft of the future will provide world-class science in focused areas for an affordable price, making it possible for many of these microspacecraft to be launched, perhaps as many as one per month.

The Jet Propulsion Laboratory, Center for Space Microelectronics Technology (CSMT) concentrates on innovative, high-risk, high-payoff concepts and devices that hold the potential to enable new space missions or to enhance current and planned space missions. The center conducts research and development in microsensors and microinstruments, advanced detectors and high performance computing. Once the concepts are proved through demonstrations, the successes are transferred to mission applications or to industry for commercialization.

The center focuses on areas of microelectronics and advanced computing that are unique to space applications. This includes sensors studying objects in space in portions of the electromagnetic spectrum that can not be readily studied from Earth because of atmospheric interference, as well as high-performance ground computing for mission data analysis and visualization.

In 1987, NASA and several Department of Defense agencies with space responsibilities established CSMT in order to create a program in space microelectronics with world-class facilities, equipment and staff.

Microdevices Laboratory

Much of CSMT's research and development work takes place in the Microdevices Laboratory, a unique 38,000-square-footfacility at JPL. It includes clean rooms for thin-film material deposition, lithography, device processing, and optical characterization.

Work at the Microdevices Laboratory encompasses a wide range of sensors designed for use on future spacecraft, including passive optical instruments, dust detectors and a variety of spectrometer instruments. A mass spectrometer, for instance, is used to identify and measure gases. An X-ray fluorescence spectrometer would be used to measure the absolute abundance of elements at the surface of an airless body, such as an asteroid. The center also is developing new micro instruments for Earth remote sensing.

Other sensors measure infrared radiation. The intensity of infrared radiation in our environment is second only to that of visible light. All objects produce radiation, most of which is emitted in the infrared waveband of the electromagnetic spectrum. Infrared extends from just beyond red light to the beginning of microwaves. NASA has a significant interest in space instruments that map in the infrared. The agency is developing instruments that look upward into the universe as well as downward to observe Earth. The center has developed a gallium arsenide-based quantum well infrared photo detector (QWIP) that has been made into large arrays and packaged into camcorder sized portable cameras. QWIP detectors have a narrow bandwidth ($\sim$1 μm) and have been made in various wavelength responses from 6 μm to 22 μm. Because gallium arsenide is a mature and producible technology, 256 by 256 and 640 by 480 element arrays can be routinely made.

In addition, scientists are currently working to improve spacecraft "eyes." Wireless digital imaging cameras the size of two sugar cubes are being developed which can operate in the ultraviolet, visible, and near-infrared realms. The active pixel sensor, a compact, solid-state image sensor technology, makes possible a veritable "camera on a chip." In many imaging applications, such sensors may ultimately replace charge-coupled devices (CCDs), which measure light digitally and are used in many still and video cameras. An active pixel sensor camera uses 100 times less power than the standard CCD camera, has superior resolution, is less susceptible to radiation damage in space, and can be made in a standard semiconductor factory. The camera features automatic exposure control and electronic pan and zoom. In addition, it comes with a built-in transmitter that can send images more than a mile. These "cameras-on-a chip" will be used in orbiters, landers, and rovers.

Still, CCDs will be used on many future space missions, and a new process has been developed at the center to build CCDs to image at ultraviolet wavelengths. That enhancement will allow a new set of NASA space instruments for ultraviolet astronomy and other remote sensing projects.

In the area of microinstruments, scientists are developing highly sensitive, light, compact, robust, low-power microaccelerometers and seismometers for planetary, cometary, microgravity, and terrestrial applications. Conventional seismometers are ill-suited for space applications; despite good sensitivity, they require careful deployment and are delicate,

heavy and power-hungry. The miniature seismometer weights less than 200 grams (about 7 ounces); normal seismometers are about the size of an overnight bag and weigh about 50 times more. To understand if Mars has a molten core, scientists want to measure Mars quakes with seismometers capable of measuring one billionth the acceleration of gravity, all within a package the size of a message pager. A prototype of a microseismometer has successfully measured earthquakes in laboratory demonstrations.

Several microdevices needed for future space missions have been developed by the center, including instruments for a microweather station that may go to Mars. Imagine fleets of nearly autonomous microlanders dispersed by one small spacecraft, each with a weather station aboard. A network of these stations could be established to supply information about the humidity and wind and the composition and temperature of the planetary atmosphere. Because of the importance of water to the atmospheric science of both Earth and Mars, the microhygrometer is the most scientifically important component of the micro weather station. A microhygrometer for direct dew-point measurements has been developed and successfully tested on NASA's DC8 for upper troposphere measurements of humidity. It has demonstrated superior performance compared to conventional, large, chilled-mirror hygrometers. Other instruments being developed in the program include micromachined silicon sensors for wind, pressure, and air temperature, a radiation densitometer to measure radiation and a micro laser Doppler anemometer to measure wind speed and direction. Surface micro weather stations also have applications in military tactical situations as tools for gathering critical information on surface conditions on land or sea. This effort has resulted in the world's first demonstration of single mode lasers suitable for spectroscopy applications that operate at ambient temperatures.

To enable scientists to learn more about the role water played in Mars' past and its impact on the planet today, the Microdevices Laboratory has developed and delivered space-qualified tunable diode lasers to detect water, as well as a variety of other gases. Measurement of water in the Martian atmosphere will be done by near-infrared diode lasers the size of pencil points. These lasers can be assembled with their electronics into instruments the size of a roll of pennies. Any data attained could help answer questions regarding the possibility of life on the planet.

One of the most innovative projects at the Microdevices Laboratory has been the development of the ballistic electron emission microscope (BEEM). Scientists working in solid-state physics must know the conditions existing at the interface of two separate materials. The BEEM method uses a scanning tunneling microscope to inject an electron tunnel current into a structure with one or more buried interfaces between different materials. See also **Scanning Tunneling Microscope**.

Electrons injected into the structure are sent ballistically–that is, without scattering or loss of energy–for distances as small as tens of billionths of a meter (nanometers). The stabilized microscope tip is scanned over the surface as the electron current is detected crossing the buried interface. The transmission of ballistic electrons gives information on the material and interface quality.

High-Performance Computing

High-performance computers are needed onboard spacecraft to enable spacecraft autonomy and to analyze and compress scientific data prior to transmission to Earth. High-performance computers are also needed on the ground to analyze and visualize data as part of the process of turning data into knowledge. Ground-based computers are also used for space mission and spacecraft design and simulation, and for theoretical studies and modeling of physical phenomena.

The center's activities in on-board computing have focused on developing a miniature flight computer using advanced technologies, including multi-chip modules and three-dimensional chip and module stacking.

Although the initial emphasis has been on system miniaturization, the limited power onboard deep space missions, has made low-power consumption a major new R&D direction. Under NASA's High Performance Computing and Communications program, the center is developing a scalable, low-power flight computer architecture that relies on commercial microprocessors and implements the fault tolerance needed for space applications in software. A single mode of the computer could be used for a simple microlander application, whereas a 50-processor parallel machine can do onboard processing of hyper-spectral science imagery.

Other scientists at the center are developing innovative magnetic and optical data storage techniques and optical processing. A major thrust is directed toward electronic neural networks modelled on the human brain, capable of pattern recognition and vehicle control in real time. See also **Artificial Intelligence: Neural Networks**.

JPL and the California Institute of Technology have been pioneers in developing technologies for massively parallel computing. A dozen years ago, the Center was building parallel supercomputers because there was no industry. Caltech/JPL partnerships with Intel, Cray Research and, most recently, Hewlett Packard have been instrumental in turning high performance parallel supercomputing into the industry known today.

The center concentrates on software and applications of high performance parallel supercomputers for NASA and Defense Department applications. These include ocean modeling, data visualization, mission design, and radar processing. The new 256-processor Hewlett Packard Exemplar system has a peak performance of 184 billion operations per second, with a memory of 64 gigabytes. This is 700 times faster than the JPL's CRAY X-MP supercomputer of a decade ago. The memory is 4,000 times larger than that of a typical desktop system. The large memory allows huge problems to be tackled. For example, all the data NASA has from previous missions can fit into the machine's memory and can be processed and visualized in real time.

Microspacecraft

In the future, we will be using more and more very advanced technology in order to reduce spacecraft size, all the while retaining the functionality of today's spacecraft.

By the year 2010, second-generation microspacecraft the size of toaster ovens that weigh 5-1/2 kilo-grams (about 12 pounds) and use 5 watts of power will travel a billion miles away and send data back to Earth. They will be able to figure out their location and navigate autonomously, all by the position of the stars.

These microspacecraft will be enabled by advances in space technology. Many of the key technologies will be derived from those in such commercial products as cell phones, low-power palm top computers, and pagers. Others are being developed specifically for space. These include a micromachined gyro, accelerometer and other micro-electro-mechanical systems, microthrusters, neural networks and spacecraft autonomy software.

The center is developing ground-based micro-spacecraft prototypes that include many of the above components to begin to investigate the systems issues that will arise when building these new miniature spacecraft.

Management

Dr. Barbara Wilson is director of the Center for Space Microelectronics Technology. Policy guidance and program oversight are provided by a board of governors. Board members include the major sponsors of the center, together with the JPL director, Caltech president and Caltech provost.

The center's scientific advisory board, composed of seven world-renowned scientists, reviews the technical program and provides advice to the board of governors and the center's director.

Programs

Many of the center's technologies have commercial as well as government mission applications. The U.S. Department of Commerce joined the center in 1991 and urged the center and its sponsors to emphasize technology applications for business. As a result, the center has initiated programs with a strong emphasis on dual-use technologies and partnerships with industry.

Currently there are 39 cooperative agreements with U.S. industry in the areas of electronics, computing, communications, automotive, and health care. Those collaborations are with companies both large and small, as well as minority- and women-owned businesses.

Key programs under the center include:

- Low- and high-temperature superconductors.
- Semiconductor lasers.
- Microsensors and microinstruments.
- Microelectro-mechanical systems.

- Infrared, visible and ultraviolet detectors.
- Submillimeter receivers.
- Advanced flight computer.
- High-performance computing.
- Advanced networking.
- Neural networks.
- Vertical Bloch line memory.

Pasadena, CA

SPACE (Minkowski). A flat space of four dimensions, of which three specify the position (x, y, z) of a point in space, and the fourth represents the time t at which an event occurs at that point. Usually, the coordinates in the space are denoted by $x_\mu (\mu = 1, 2, 3, 4)$ with $x_1 = x$, $x_2 = y$, $x_3 = z$, $x_4 = ict$, where $i^2 = -1$. It is also possible to write $x_4 = ct$, but then it is necessary to associate with the space the metric g^{ij}, where $g^{11} = g^{22} = g^{33} = 1$, $g^{44} = -1$.

SPACEPORTS: RUSSIAN FEDERATION. Russia's spaceports (launch sites) serve as the basis for all Russian activities in space, enabling an independent policy in exploration and use of outer space. They comprise a number of facilities, equipment, and land areas designed for receiving, storing, assembling, testing, prelaunch preparation, and launching rockets with spacecraft. Depending on its location, a spaceport may have one or several launch azimuths along which tracking stations are located.

The major facilities at spaceports are the launch and technical maintenance complexes, the fueling and decontamination stations, landing complexes, storage facilities of various types, launch debris impact areas, and telemetry monitoring stations. In addition, spaceports have plants for producing rocket propellants, airports, railroads, motor vehicle roads and various supply lines, as well as living quarters and social amenities.

Now Russia has three spaceports on its territory: Plesetsk, Kapustin Yar and Svobodnyy and, in addition, uses the Baikonur spaceport, which it acquired on a 20 year lease from the Republic of Kazakhstan in 1994. A map of these spaceport locations is provided in Fig. 1.

History

Spaceport construction followed logically from the need to ensure independent and efficient access to space for the Soviet Union and subsequently the Russian Federation. Spaceport construction started when a launch site was built for testing ballistic missiles in the region of the Kapustin Yar village in the Astrakhan Oblast. In 1946, a reconnaissance team headed by V.I. Voznyuk, selected the site of the future launch facility. The group studied seven regions of the USSR that seemed promising for this purpose and gathered and analyzed material related to the economy, weather, services, development level, construction potential, etc. Upon this group's recommendations the launch site was selected near the Kapustin Yar village on the lower Volga. V.I. Voznyuk was appointed the first head of the missile launch site. Under his leadership, the first launch of the R-1 ballistic missile took place from the Kapustin Yar launch site as early as October 1947. Under the leadership of S.P. Korolev, between 1948 and 1956, the first Soviet ballistic and geophysical missiles were tested at this spaceport. Subsequently launch complexes were constructed for launching satellites for various purposes and also for vertical launch of the Vertikal geophysical missile. At the launch site an infrastructure was built to enable preparation work, launch spacecraft and provide all necessary services for the personnel to live at the site.

The injection of the first "small" artificial Earth satellite, later named Kosmos-1, on 16 March 1962 may be considered the point at which the Kapustin Yar launch site became a spaceport. Kapustin Yar became an international spaceport on 14 October 1969 when the first international satellite, Interkosmos-1 was launched.

The Kapustin Yar spaceport functioned as the launch facility for "small" missiles and "small" research satellites. This specialization continued until 1988, when the need to launch such satellites dropped sharply and launches from Kapustin Yar were terminated. However, the launch and technical complexes for Kosmos type launch vehicles were continuously maintained in working condition, which made it possible to use this site in 1996 to launch the German spacecraft ABRIXAS and MegSat.

In addition to construction of launch pads, the Znamensk town was built for spaceport personnel to live in. During different periods of time, V.I. Voznyuk, Yu.A. Pichugin, P.G. Degtyarenko, N. Ya Lopatin, N.V. Mazyarkin, V.K. Tonkikh, and V.P. Yushchenko headed the spaceport. The Kapustin Yar spaceport is currently under the authority of the Russian Ministry of Defense.

The next spaceport built was Baikonur. Construction of the Baikonur launch site was required to support the development of the R-7, the first Soviet intercontinental ballistic missile. Its flight range exceeded 8000 km and required equipping new launch azimuths eastwards through virtually the entire Asian part of the Soviet Union. New drop zones of LV separable parts and new telemetry stations were needed. A new launch site was required to launch these missiles. For this purpose, in the early 1950s, a commission was created to develop the specifications for the new launch site and recommend the most desirable areas of the country for constructing it.

The commission considered three locations for the launch site. As a result of their deliberations, a site in Kazakhstan in the vicinity of the Aral Sea and the town of Kzyl-Orda was selected. In February 1955, the USSR Council of Ministers adopted a Resolution concerning construction of the launch site near the Tyura-Tam railroad station in the Kzyl-Ordinsk Oblast of the Kazakh SSR. A.I. Nesterenko was appointed the first head of the site.

The major structures that had to be build were the launch pads for intercontinental ballistic missiles (ICBM) and the technical facilities of the launch site. By November 1956, construction of most of the facilities and

Fig. 1. The spaceports of the Russian Federation.

installations were completed to provide flight tests of ICBMs. Facilities constructed included the launch complex, the launch control station, the assembly and test facility, some of telemetry stations, and the computer center building. The water line, water pumping station, and electric power station were all in operation. Motor vehicle roads and railroad lines were built.

On 15 May 1957, the first test launch of an R-7 ICMB took place but it failed. The second launch, planned for 9 June 1957 did not occur because of defects in the missile equipment. The third missile launch took place on 12 June 1957 and was unsuccessful. The fourth and fifth launches occurred on 21 August, and 7 September 1957 and were finally successful. On 4 October 1957, the first artificial Earth satellite was launched from Baikonur and on 12 April 1961 a spacecraft carrying the planet's first cosmonaut, Yu.A. Gagarin was sent into space from there. Various launch and maintenance complexes were built at the launch site later. They were intended for preparing and launching spacecraft using launch vehicles of light (Tsiklon-M), intermediate (Soyuz, Molnia, Zenit), heavy (Proton) and super heavy classes, and the launch site infrastructure was developed. Now, all manned spacecraft and satellites into geostationary orbit (communications, television broadcast) are launched from Baikonur. This spaceport is also used for launching satellites into low and medium orbits (the GLONASS navigational system, Meteor weather satellite system, satellites for studying the Earth's natural resources, etc.), and also for launching unpiloted interplanetary probes and commercial spacecraft.

After the dissolution of the USSR, Baikonur spaceport became the property of the Republic of Kazakhstan and was leased by the Russian Federation. Now most of facilities at Baikonur are under the authority of the Russian Aviation and Space Agency (the launch complexes for the Soyuz, Molnia, Zenit, Tsiklon-M and Energia launch vehicles, one launch facility for the Proton, all assembly and test facilities, the oxygen-nitrogen plant). The Russian Ministry of Defense is responsible for the other Proton launch complex and the measurement complex. In 1990 the Baikonur Launch Site was renamed the Baikonur Spaceport.

The living area founded in 1955 was extended together with the spaceport. It had different names during its existence, and finally, in 1995, was renamed the Baikonur town. At different periods of time, the spaceport was headed by A.I. Nesterenko, K.V. Gerchik, A.G. Zakharov, A.A. Kurushin, V.I. Fadeyev, Yu.N. Sergunin, Yu.A. Zhukov, A.L. Kryshko, A.A. Shumilin, and L.T. Baranov. Now the Baikonur Federal Space Center, whose director is Ye.M. Kushnir, performs general work coordination of Russian Aviation and Space Agency facilities at Baikonur spaceport.

At different times throughout the spaceport's existence, the following leading scientists worked there: M.V. Keldysh, S.P. Korolev, I.V. Kurchatov, N.A. Pilyugin, M.K. Yangel, G.N. Babakin, V.N. Chelomey, V.P. Glushko, V.P. Barmin, V.N. Solovyev, B. N. Petrov, and V.F. Utkin.

For outstanding accomplishments in the testing of space technology, the following personnel of the spaceport were named Heroes of Socialist Labor: A.I. Nosov, A.S. Kirillov, V.A. Bokov, A.A. Shumilin, Ye.I. Nikolayev, and A.B. Berezin; The State Prize was awarded to B.A. Bululukov, A.P. Zavalishin, A.A. Shumilin, S.V. Limont, V.A. Menshikov, V.Ya. Khilchenko, Yu.N. Sergunin, V.A. Nedobezhkin, and V.I. Katayev.

Further development of space exploration and activities made it necessary to build the Plesetsk Spaceport in the northern regions of the USSR. At first, the Plesetsk Spaceport was established as a launch site at the Angara facility, where the first combat group of R-7 ICBMs was stationed. Construction of the Plesetsk launch site started in 1957. The launch site was built very rapidly in the severe northern climate. This work was headed by M.G. Grigoryev. During the 1960s and 1970s, a highly developed infrastructure, including launch and technical complexes, was built to prepare and launch spacecraft using the Soyuz, Molnia, Kosmos, and Tsiklon launch vehicles.

The only missile launch site in Europe, Plesetsk enables to launch spacecraft for defense, socioeconomic, and scientific purposes and also in the framework of international collaboration programs. The Mirnyy town was founded simultaneously with construction of the launch site facilities and implementation of space programs. Plesetsk launch site was granted the status of Spaceport in November 1994. During various periods of time, the launch site was headed by M.G. Grigoryev, S.F. Shtanko, G.Ye. Alpaidze, Yu.A. Yashin, V.L. Ivanov, G.A. Kolesnikov, I.I. Oleynik, A.N. Perminov, A.F. Ovchinnikov, G.N. Kovalenko. Now, Plesetsk is under the authority of the Russian Ministry of Defense.

The Svobodnyy Spaceport was founded in 1993 and received official spaceport status in March 1996. The Svobodnyy Spaceport was formed using the facilities of a decommissioned missile division in the Amur Oblast. The existing infrastructure of the spaceport had to be modified for launching light-class launch vehicles derived from decommissioned ICBMs. The first head of the spaceport was A.A. Benediktov.

Baikonur Spaceport

Baikonur Spaceport is located within the Republic of Kazakhstan. The geographical coordinates of the spaceport are 46° North latitude and 63° East longitude. A schematic map of the spaceport is presented in Fig. 2. The total area of the spaceport is 6,717 km^2 (2,593 square miles). In accordance with a treaty between the Russian Federation and the Republic of Kazakhstan on the basic principles and conditions for use of Baikonur, signed by the heads of state on 28 March 1994, Baikonur was leased to the RF for 20 years. To ensure effective use of Baikonur spaceport to implement various space programs, Russia and Kazakhstan have signed appropriate agreements concerning lease conditions. This has made it possible to create a legal foundation for the Russian Federation's use of Baikonur, as well as the most favorable conditions for efficiently investing funds in the spaceport's ground-based infrastructure, which is necessary to implement space programs. The property rights to the real and movable property built, acquired, and delivered by the Russian Federation to Baikonur belong to it, as the party providing the funds.

Before 1993, Baikonur Spaceport was fully under the authority of the Russian Federation Ministry of Defense. Since 1993, the Russian Space Agency, subsequently the Russian Aviation and Space Agency, has been taking an active part to ensure functioning and use of all facilities. From 1993 to 2000, approximately 80% of the spaceport infrastructure, which is used by space industry organizations, was transferred to the Russian Aviation and Space Agency.

Baikonur spaceport includes nine launch complexes with 15 launch pads and 11 assembly and test areas with 34 technical complexes for assembly, testing and prelaunch preparation of launch vehicles and spacecraft; three fueling and decontamination stations for fueling spacecraft and upper stages with propellants and compressed gas; a measurement complex with a powerful computer center, and an oxygen and nitrogen plant with a total production capacity of up to 300 tons of cryogenic products per day. The spaceport infrastructure includes an advanced electric power supply grid, which contains more than 600 transformer substations and 6,000 km (3,728 miles) of electric transmission lines; two first-class airports, including Yubileynyy, can receive different classes of aircraft; more than 400 km (249 miles) of railroad tracks; more than 1,000 km (621 miles) of motor roads and 2,500 km (1,553 miles) of communications lines.

The Russian Federation uses Baikonur spaceport to satisfy the demands of the state for space-based means of communications; television and radio broadcasting; remote sensing of the Earth; time standards and geographic navigational coordinates of various types to users on the ground, in the air and at sea; and implementation of manned and international collaborative space programs.

The Baikonur spaceport plays an extremely important role in implementing Russia's space programs, since it occupies the leading place among Russian spaceports with regard to the number of space launches. Thus, from 1996–1999, 70% of all Russian launches took place from Baikonur; the analogous figure for 2000 was 83%. Spacecraft of various purposes and automated interplanetary probes are prepared and launched from Baikonur into orbits from 200 km to 40000 km high using light-intermediate- and heavy-class launch vehicles. The azimuth of launches has ranged from 35 to 192°.

To support preparation and implementation of spacecraft launches, Baikonur has space rocket complexes for the Proton, Soyuz, Zenit, Tsiklon-M, and Rokot vehicles. These complexes comprise launch and technical facilities for preparing launch vehicles, upper stages, and spacecraft. The technical facilities are located in the assembly and test areas with sites for assembly and testing of launch vehicles and spacecraft, fitted with all necessary technical, installation, rigging, docking, and crane equipment.

Baikonur is a unique spaceport due to launch facilities for heavy Proton launch vehicles, which are used to launch all space station modules, including those for the International Space Station (ISS), Russian television broadcasting satellites, most of the relay, communications, and navigation

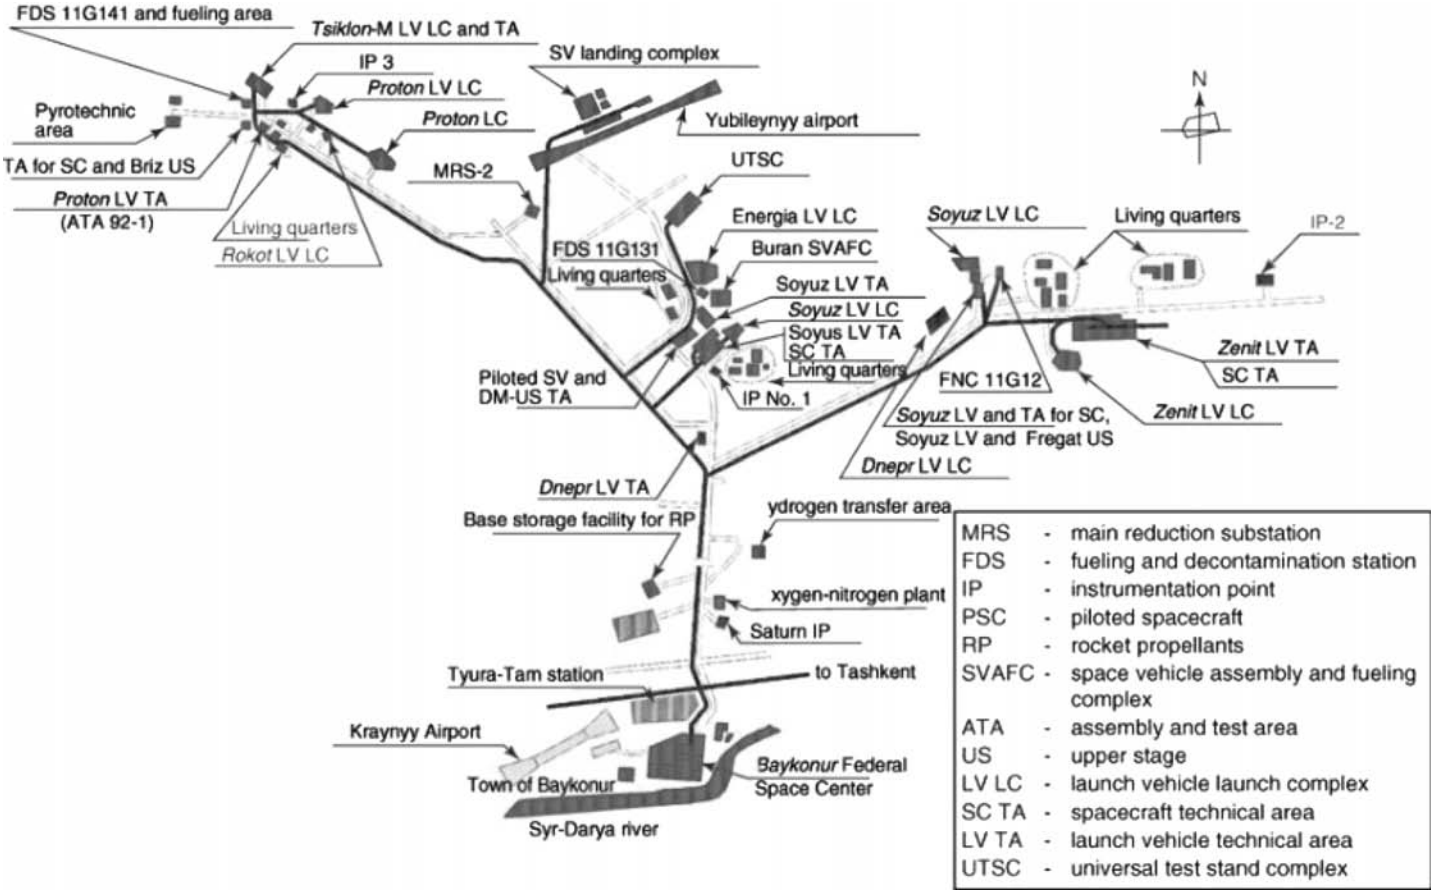

Fig. 2. Schematic map of Baikonur.

satellites, and also interplanetary probes. The launch facilities for Proton were developed under the direction of General Designer V.P. Barmin. The first launch of a Proton vehicle with a heavy spacecraft occurred on 16 July 1965. The weighty contribution of Baikonur to the conquest of space involved Proton launches with interplanetary probes to the Moon, Venus, Mars, and the Salyut and Mir orbital stations, as well as launches of Ekran and Gorizont satellites for national economy programs. Both transport and cargo vehicles in the framework of manned flight programs were launched from Baikonur.

The space rocket complexes developed at Baikonur for Soyuz launch vehicles are well known throughout the world due to launching all manned spacecraft with Russian and international crews. The Design Bureau of General Machine Building developed these legendary launch complexes under the direction of General Designer V.P. Barmin.

The contribution of Baikonur to the implementation of Russia's national space programs may be evaluated by the number of spacecraft launched in each of these programs. Thus, there were launched from Baikonur: 95% of spacecraft in the Earth space observation and remote sensing programs; more than 70% of the spacecraft in the navigational program; 25% in the communications and television broadcasting programs; more than 40% in the weather satellite program; more than 30% of the spacecraft in the scientific research program; and 100% spacecraft in the manned spacecraft program. The Baikonur Spaceport was used to implement such space programs and missions as Vostok, Voskhod, Salyut, Mir, Mars, Venera, Luna, and Energia-Buran. Baikonur played the largest role in the implementation of the Mir program. Approximately 220 organizations and 80 scientific-research institutions participated in the Mir program.

The history of the spaceport is associated with the construction of launchers. The first launcher for the Soyuz launch vehicle was put into operation in 1957. The second, analogous to it, in 1961. Two launchers for Tsiklon-M were put into operation in 1967. The first Proton launcher went into operation in 1965, the second in 1966, and two more in 1979.

Launch complexes for the Energia launch vehicle (General Designer B.P. Barmin) were built at the spaceport in the framework of the Energia-Buran program. On 15 May 1987, these facilities provided the successful test launch the new superpowerful Energia launch vehicle from Baikonur. On 15 November 1988, this launch vehicle was used to insert the 30-ton reusable orbital spacecraft Buran (unmanned version) into near-Earth orbit. The success of this outstanding experiment was due to the ground-based test facilities for this program that already existed at this spaceport. The Energia-Buran program was preceded by the grandiose N-1 lunar program adopted by the USSR government in 1964. Between 1969 and 1972, there were four launches of the N-1 launch vehicle, which were unsuccessful. In 1976, work related to N-1 launch vehicle was terminated completely. The unique ground-based complex created for this program was closed down, but at the end of the 1970s, rebuilding was started and new ground-based facilities for the Energia-Buran complex began to develop. As a result, a launch complex and a universal multisystem launch stand were built. A special landing facility was built to allow the orbital spacecraft to land at Baikonur. In the early 1990s, the Energia-Buran program at the spaceport was terminated, the facilities were closed down and some of them were used for other programs.

At the same time as the Energia-Buran complex was being built at Baikonur, a ground complex was also built for Zenit — a new generation of middle class launch vehicles — which could insert a payload of 15 tons into near-Earth orbit. A key feature of the Zenit complex is the maximum level of prelaunch automated operations. Zenit's launch facility was developed by the Design Bureau for Transport Machine Building under the direction of Chief Designer V.N. Solovyev. Silos for Rokot and Dnepr were reequipped to launch spacecraft. The first launch of Rokot occurred in 1994, and the first one of Dnepr — in 2000.

The Baikonur Spaceport is used for international programs in which Russia participates. These include: Phobos, Vega, Interkosmos, IRS, and the International Space Station. Plans for collaboration with the world community for developing and using the International Space Station were designed specifically for Baikonur. In recent years Baikonur began to be used extensively for commercial space projects. The Proton and Soyuz launch vehicles have the same capacities as their Western analogs, and in the near future, we can expect expansion of their use for spacecraft launches in the world market. The first two commercial launches occurred

in 1996; in 1997–2000 there were already 33 spacecraft launched from Baikonur. Foreign partners actively collaborate with Russian enterprises in marketing these rockets in the world market.

The practical implementation of the principles of Russia's international collaboration in the launch services market started with establishing of the ILS joint venture based on the Lockheed-Khrunichev-Energia International, Inc. As a result, the Proton space rocket system entered the market and demonstrated its capabilities.

The Starsem Company in the Globalstar and Cluster programs used the facilities for the Soyuz launch vehicle. In the framework of these programs there were 10 launches of Soyuz LV since 1999.

The Baikonur Spaceport is a component of the Baikonur Complex, which also includes an administrative center — the Baikonur town. The infrastructure of the Baikonur town includes more than 300 apartment buildings, six hotels, a hospital with 1600 beds, an inpatient clinic with 360 beds, and two out-patient clinics that handle 470 and 480 patients a day. The town has a whole series of educational institutions: more than 10 schools for general education, a branch of the Moscow Aviation Institute, a communications technical school, a medical school, and others.

The future prospects for Baikonur rest on technical modifications of the launch and technical complexes for Proton LV to support launches of Proton-M, including launches involving the Briz-M, DM-03 and KVRB upper stages; updating of the launch and technical complexes for Soyuz to support launching of Soyuz-2, including launches with the Fregat upper stage; reequipping the infrastructure of the Zenit launch complex for launching Zenit with its new control system; and developing of new work sites for preparing and testing spacecraft in the framework of the Russian Federal Space Program. See also **Launch Vehicles: Russian Federation**.

Plesetsk Spaceport

The Plesetsk Spaceport is located in the Arkhangelsk Oblast and has geographical coordinates of 63° North latitude and 41° East longitude. A schematic map of the complex is provided in Fig. 3. The total area of the complex is 1,762 km^2 (680 square miles). The Plesetsk Spaceport is used for launching spacecraft for scientific, social and economic, and defense purposes and also in the framework of international and commercial space programs. Plesetsk has six launch complexes with nine launch pads, six assembly-test areas, containing 37 technical complexes for assembly, testing, and preparation of launch vehicles and spacecraft; two fueling and decontamination stations; and a measurement complex with a computer center. The spaceport's infrastructure includes a well-developed network of power lines, whose total line extent is 152.4 km (95 miles), railroads and asphalt-concrete roads, a water and heat supply network, and the Pero airport. As the major site of space launch on Russian territory, the spaceport plays a key role in providing the country with independent and free access to space.

During Plesetsk's existence, approximately 1,500 launches of space rockets took place from there. This represents approximately 60% of all space rocket launches from Russian spaceports. In the 1980s, up to 60% of all space rockets were launched from Plesetsk. In the 1990s, the number of launches of space rockets decreased, and between 1996 and 1999, this was approximately 30%.

The role of the Plesetsk spaceport in implementing Russia's national space programs can be evaluated by the number of launches for each program. Thus, Plesetsk launched 35% spacecraft for the space observation program, 75% for communications and television broadcasting, more than 25% spacecraft for navigation, approximately 70% spacecraft for the remote Earth sensing program, approximately 60% spacecraft for the weather satellite program, and up to 70% for the scientific research program.

Plesetsk's participation in the implementation of national space programs has been associated with such projects as Kosmos, Molnia, Tsikada, Meteor, Okean, Foton, AUOS, and Prognoz. The international missions launched from Plesetsk include: MAS-1, Magion, Gelisat, Tubsat, Astrid, Faysat, COSPAS-SARSAT, and Bion. The history of the Plesetsk launch site as an official spaceport began with the rebuilding of the R7-1 ICMB launch facilities for Soyuz and Molniya launch vehicles (General Designer, B.P. Barmin) and with founding in 1964 of a spacecraft testing and launch administration.

On 17 March 1966, the first spacecraft, called Kosmos-112 was launched from launch pad No. 1 of the Angara facility. As the number and type of satellite launched in the Soviet Union increased, the process to build new launch and technical complexes continued at Plesetsk spaceport. The first standard launch complexes specially for Kosmos launch vehicles were developed and put into operation in the last half of the 1960s and in the

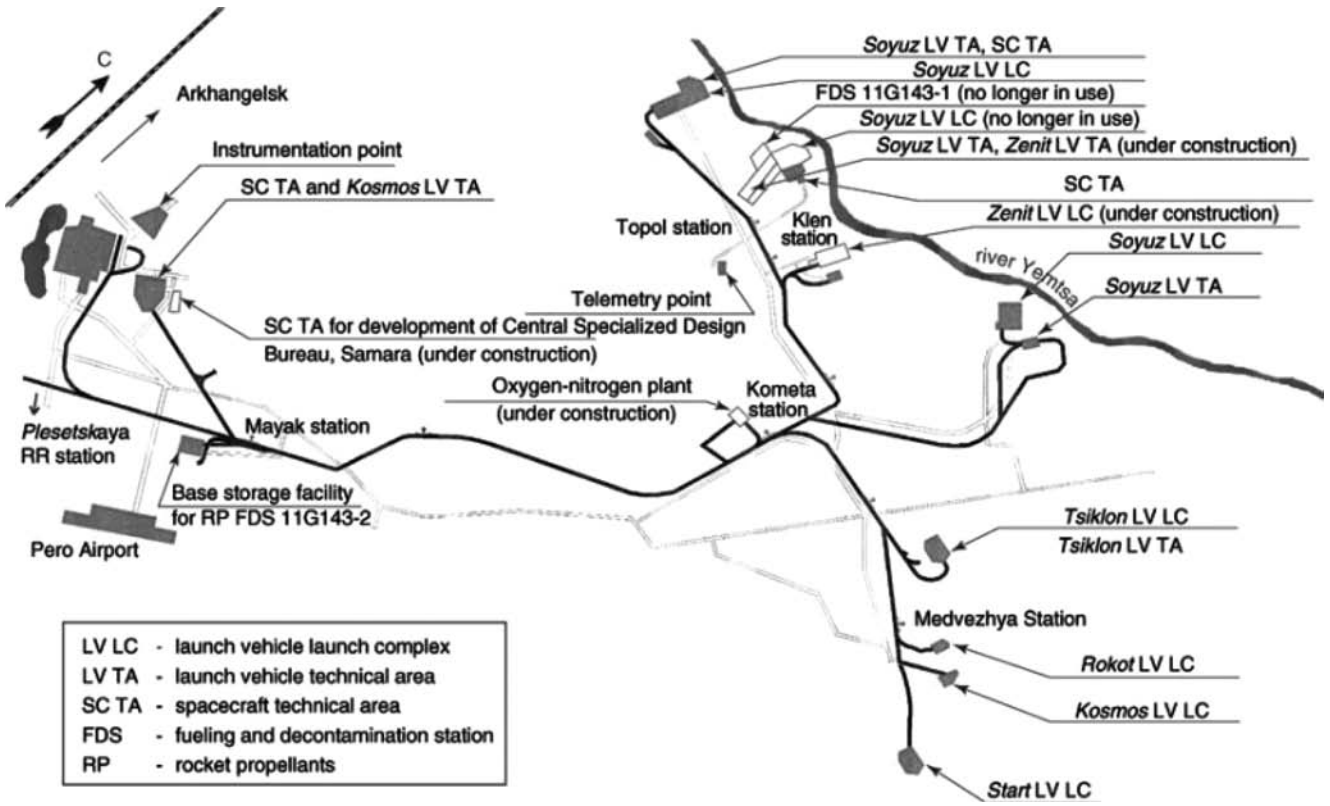

Fig. 3. Schematic map of the Plesetsk spaceport.

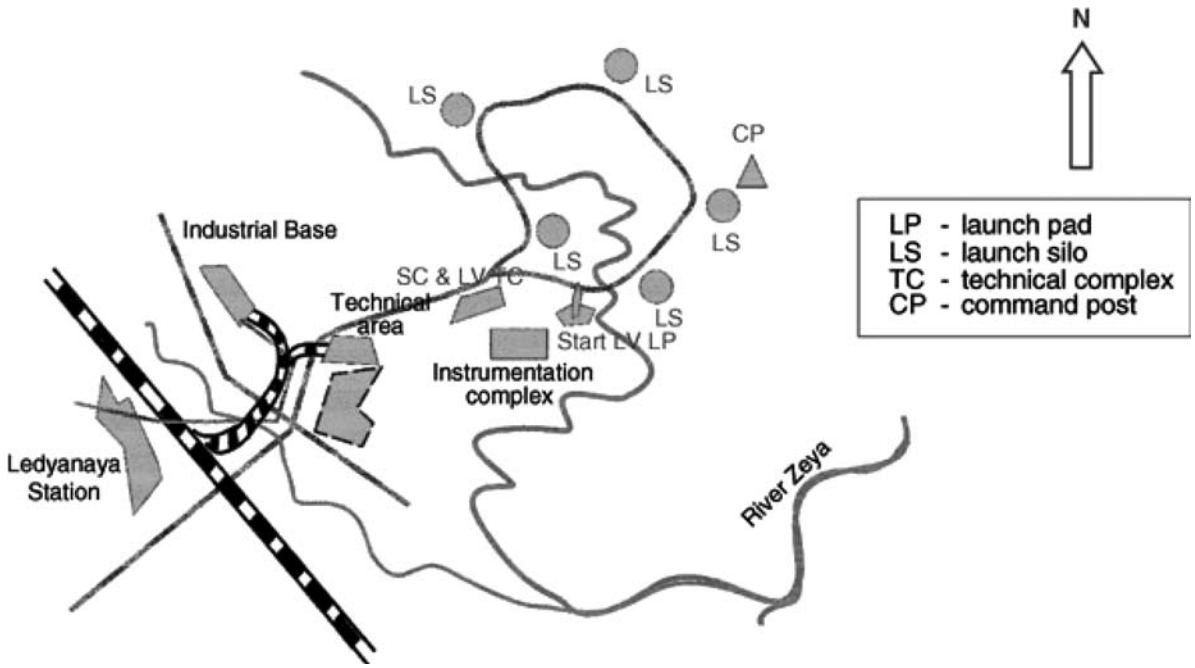

Fig. 4. Schematic map of the Svobodnyy spaceport.

early 1970s (Chief Designer, V.N. Solovyev). More than 450 space rockets were launched from these complexes. Now one of these was refitted to launch Rokot launch vehicles. In the 1970s, launch and technical facilities for the Tsiklon-3 vehicle were built and put into operation in 1980 at Plesetsk, and since then they have been used for hundreds of launches.

The need to improve existing space rocket complexes and develop new ones determine the future prospects for Plesetsk, including updating the launch and technical complex of the Soyuz vehicle to prepare and launch Soyuz-2, and the refitting of the Kosmos launch facility for Rokot LV, supporting measures to launch Start LV, development of a unified launch and technical complex to prepare and launch Angara light- and heavy-class vehicles, and development of technical complexes for future spacecraft.

Svobodnyy Spaceport

This spaceport is located in the Svobodnensk Region of the Amur Oblast in Khabarovskiy Kray on a site whose geographical coordinates are 51° North latitude and 128° East longitude. It was originally developed by the Soviet Union as a launch site for intercontinental ballistic missiles. Construction started in 1957 and it was declared operational for R-7 rockets in December 1959. The existence of Plesetsk Cosmodrome was originally kept secret, but it was discovered by British physics teacher Geoffrey Perry and his students, who carefully analyzed the orbit of the Cosmos 112 satellite in 1966 and deduced it had not been launched from Baikonur Cosmodrome.[1] After the end of the Cold War it was learned that the CIA had begun to suspect the existence of an ICBM launch site at Plesetsk in the late 1950s. The Soviet Union did not officially admit the existence of Plesetsk Cosmodrome until 1983.

A schematic map of the complex can be seen in Fig. 4. The total area of the spaceport is approximately 972 km^2 (375 square miles). The spaceport infrastructure includes technical complexes for launch vehicles and spacecraft, the launch facility (launch pad and temporary command post), the instrumentation stations along the launch azimuth, the communications and data transmission lines, motor roads and railroads, storage and support structures, and a living area. This infrastructure was built to launch spacecraft using the Start-1 launch vehicle. As of 1 January 2001 three spacecraft had been launched from Svobodnyy, including the Russian communications satellite Zeya (March 1997), the American Early Bird-1 (December 1997) and the Israeli EROS-A1 (December 2000). The spaceport has five launch silos developed for RS-18 missiles, which are to be refitted for Rokot and Strela launch vehicles. Technical complexes plan to be built for preparing spacecraft.

Plesetsk is used especially for military satellites placed into high inclination and polar orbits since the range for falling debris is clear to the north which is largely uninhabited arctic and polar terrain. It is situated in a region of taiga, or flat terrain with boreal pine forests. Plesetsk is Russia's equivalent to the U.S. Air Force's Vandenberg Air Force Base in California.

The use of the cosmodrome will likely increase in future since there are concerns with security in operating the Baikonur Cosmodrome in now-independent Kazakhstan, which also demands rent for its continued use. Plesetsk is not ideally suited for low inclination or geostationary launches because of its high latitude (as compared to the Kennedy Space Center, at around 28° north or Center Spatial Guyanais at Kourou, the ESA facility, which is at 5° north). In spite of this, the new all-Russian Angara rocket is designed to be launched primarily from Plesetsk when it comes into service.

Future Prospects for Development of Russian Spaceports

Future prospects for the general development of spaceports will be determined by their geographic location and their national ownership, the potential of existing launch vehicles and new improved vehicles in the future. The need to accomplish the required number of spacecraft launches, considering geopolitical and economic changes expected in the future, predetermined the use of Russian spaceports. Baikonur will be used for Russia's Federal Space Program and international and commercial space projects. Plesetsk is intended for launching spacecraft for defense, scientific, social and economic purposes, as well as for international and commercial space projects. Svobodnyy will be used for launching defense spacecraft and spacecraft for commercial space projects. Thus, Baikonur requires the implementation of measures to maintain its facilities in working order to prepare and launch spacecraft and updating of advanced launch and technical complexes taking into account future improvements of launch vehicles and spacecraft. Plesetsk requires, first of all, construction of a space rocket complex to support preparation and launch of Angara family vehicles, and improvement of the entire spaceport infrastructure. Svobodnyy needs to rebuild existing facilities and construct new ones considering the tasks that will be assigned to this spaceport.

Development of spaceports in the future will be directed at

- maintaining the high technical readiness and capacity of their infrastructure;

[1] The *New York Times* published his discovery shortly before Christmas in 1966.

- raising the level of automated processes involved in preparing and launching space rockets;
- standardizing facilities for preparing launch vehicles, upper stages and spacecraft, and launching rockets;
- ensuring high reliability and safety of work performed to prepare and launch rockets;
- decreasing environmental harmful impact and operational costs.

Russian Aviation and Space Agency, Russian Federation

SPACEPORTS: UNITED STATES. Orbital launch vehicle sites for satellites and interplanetary probes are called spaceports. The best known spaceports are **Cape Canaveral Air Station**, and the **Kennedy Space Center** in Florida, **Vandenberg Air Force Base** in California, **Baikonur** in Russia and **Kourou** in French Guiana. Spaceports are usually constructed as close to the equator as possible. Launching near Earth's equator allows rockets launching eastbound to receive extra velocity from Earth's rotation, allowing launch vehicles to potentially carry more payload.

A rocket launch site is built as far as possible away from major population centers in order to mitigate risk to bystanders should a rocket experience a catastrophic failure. In many cases a launch site is built close to major bodies of water to ensure that no components are shed over populated areas.

The Eastern Test Range (ETR) is the familiar designation of a group of bases, facilities, and installations that support space vehicle launches from Cape Canaveral Air Station (CCAS) and the Kennedy Space Center (KSC) and ballistic missile test launches from or near the Cape Canaveral Air Station. It is operated by the United States Air Force's 45th Space Wing, which provides services to itself as a launch agency as well as to the other Government and private agencies that use the launch bases at Cape Canaveral and KSC. The expression "familiar designation" is used because the current official designation of the Range is simply the Eastern Range (ER). However, the term "ETR" is probably used more frequently than "ER." The Kennedy Space Center is the popular name of the National Aeronautics and Space Administration (NASA) launch installation on Merritt Island as well as the name of the NASA center that manages and operates it. The formal designation of the center is the John F. Kennedy Space Center, NASA.

Eastern Test Range (ETR)

The ETR, or "The Range" as it is often called, extends from the Atlantic Coast of central Florida, including the well-known Cape Canaveral launch base and its Headquarters about 20 miles south at Patrick Air Force Base, southeast along the Bahamas, the West Indies, and on to Ascension Island in the South Atlantic Ocean. Recently, bases in Bermuda and Newfoundland have been added to support launches that have more northerly azimuths.

Patrick Air Force Base serves as the administrative center of the ETR and functions also as a data processing facility and as the location for some instrumentation such as radars and telemetry antennae that benefit from a different perspective of the vehicles in the early launch phase. Patrick also has an operating airfield that serves as a home base for both fixed-wing planes and helicopters supporting launches.

History. In 1946, after the end of World War II, a committee, established to determine the site of a long-range proving ground for missiles, chose Cape Canaveral, Florida, as the launch base. Actually, the Cape Canaveral site was the group's second choice. The preferred site was El Centro, California, whose range was down the Gulf of California along the coast of Baja California. This site had several advantages, including more predictable weather and the proximity to many of the American aerospace contractors. However, the government of Mexico refused to allow overflights of Baja California. Flight along the coasts of the Bahamas from Cape Canaveral was acceptable to the British government, which then controlled the Bahamas. A third candidate, in northern Washington State that had a range along the Aleutian Islands, was rejected for reasons of weather and remote location.

Cape Canaveral, even as a second choice, had many advantages, both technical and administrative. As shown in Fig. 1, the area was located on a promontory extending into the Atlantic Ocean and was not near any large population centers. It would allow launch over open water but still near enough to a number of islands that could support instrumentation for tracking the missiles.

In retrospect, the Cape Canaveral option proved exceptional in a way only visionaries at the time could have foreseen. When the Space Age dawned, the easterly launch azimuth presented the designers of space launch vehicle with an additional velocity contributed by the Earth's rotational velocity. El Centro whose launch azimuth was approximately south would not have had this advantage, and the Aleutian range that had a generally westerly azimuth would have had the penalty of having to provide additional velocity to compensate for the Earth's rotational velocity. A secondary advantage of Cape Canaveral was its lower latitude, a consideration that became important only after the advent of geosynchronous satellites. Of course, the eventual need for polar orbiting satellites would necessitate establishing a West Coast launch base that could safely accommodate southerly launch azimuths. Interestingly, when this need was recognized, the choice of such a base was not El Centro, but the area now known as Vandenberg Air Force Base in California.

The new range would be a joint project of the Air Force, the Army, and the Navy under the management of the Air Force. In the course of its history, there would be several changes of name, both of the Range itself and the military organizations managing it. The managing organizations included Advance Headquarters, Joint Long Range Proving Ground; Headquarters, Long Range Proving Ground Division; Headquarters, Air Force Missile Test Center (AFMTC); Headquarters, Air Force Eastern Test Range (AFETR); Detachment 1 SAMTEC, ETR; Headquarters, Eastern Space and Missile Center (ESMC); and finally in 1991, 45th Space Wing. The Installation would also undergo a number of different designations starting with Bahamas Long Range Proving Ground, Long Range Proving Ground, and proceeding through Florida Missile Test Range, Atlantic Missile Range, and Eastern Test Range to the present title of simply Eastern Range. There were good and sufficient reasons for the changing terminology, but the basic mission of the establishment remained substantially the same as always. Some variations were necessitated by the changes of clientele from aerodynamic missiles to ballistic missiles, and to the current situation where most of the customers are involved in launching spacecraft into Earth orbit.

After sufficient preliminary work had been accomplished, the new range was ready for its first launch, which, ironically, was not one of the aerodynamic missiles for which it had been designed. On 24 June 1950, a vehicle called Bumper, a two-stage vehicle consisting of a captured German V-2 as a first stage and a liquid propellant WAC Corporal as a second stage, was launched from Complex 3. See Fig. 2. The launch, historic though it was, was not a success; the vehicle was destroyed by Range Safety. Less than a week later, a second Bumper was launched but it was not a complete success. Although the launches did not meet their mission objectives, there were some positive results. The launch complex was validated, the tracking devices worked, and the capability of Range Safety to destroy a potentially dangerous missile was proven.

During the next several years, many different missile projects were launched and tested at the Cape. Early projects included Lark, Matador, Mace, Snark, Bomarc, and Navajo. The Eastern Range was also the launch

and test site for the Redstone, Jupiter, Thor, Polaris, Poseidon, Trident, Atlas, Titan, and Minuteman missile systems.

The coming of space vehicles was signaled by the selection of the Vanguard Earth Satellite Project which was intended to launch at least one instrumented satellite into Earth orbit as part of the U.S. contribution to the International Geophysical Year in 1957 and 1958. The Navy was selected to manage this program based partly on the Naval Research Laboratory's experience with the Viking sounding rocket and its associated scientific payloads. Although it was assigned to the Navy, it was an essentially civilian project that would not interfere with the Department of Defense military missile projects and did not carry the high priorities assigned to those projects. After the Soviet Union launched Sputniks 1 and 2 in October and November 1957, before Vanguard had attempted to launch a full-up vehicle, the Army was directed to proceed with preparations to launch a vehicle that would add a fourth stage to the Jupiter-C and attach to the stage a small scientific satellite. After the first Vanguard attempt to orbit a satellite failed in December 1957, the Army team launched the first U.S. satellite, Explorer 1, on 31 January 1958. Second attempts by both

Fig. 2. The Bumper V-2 was the first missile launched at Cape Canaveral on July 24, 1950. (*courtesy of NASA*).

the Vanguard and Jupiter-C teams failed in February and March, before the first Vanguard success, Vanguard 1, on 17 March 1958.

The creation of NASA in October 1958 added a new presence to the Range. Immediately, the only discernible difference was the transfer of the Vanguard Project to the new agency, but soon a NASA Atlantic Missile Range Operations Office (AMROO) was established to represent NASA interests at the Range. The new NASA projects leaned heavily on the military IRBMs and ICBMs. The Delta (sometimes called Thor-Delta) was a further adaptation of the Vanguard upper stages that had the Thor as a first stage and was designed to place a variety of scientific and applications payloads into Earth orbit. NASA used a new Air Force launch vehicle, called the Atlas Agena that used the Atlas as a first stage and a new hypergolic propellant upper stage called Agena for many of its early lunar and planetary missions. The versatile Agena was also used as the upper stage for the Thor and the Titan at Vandenberg Air Force Base, but only Atlas Agena vehicles were launched from the ETR. The capability of the Atlas to place payloads into orbit without an upper stage allowed using it in NASA's first manned space program, the well-known Mercury project. Interestingly, the early space launches followed the pattern of the aerodynamic missiles and the succeeding ballistic missiles in suffering many failures, either of the launch vehicle or of the payload after a successful launch, in the early days of spaceflight.

The next logical step in spaceflight, after demonstration of the achievability and usefulness of space as a scientific and applications medium, was the introduction of the human into the space arena as a part of the mission aloft, rather than as a ground-based operator. The first of these to impact the Range was Project Mercury, a program designed to demonstrate that humans could successfully operate in space and be safely returned to Earth. Seven suborbital flights of spacecraft without astronauts aboard were conducted using both the Redstone and the Atlas as launchers between September 1959 and March 1961. Two successful flights and one unsuccessful flight were flown aboard Atlas, and three successes and one failure were experienced with the Redstone. One suborbital launch, Mercury Redstone 2 (MR-2), carried as a passenger a chimpanzee nicknamed "Ham" and resulted in a successful flight and recovery on 31 January 1961, the third anniversary of the launching of Explorer 1.

The Mercury and Gemini Programs. On 5 May 1961, Astronaut Alan Shepard was launched on a Mercury Redstone 3 rocket (Fig. 3) to a range of 260 nautical miles with subsequent successful recovery of the pilot and the spacecraft Freedom 7. On 21 July of the same year, Astronaut Virgil Grissom made a similar flight aboard the spacecraft Liberty 7, (Fig. 4) although the spacecraft was not recovered.

Even before the Shepard and Grissom suborbital flights, an unsuccessful flight of an unmanned spacecraft on Mercury Atlas 3 occurred, followed by the successful flight of Mercury Atlas 4, also unmanned, on 13 September 1961. The next Mercury Atlas flight on 29 November 1961 carried the

chimpanzee called "Enos" into a planned three-orbit flight with successful deorbiting and recovery of both the passenger and the spacecraft, although the flight was shortened to two orbits because of some flight anomalies. The program was now ready for the manned orbital phase that consisted of four flights of increasing duration. All resulted in successful flights and recoveries, though not without some anomalies and difficulties.

Astronaut John Glenn became America's first man in orbit aboard Friendship 7 (Fig. 5) launched into a three-orbit mission and successful recovery on 20 February 1962 by Mercury Atlas 6. Astronaut Scott Carpenter in Aurora 7 followed on 24 May 1962 on another three-orbit mission marred by an overshoot of the intended landing area by several hundred miles. On October 3, Astronaut Walter Schirra in his Sigma 7 spacecraft flew a successful six-orbit flight with subsequent successful landing and recovery. The Mercury program concluded on 16 May 1963, when Astronaut Gordon Cooper in Faith 7 spacecraft splashed down safely after a flight of 22 orbits of the earth, 34 hours and 20 minutes after lifting off from Complex 14 aboard Mercury Atlas 9. See also **Spaceflight: U.S. Manned (Mercury, Gemini, Apollo, Skylab, Apollo-Soyuz Project and Space Shuttle Program)**.

The next step in the manned programs was the Gemini Project, which would demonstrate the capability to rendezvous and dock in space, as well as amassing more experience on manned flight to achieve longer time in orbit and at higher altitudes. The program, as indicated from its name (the name of the constellation Gemini translates to The Twins), would use a two-person spacecraft and an Agena stage, called the target vehicle, modified to achieve multiple restarts and equipped with a docking adapter, by which the Gemini and the target vehicle would be physically attached. The Gemini were boosted by a modified Titan II launch vehicle from Complex 19. The target vehicles were boosted by Atlas Agena vehicles launched from Complex 14, the same complex that was the site of the orbital Mercury launches. On 14 April 1964, less than a year after the last Mercury launch, Gemini 1, an unmanned spacecraft, was launched successfully into orbit. On 19 January 1965, a suborbital mission called Gemini 2 was also successful. Between March and August of that year, three manned flights were successfully carried out in which

Fig. 4. Astronaut Virgil I. Grissom climbs into "Liberty Bell 7" spacecraft the morning of July 21, 1961. Backup Astronaut John Glenn assists in the operation. The Mercury-Redstone 4(MR-4) successfully launched the Liberty Bell 7 at 7:20 am EST on July 21, 1961. MR-4 was the second in a series of successful U.S. manned suborbital flights. (courtesy of *NASA*).

the number of orbits was increased from three to 120 and the apogee was increased from 121 to 188 nautical miles. The next mission was to demonstrate actual rendezvous and docking with the target vehicle, but the Agena malfunctioned and did not achieve orbit. An alternate mission involving rendezvous of two Gemini spacecraft was substituted, and the program continued while the Agena problems were addressed and solved. The program, which ran through November 1966, ultimately achieved rendezvous on that mission and on five additional missions and achieved docking with the target vehicle on four. There were difficulties with the Gemini spacecraft itself on one mission and both the target vehicle and a substitute on another, but the final three missions were all successful in rendezvous and docking and included some extravehicular activity (EVA) on all three.

A total of 10 Gemini launches were flown from Complex 19 in 1965 and 1966, marking the beginning of sophisticated manned space flight (Fig. 6). Two of the largest and most advanced launch facilities built at Cape Canaveral Air Force Station by the National Aeronautics and Space Administration (NASA) were Launch Complexes 34 and 37. Here, the first of 15 launches of the Saturn space vehicle occurred on October 27, 1961. Launch Complex 34 was also the site of the January 27, 1967, fire that claimed the lives of astronauts Gus Grissom, Edward White and Roger Chaffe (Fig. 7). These complexes went on to launch the first series of the three-man Apollo space flights.

Fig. 6. NASA launched the Gemini 5 spacecraft, August 21, 1965 at 0900 EST on a planned eight-day mission from Complex 19. Astronaut Gordon Cooper was the Command Pilot and Charles Conrad the Pilot. This was the longest manned spaceflight at the time. (*courtesy of NASA*).

The Eastern Range Facilities

Cape Canaveral Air Station. The heart of the ER and its predecessors is, of course, the launching area itself; without it there would be no requirement for the remainder of the ER, but it would not carry out its mission without the rest of the ER. In its own history, it has undergone a number of name changes. Originally designated as Operating Sub-Division 1, it was redesignated as Cape Canaveral Auxiliary Air Force Base in 1951, Cape Canaveral Missile Test Annex in 1955, Cape Kennedy Air Force Station in 1964, Cape Canaveral Air Force Station in 1974, and Cape Canaveral Air Station (CCAS) in 1990. Throughout all of the nomenclature machinations, the basic mission did not change, and the area was familiarly known as "The Cape."

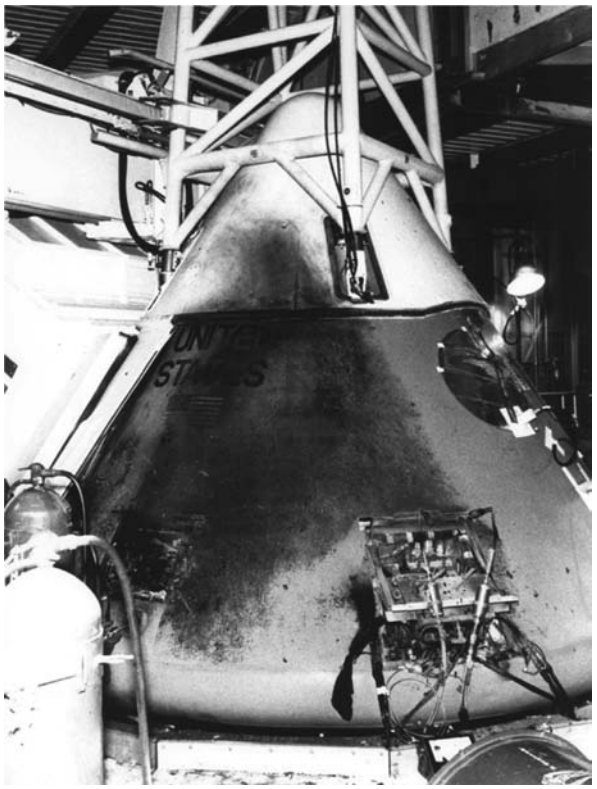

Fig. 7. This photograph shows Apollo 1's Command Module a day after the fire that took the lives of astronauts Lt. Col. Virgil "Gus" Ivan Grissom, Lt. Col. Edward Higgins White II, and Lt. Cdr. Roger Bruce Chaffee. The photograph was taken in the White Room at Launch Complex 34 where the Command Module was taken. The exterior effects of the intense heat of the flash fire can be seen. An investigative board was promptly set up to examine the accident and identify the cause of the fire. The final report gave the results of the investigation as well as detailed suggestions for major design and engineering modifications, revisions to test planning, manufacturing procedures, and quality control. With these adjustments, the Apollo program became safer and successfully sent astronauts to the Moon. (*courtesy of NASA*).

Launch Complexes. If the *raison d'être* for the ETR is the Cape, then the reason for the existence of the CCAS is the collection of the launch complexes located there. Typically, a launch complex consists of a launch pad, a service structure, an umbilical mast or structure, and a launch control center.

The launch pad is the platform on which the missile rests during launch preparations and from which it is actually launched. This platform contains a multiplicity of connections to the vehicle. Fluid connections and the necessary controls are included to load propellants into the vehicle and to unload in case of a launch delay or at the conclusion of a servicing or "tanking" test. Pneumatic connections are included to allow loading gases used as pressurants or in small control devices. There are also electrical connections that allow controlling vehicle functions remotely during launch preparations and instrumentation connections for monitoring the state of the vehicle and pad systems.

The service structure, variously and familiarly known as a gantry or a tower, gives workers access to the vehicle during launch preparations and can be of assistance in positioning and assembling the vehicle on the launch pad. Typically this structure has a number of platforms that allow circumferential and vertical access to the assembled vehicle. Necessarily, the service structure must be removed to a safe distance for the actual launch, so many of these platforms must either fold or retract to allow movement of the structure. Most service structures are mounted on railroad type wheels that allow movement to the retired positions on permanent tracks. Some projects have used service structures that can be rotated from the vertical to the horizontal to the vertical for assembling the vehicle, serve as a series of work platforms for prelaunch activities, and then rotate from the vertical to the horizontal before final launch preparations.

Some functions, which for reasons of accessibility cannot be routed through the launch platform, must be maintained even after the service structure has been retired or rotated away from the vehicle. These are typically accomplished by a connection on a mast that remains near the vehicle even after the service structure is withdrawn. These are generally referred to as "umbilical" masts or towers. The connections are severed either by movement of the vehicle at liftoff or by a mechanism on the mast itself, which senses liftoff and initiates disconnect. Originally, umbilical masts were rather flimsily constructed and had to be replaced after each launch. Recent improvement in materials and design have made possible permanent umbilical towers that require minimum refurbishment after each launch.

The launch control center, commonly called the blockhouse, was generally a heavily reinforced structure from which most prelaunch launch operations were supervised and from which the launch crew directed the actual launch. It provided a safe environment for the launch crew to direct operations during final launch and during other hazardous operations.

Other installations on a launch complex might include propellant tanks, both cryogenic, such as liquid oxygen and liquid hydrogen, which must be stored at high pressure to maintain the liquid state; so-called storable propellants, such as hydrazine and nitric acid, that can be kept at ambient temperatures: the necessary fluid lines and controls to load and unload the vehicle; and pressurant tanks that typically contain liquid or gaseous nitrogen for maintaining so-called blanket pressures in tankage when empty.

The following is a listing of the launch complexes at the Cape and a description of the projects which used them, some of the majors events associated with them, and their current status. Complexes were given numerical designations, 1, 2, 3, etc. Generally, if a complex has two launch pads they were designated A and B although there were some exceptions to this practice. Some complexes were planned but never built. This accounts for the fact that some numbers are not listed. Most of the complexes that are still active or play a noteworthy role other than for launching are mentioned specifically.

Complexes 1 and 2 were constructed for the Snark winged missile program and also supported some launches of the Matador, another aerodynamic missile. These complexes remained active until 1960.

Complexes 3 and 4 were designed to support the interceptor missile Bomarc. Complex 3, however, did support the Cape's first launches — those of the Bumpers in April 1950. It was later used by other projects, including the X-17 used to test reentry nose cones, some early Redstones, and some Polaris operations.

Complex 5 and Complex 6 were used for the Redstone project, an Army ballistic missile whose range was approximately 200 miles. There were two launch pads with a common blockhouse, and the facility was usually called Complex 5/6 or simply 56. The complex is best known as the site of all six Mercury Redstone missions, including that of America's first man in space, Alan Shepard, and the subsequent flight of Virgil (Gus) Grissom. It was also used for several early Explorer and Pioneer missions, including the first successful American lunar flyby mission by Pioneer 4 launched by a Juno 11 on 3 March 1959.

Complexes 9 and 10 were used for the long-range, rocket-booted, ram jet powered aerodynamic missile Navaho.

Complex 11 was used for the Atlas ICBM. It was also the site of the first orbital use of the Atlas. On 18 December 1958, almost the entire Atlas, minus jettisoned booster section, was placed into orbit as Project SCORE. The vehicle was equipped with communications equipment which was used to broadcast President Eisenhower's Christmas greeting to the world from space.

Complex 12 was used for the numerous Atlas ICBM launches and for two unsuccessful launches of multistage Atlas Able vehicles on projected lunar missions in 1960. NASA's flights of the Ranger Program, designed to take a series of television views of the Moon before impact, were launched from here as were several Mariner missions that flew by Venus and Mars. The first Orbiting Astronomical Observatory (OAO) and two Orbiting Geophysical Observatories (OGO) were launched from Complex 12. Some OGOs were launched from the Western Test Range into near circular polar orbits; they were nicknamed POGO for Polar Orbiting Geophysical Observatory to distinguish them from the ETR launched OGOs which were nicknamed EGO for Eccentric Orbiting Observatory. The first three Applications Technology Satellites were also launched from here.

Fig. 8. Complex 17, which is still active, is shown in the 1991 photograph, taken from the east. Note the Delta vehicle on the left pad, 17B. Even though the service structure surrounds the vehicle, the thrust augmenting boosters are visible. The wedge-shaped blockhouse is located at the intersection of the covered cable trenches running west from each pad (*USAF photo*).

Complex 13 was used by both the USAF and NASA for their Atlas Agena launches. The USAF launches were usually classified missions; NASA missions launched from Complex 13 included one OGO/EGO and five Lunar Orbiter missions that provided photographic coverage of most of the Moon's surface in support of the Apollo Program.

Complex 14 was used for the Atlas ICBM project and for the NASA Atlas Mercury Project. It was also used for an unsuccessful launch of a lunar mission by the Atlas Able vehicle in November 1959. The Atlas Agena target vehicles for the Gemini Program were launched from here.

Complexes 15 and 16 were used for the Titan ICBM program. Complex 16 was also used for the Pershing solid propellant missile.

Complex 17 was designed for the Thor Intermediate Range Ballistic Missile. It has also been used for the Thor-Able, Thor Able Star and Delta launches by the USAF, NASA, and Boeing (formerly McDonnell Douglas). The Boeing usage is for commercial and government contracted launches. Current vehicles still being launched at Complex 17 include both Delta 2 and Delta 3 vehicles. Complex 17 stands ahead of all other complexes on the Cape in the number of missile and space launches. From the first Thor launch in January 1957 through the end of 1998, the complex supported 276 launches. The number of first and spectacular missions is so large that only a few can be mentioned, with the obvious danger of omitting some equally outstanding in some opinions. From a technological point of view, the first restart of an upper stage flight in flight, that of the Able Star second stage on the launch of the Transit 1B Navy's navigation satellite on 13 April 1960, is important. TIROS 1 (for Television Infrared Observation Satellite), America's first weather observation satellite, was launched by a Thor Able on 1 April 1960. The active communications satellite Telestar 1, the world's first privately owned satellite was launched on a Delta on 10 July 1962. SYNCOMs 2 and 3 and Intelsat 1 are important milestones in the development of geosynchronous satellites. The Mars Pathfinder mission, with the Rover Sojourner, launched on 4 December 1996, is a more recent accomplishment. A 1991 aerial view of Complex 17 is shown in Fig. 8. This photo was taken from the east (Atlantic Ocean) side and shows the two service towers around two Delta vehicles being prepared for launch. The solid propellant strap-on motors are clearly visible on the vehicle on Pad 17B, to the viewer's left.

Complex 18, a two-pad complex, was built for the Thor IRBM program. When the Navy's Vanguard Earth Satellite project for the International Geophysical Year was established with a short lead time until its first launch in 1956, arrangements were made with the Air Force for the new program to share Complex 18. All 14 Vanguards were launched from Pad 18A, Thors were launched from 18B, and the blockhouse and other facilities were shared. The Air Force later used the complex for launches of the Blue Scout, a version of NASA's four-stage solid propellant launch vehicle.

Complexes 19 and 20 were built for the Titan ICBM projects. Complex 19 was also the launch site of the NASA Gemini two-person spacecraft. Complex 20 was modified to accommodate the Titan IIIA, which consisted of the two liquid stages of the upcoming heavy-lift IIIC space launch vehicle. Four successful launches of the Titan IIIA were successfully conducted by May 1965, after which the complex was deactivated.

Complexes 21 and 22 were built for the USAF Bull Goose decoy missile program and were also used by the Matador follow-on program called MACE.

Complexes 25 and 29 were built for the Navy's Fleet Ballistic Missile Program. Launches of Polaris, Poseidon, and Trident I took place here.

Complex 26, a two-pad complex, was built for the Army's Jupiter IBM and Army/NASA Juno space programs. It was the site of the launch of the first U.S. Earth satellite, Explorer I, on 31 January 1958. The successful flight and recovery of the two space monkeys, Able and Miss Baker began from Complex 26 on 29 May 1959. Complex 26 was declared a national historic landmark in 1964.

Complex 30 was a dual launch pad used for the Army's solid propellant Pershing missile program.

Complexes 31 and 32 were built for the USAF solid propellant multistage Minuteman ICBM. They included both surface and below ground (silo) launch capability.

Complexes 34 and 37 were built for NASA's Saturn 1 and 1B heavy-lift space vehicles. They were the sites of five vehicle development launches of these vehicles, some of which carried payloads as secondary objectives. Complex 34 was the site of two suborbital launches of Apollo hardware, as well as the launch Apollo 7, the first manned orbital flight in the program. It also has the unenviable distinction of being the site of the fatal spacecraft fire that took the lives of Astronauts Grissom, White, and Chaffee. Complex 37 saw the orbital launches of five unmanned tests of Apollo hardware. Complex 37 has been assigned to Boeing under the Air Force contract for its Evolved Expendable Launch Vehicle (EELV).

Complex 36, built for the Atlas Centaur space vehicle, has two pads, 36A and 36B. The first stage of the rocket is a modified Atlas, and the second stage (Centaur) is the first successful cryogenic (hydrogen/oxygen) upper stage. It has been used by NASA for a number of space launches, including lunar and planetary missions. It is still in regular use for USAF missions and by the Lockheed Martin Corporation (formerly General Dynamics) for commercial launches and for NASA contracted launches. The Surveyor soft landing missions to the Moon in the early 1960s; the interplanetary Pioneer 10 and 11 missions to Jupiter, Saturn, and eventually out of the solar system; Mariner missions to Mercury, Venus, and Mars, as well as a number of commercial and government communications satellites were among the many launches from Complex 36.

Complex 39 is at the Kennedy Space Center. It was designed for the Apollo program's Saturn V lunar launch vehicle and was also used for the Saturn 1B vehicles used in the Skylab and Apollo–Soyuz Test Program launches. It has been modified for Space Shuttle requirements and is still in regular use. It will be discussed further in the section of this article called The Kennedy Space Center.

Complexes 40 and 41 were built for the USAF's Titan IIIC space vehicle program; construction was completed in 1965. This approach, sometimes called ITL, for Integrate, Transfer, and Launch, was a new concept for the Cape. The core vehicle consisting of two Titan stages and upper stages were assembled and prepared in the Vertical Integration Building (VIB) on a platform on wheels that also served as the launch vehicle and launch umbilical tower. This part of the whole assembly was then transported by locomotives to the Solid Motor Assembly Building (SMAB) where the two large solid motor boosters, already checked out in the SMAB, were attached to the core. This assembly was further transported on the rails to the launch pad itself where the launch platform was secured in place. A service structure was provided at the pad to facilitate payload installation and final preparations for launch. The VIB was located several miles from both the SMAB and the launch pad, so it could be used as laboratory and office space without the personnel constraints of the traditional blockhouses or launch control centers. Complex 41 was modified to accept NASA's Centaur upper stage for the NASA Titan Centaur Viking Mars lander/orbiter program and Voyager outer planets

program and the joint Germany/US Helios solar research program in the 1970s. Complexes 40 and 41 have been further modified to accept the larger USAF Titan 4 vehicle that can accommodate either a Centaur upper stage or the solid propellant Inertial Upper Stage (IUS) or can accomplish certain missions without an upper stage above the Titan IV core vehicle. They are still used by the USAF for military missions and by Lockheed Martin for either commercial launches or for NASA spacecraft launches. Complex 41 will be used by Lockheed Martin under the Air Force contract for its Evolved Expendable Launch Vehicle (EELV) after the Air Force's need for the complex for Titan IV launches. Some other facilities in the ITL and elsewhere on the Cape have been assigned to either Lockheed Martin or to Boeing for their EELV programs.

Complex 46 was built between 1984 and 1986 to support the Navy's Trident II ballistic missile program. Between January 1987 and 1989, 19 Trident II launches were conducted from this complex. With no new Trident requirements for the complex forthcoming, Spaceport Florida Authority (SFA), with the aid of an Air Force grant, redesigned the complex to accommodate small commercial space launch operations. The completed complex has been used by Lockheed Martin for launches of variants of its Athena space launch vehicles for such missions as NASA's Lunar Prospector and the commercial/international ROCSAT for the Republic of China Satellite.

See also **Launch Vehicles: U.S. Expendable**.

Industrial Area and Missile Assembly Buildings (Hangers). The launch complexes are the heart of the launch base, but they could not exist without a myriad of other functions and facilities at Cape Canaveral. Many of the functions are provided in the Industrial Area, which is located a safe distance from the launch complexes. These include such prosaic things as cafeterias, dispensaries, office buildings, distribution of utilities such as water, electricity, communications and sewage, maintenance of roads and grounds, security, fire protection, and janitorial services to give a few examples. Less prosaic features of the Industrial Area are the Missile Assembly Buildings as well as spacecraft and space payload preparation buildings.

An obvious need exists for a facility to receive the launch vehicle from the factory, inspect and refurbish it, and prepare it for transfer to the launch complex for launch, as well as to store missiles not yet ready for flight or awaiting a pad assignment. These functions are accomplished in Missile Assembly Buildings commonly referred to simply as hangars. In the early hurry-up days of the missile programs, a standardized structure, essentially an aircraft hangar, was provided by the Range to incoming projects. The use of a standardized building expedited the availability of the hangars for the new projects which were typically operating under high priority and accelerated schedules. The typical hangar had an area of about 41,000 square feet. A high bay area with a number of cranes was included along with large sliding doors at both ends of the hangar. On each side of the high bay was a two-story concrete block structure. This could be used by the project for offices, guidance laboratories, telemetry and data labs, etc. The office and lab spaces were generally air conditioned because of the hot and moist coastal Florida climate; the high bay areas themselves were not air conditioned; environmental control for the high bay consisted of opening and closing the large doors.

Propellant Storage and Explosion Proof Areas. There are functions that are neither compatible with the industrial area nor is it feasible to locate them near the complexes where their work may be interrupted by launch activity. Such facilities include propellant storage areas and explosion proof areas. Those launch complexes using propellants such as RP-1, a kerosene-like substance used as a fuel in many launch vehicles; liquid oxygen, a cryogenic oxidizer used in conjunction with RP-1; liquid hydrogen, a cryogenic fuel used in some space vehicle stages; and other commodities such as liquid and gaseous nitrogen and liquid helium maintained storage vessels in the complexes for direct servicing of the vehicle during countdown. It is, however, the responsibility of the ETR to maintain sufficient quantities of these commodities to keep the storage tanks at operational levels. At one time, the ETR actually operated a LOX (familiar name for liquid oxygen) and LIN (familiar name for liquid nitrogen) manufacturing plant on Cape Canaveral. They are now supplied commercially, but the ETR is responsible for maintaining supplies and facilities to fill project needs.

Other projects use storable, that is, noncryogenic, liquid propellants sometimes as either the principal propellants for the missile stages or as the propellants for upper stages or spacecraft. The principal fuel of this type is a hydrazine variety, and the usual oxidizer is a form of nitric acid. For some projects, these propellants can be loaded into the vehicle well in advance of the actual launch countdown, so that there is no need for last minute loading capability at the complex as that for cryogenic propellants. Other projects prefer to load these propellants during the launch countdown and maintain on-pad facilities to maintain strict temperature control and to measure the load precisely. The ETR maintains storage facilities for the commodities and delivers them to the complexes as needed.

Solid propellant launch vehicles such as Minuteman and Pershing included storage facilities for these motors in their launch complexes. However, the need in space vehicles for solid propellant upper stages for actual spacecraft injection into orbit dictates that a facility for storing such motors be provided until the motors enter the actual processing flow which is normally when the solid motor is mated to the spacecraft. The use of solid propellant strap-on motors in the first stages of space launch vehicles to increase performance has resulted in the need for storage facilities for many such items until they enter the launch preparation flow. The ETR operates such storage facilities for the various Range users.

The advent of sophisticated satellites that have their own propulsion and controls system dictated the need for explosion proof areas where satellites could be fueled and their control systems serviced. Other such facilities accommodated the mating of a spacecraft to a solid propellant upper stage and sometimes a dynamic balancing of a spin-stabilized upper stage/satellite combination. Safety concerns dictated locating such facilities in relatively remote areas of the Cape.

Range Control Center. As the blockhouse or launch control center is the focal point for the actual launches, so is the Range Control Center the focal point for all of the functions that the ETR performs to support a project, as well as the center of its own mission of providing Range Safety. Here, all the information is gathered that is necessary for the ETR to ascertain that it is ready to perform its functions for a launch. Ground safety and security must verify that the launch danger area is clear; instrumentation coordinators must ascertain that the necessary radars, telemetry sites, and other instrumentation necessary for either the project requirements and safety monitoring are ready; and range safety officers must verify that there are no ships or aircraft in the prohibited areas and that the instrumentation required for the range safety function is operational. These operations are coordinated by such officials as the Superintendent of Range Operations (SRO), Range Control Officer (RCO), and the Range Safety Officer (RSO). In earlier days, this building was in the heart of the industrial area, but it has been replaced by a new facility near the south end of the Cape.

A historical footnote to the reporting of status by instrumentation sites involves the famous expression "AOK" which is now generally attributed to the manned space program. Actually, this term has been in use at least at the ETR for many years before the manned space programs. When asked for readiness to support over communications circuits from remote sites, the operators at the sites had a choice of three replies. AOK meant that the site was operational and that it would support its requirements. CNY meant that the site was not operational and did not expect to be operational for the operation: BEX meant that the site could not meet its requirements at the time of the report but that it anticipated that it would be operational by the time its support was scheduled. The use of three letters for each readiness condition was intended to assist in recognizing the status signal over potentially noisy communications circuits.

Skid Strip. The landing strip is another prominent feature of the Cape. It was built in the early 1950s for the Navaho X-10 test vehicle. It was used in the mid 1950s as a landing area for Snark missiles which might be reused after successfully landing. The Snarks were equipped with landing skids instead of wheels; hence the name skid strip. Originally a $10,000 \times 200$ foot configuration, it has since been widened to 300 feet, resurfaced, and expanded to include a taxiway and a parking apron. It is frequently used for cargo aircraft delivering launch vehicles and spacecraft to the launch site. The skid strip has also been used by passenger aircraft bringing distinguished visitors to the USAF and NASA areas for tours or for observing important launches.

Downrange and Tracking Stations. As early as 1954, the Eastern Test Range had three tracking sites equipped with tracking, telemetry, or

photographic instrumentation. There was launch coverage instrumentation at the launch site at Cape Canaveral, and there were additional stations at Jupiter Auxiliary Air Force Base south of Cape Canaveral on the Florida mainland and at Grand Bahama Island in the Bahamas. Additional stations usually called Auxiliary Air Force bases were soon added on the islands of Eleuthera, San Salvador, Mayaguana, and Grand Turk in the British West Indies; in the Dominican Republic on the island of Hispaniola, and at Mayaguez in Puerto Rico. A submarine cable was incrementally constructed connecting all of the stations and was completed in December 1956. Some instrumentation was also located at Patrick Air Force Base to afford different viewing angles than was possible from the Cape itself during the launch phase.

The distance covered by these stations (about 1,200 miles from the Cape to Mayaguez) was sufficient for the early programs. However, when the much longer range aerodynamic Snark and Navaho missile programs were approved, much longer distances had to be accommodated. Antigua and St. Lucia in the Lesser Antilles and Ascension Island, approximately 5,000 miles from the Cape in the South Atlantic, were selected, and negotiations with the British governments ensued. A fourth at Fernando de Noronha, an island off the coast of Brazil, was also selected, and an agreement with the Brazilian government was negotiated. Antigua, St. Lucia, and Ascension were operational in 1958, and Fernando, as it was usually called, became operational in the summer of 1958. Even with the additional range stations, there were areas, where air breathing vehicles at relatively low altitudes, could not be tracked by land-based instrumentation. As many as 12 small telemetry ships were positioned downrange to cover the gaps between the island-based instrumentation. As a matter of history, the ETR supported its first 5000-mile long mission (a Snark test flight) in October 1957.

Although the Snark and Navaho programs were the impetus for extending the range, the new Intermediate Range Ballistic Missiles (IRBMs) such as the Army's Jupiter and the Air Force's Thor, as well as the Intercontinental Range Ballistic Missile (ICBMs) such as the Atlas, Titan, and Minuteman programs, after a slow start, eventually became major range users. A few years later, the new space vehicles became the largest users in terms of launches, and the Navy's Trident program remains a major user. Ballistic missiles and space launch vehicles that have higher trajectories than aerodynamic missiles could be tracked continuously from fewer stations, allowing the phase out of some downrange stations as the workload shifted from aerodynamics to ballistic and space launches. There have also been some notable additions to "downrange." Additional ships that have more sophisticated instrumentation were added and subtracted as workloads varied. Instrumented aircraft were also added that operated from bases in South Africa and Mahe in the Indian Ocean.

The downrange stations were usually officially designated as Auxiliary Air Force Bases, but there was frequently only one military person on site, usually an Air Force Officer, who held the title of Base Commander and among whose many duties was dealing as United States Government official with the local authorities. In the early days of Range operations, there was a Base Manager, an employee of the Range contractor (for many years Pan American World Airways) who ran the day-to-day operations of the station except for the instrumentation. A person called the Instrumentation Manager was an employee of Pan Am's instrumentation subcontractor, the Radio Corporation of America (RCA) Service Company. Most of the personnel at a downrange station were either from the Air Force, Pan Am, or RCA, although indigenous personnel were employed where feasible. For simplicity, the terms Pan Am and RCA are used here rather than trying to trace the various contracting and subcontracting schemes used during the history of the Range.

Range Instrumentation. The Range used a variety of instrumentation in its host responsibility of providing data to the Range users and in its own responsibility of ensuring that the launched vehicles did not pose a hazard to life or property. Trajectory information for both purposes was principally obtained by radars that tracked a transponder or beacon in the vehicle. These radars were also capable of echo or skin tracking, but the use of airborne beacons improved both the range to which something could be tracked and the accuracy of the data. There were other tracking devices used ranging from very complicated systems to such simple devices as optical gunsights and wire sky screens for close tracking, but precision tracking radars were the principal means for obtaining trajectory data. Telemetry antennas of varying sophistication were another important asset provided by the Range.

Command/control as used today is principally a method of either terminating the thrust of an errant vehicle or initiating an airborne destruct package in a vehicle if it has malfunctioned. This is the common conception of command/control, but there have been launch vehicle projects which have used this system to operate some vehicle systems usually as a backup to an airborne system.

Range Support and Safety. The preparation and launch of missiles, space launch vehicles, and spacecraft are potentially dangerous, so each participant in the process has a serious responsibility for safe conduct of such operations. The vehicle or spacecraft manufacturer or contractor, as well as the sponsoring agency, typically have safety organizations, but the Range as host has the overall responsibility for operations conducted on its facilities. To carry out this responsibility, the Range requires of its tenants detailed information about such hazardous items as pressure vessels, pyrotechnic devices, radioactive sources, and propellants that are used.

In the exercise of its responsibility to ensure flight safety, the Range requires each project to equip its vehicles with devices to assist real-time tracking by the Range, explosive or other means to either stop propellant flow (cutoff) or actually to destroy the vehicle (destruct), and receivers in the vehicle to accept cutoff and destruct radio-frequency signals from the ground and transmit these received signals to the appropriate devices. In perhaps overly simple terms, the Range Safety Officer (RSO) is presented with a plotting board display or display that shows the actual trajectory as measured by a tracking radar, for instance, and the predicted instantaneous impact point of a vehicle if thrust were terminated at a given instant. These are overlaid on a prepared chart showing such things as the nominal trajectory, the estimated normal deviation from the nominal, lines showing what areas are to be protected, and lines showing how far from the protected areas pieces of a destroyed vehicle might travel because of such factors as their size and density or human reaction time.

The RSO is also presented with other data, such as telemetry, indicating the performance of the vehicle. If the RSO determines that a flight is performing unsafely or that it will violate destruct criteria, the RSO can send appropriate signals to the vehicle which, when received by the command receivers aboard, will initiate cutoff and/or destruct.

Meteorological support is another important service of the Range. Even relatively routine information such as temperature, precipitation, and winds becomes vital when certain operations are scheduled. For instance, hoisting a spacecraft to the top of a launch vehicle by a crane cannot be done in high winds. The safety function of the Range itself demands certain ceiling and visibility minimums to allow optical tracking and observation of a launched vehicle early in flight. Weather balloon data on weather aloft is provided to the projects to allow determining whether such things as wind velocity and shear might compromise their control systems. Lightning data and prediction is important to both ground tasks and to launch operations. Activities on launch complexes are understandably restricted during thunderstorms. It is also necessary to know the state of the atmosphere aloft before a launch, so that a rising vehicle would not trigger lightning as it passed through dangerous levels.

In addition to the support given to launches from the ETR and KSC, the Range is called upon to support launches from ships and from submarines in the Navy's Polaris, Poseidon, and Trident ballistic missile programs. Support has also been rendered to United Kingdom submarine launches. Airborne launches of the Air Force's Hound Dog air-to-ground missile were a frequent customer between 1959 and 1965. Seventy-seven Hound Dogs were launched from B-52 aircraft over the Range in that period. Support was also given to Skybolt, the proposed, but eventually canceled, successor to Hound Dog in the early 1960s. The Range has also given some support to the European Space Agency's Kourou launch site in French Guiana. Recently support has been given to the air-launched Pegasus space launch vehicle.

The Cape Canaveral Air Force Station, a National Historic Landmark, is located on Patrick Air Force Base in the Cocoa and Cocoa Beach vicinity on the east coast of Florida. The Air Force Space and Missile Museum is open to the public daily. Please call 321-853-9171, or visit the museum's website, https://www.patrick.af.mil/45sw/ccafs/museum.htm, *for further information. Visitors may also be interested in the nearby Canaveral*

National Seashore, http://www.nps.gov/cana/. *You can also download (in pdf) the Cape Canaveral Air Force Station National Historic Landmark nomination*. http://www.cr.nps.gov/nhl/themes/Scanned%20Nominations/Aviation/Cape%20Canaveral00.pdf.

John F. Kennedy Space Center (KSC). The Kennedy Space Center (KSC) consists of almost 84,000 acres and an additional area of about 56,000 acres of submerged, formerly state-owned land. The location of the Kennedy Space Center with respect to Cape Canaveral is shown in Fig. 1.

Like the Eastern Test Range, KSC has undergone changes of name in both of its definitions. Organizationally, it was originally the Launch Operations Directorate (LOD) of the Marshall Space Flight Center (MSFC) in Huntsville, Alabama. MSFC was created in December 1958 when the Development Operations Division, including the Missile Firing Laboratory at Cape Canaveral, of the Army Ballistic Missile Agency at Redstone Arsenal in Alabama was transferred to NASA. In July 1962, LOD was raised to the status of an independent NASA Center and became the Launch Operations Center (LOC). After President Kennedy's death in 1963, the name was changed to the John F. Kennedy Space Center, NASA. This is usually shortened to Kennedy Space Center, or simply KSC. As a physical entity, the area was originally called the Merritt Island Launch Area (MILA); that eventually also became the Kennedy Space Center.

There were other NASA elements operating in the Cape Canaveral area in this period. The Navy's Vanguard Project was transferred to the Beltsville Space Flight Center (soon renamed Goddard Space Flight Center) of NASA when that new agency was created on 1 October 1958. The Cape-based Vanguard Operations Group (VOG) became the Field Projects Branch of GSFC and later the Goddard Launch Operations Division, which eventually assumed launch responsibility for Delta, Atlas Agena, and Atlas Centaur launches at the Cape, as well as for Thor Agena launches at Vandenberg Air Force Base in California.

The coming of the Mercury program to the Cape brought a detachment of the Space Task Group to Florida to support the Mercury Redstone and Mercury Atlas launches. This group eventually became the Florida Operations Group of the new Manned Spacecraft Center (MSC) in Houston. This was later renamed the Lyndon B. Johnson Space Center (JSC). This Florida Operations Group was transferred to the Kennedy Space Center in December 1964 after the conclusion of the Mercury program and before the first manned launch in the Gemini program.

The Atlantic Missile Range Operations Office which had been the official conduit for NASA's support requirements to the Range and the Range's commitment to support NASA was disbanded, and its functions were taken over by KSC's NASA Test Support Office at Patrick Air Force Base. The consolidation of NASA launch elements in Florida under KSC was finalized in October 1965 when the Goddard Launch Operations Division was transferred to KSC and became the Unmanned Launch Operations Directorate.

The Apollo Program. The Apollo program was NASA's implementation of President Kennedy's declaration of 25 May 1961 that America "should commit itself to achieving the goal, before this decade is out, of landing a man on the Moon and returning him safely to the earth." At this time, there was no launch vehicle of sufficient power to do this, no spacecraft to take astronauts to the surface of the Moon and get them back to Earth, and no facility from which to launch the vehicle and spacecraft. The launch vehicle task fell largely to MSFC, and the spacecraft portion was assigned to MSC/JSC. The task of establishing a base for preparing and launching these elements clearly belonged to KSC.

Even though the launch vehicle, which would emerge as the Saturn V, had not been finally designed, it was clear that its size would preclude the possibility of using an existing Cape complex or of building a new complex on the Cape. A joint DOD/NASA task group pondered the question locating the launch base, and, after considering alternatives, including sites in Hawaii, Texas, California, Georgia, and islands in the Caribbean, selected Merritt Island. Other sites offered some appealing characteristics, but Merritt Island offered the opportunity to use many of the existing capabilities of the Atlantic Missile Range (AMR), and it allowed LOC/KSC to continue operating on the Cape at the same time as the Merritt Island Launch Area (MILA) was being built.

Complex 39 and the Vehicle Assembly Building. It was decided that the vehicle and its launch platform would be integrated vertically in a "hangar" on MILA to minimize time on the pad. The Apollo spacecraft elements would be checked out in the MILA industrial area and mated with the launch vehicle before the entire combination of launch vehicle, spacecraft, and launcher would be transported to the pad in the vertical position. There would be the capability of returning the combination to the hangar in case of weather or technical problems. The hangar, which would be larger than any existing one to accommodate the eventual 363-foot launch vehicle, is now known as the Vehicle Assembly Building (VAB). Its dimensions are 716 feet in length, 518 feet in width, and 526 feet in height. The VAB consisted of a high bay containing four bays or checkout cells, each large enough to accommodate a mobile launcher carrying a fully assembled space vehicle; a transfer aisle between the pairs of checkout cells; considerable office space, and a low bay for work on individual stages and components. A multiplicity of lifting devices as large as the two 250-ton bridge cranes with hook heights of 462 feet were included. Upward telescoping doors on each cell allowed access from and to the outside of the building. Only three of the high bay cells in the VAB were activated.

Operations in the VAB and at each of the two launch pads were controlled by personnel in the Launch Control Center (LCC) constructed to the southeast of the VAB. Not to be confused with most launch control centers or blockhouses on the Cape, this was a four-level building whose function was to check out the vehicle during preparations both in the VAB and at the launch pad. It was about three and a half miles from the pads, so it was not in the danger area and could provide support, such as offices, labs, data stations, and even a cafeteria, in addition to the actual control rooms called firing rooms. There were four of these firing rooms provided but, like the cells in the VAB, only three were fully equipped. A cable way and a personnel access corridor were provided between the third level of the LCC and the VAB.

The launch pads themselves were a major construction feat. Because the selected area was marshy, as was much of MILA, the entire pad had to be elevated with the bottom of the flame trench at ground level. Beneath the surface of the elevated pad were four floors containing terminal connection rooms, high-pressure gas systems, and emergency egress rooms for the astronaut crew and the pad close-out crew. A water system to cool the flame from the rocket engines was also there. Propellant storage tanks and other facilities similar, except in size, to Cape complexes for liquid fueled projects were also included within the pad perimeter. Pads 39A and 39B are essentially identical; several identical pads were planned at one time but were never built.

Essential to the mobile concept of operations were the mobile launchers, transportable steel structures that moved the Saturn V launch vehicles from the VAB to the launch pad. Three identical mobile launchers were built, each 445 feet tall and weighing 12,600,000 pounds when carrying an unfueled Apollo Saturn stack. The launcher consisted of a two-level base whose area is about a half acre and an umbilical tower capped by a 25-ton hammerhead crane. The bases contained a computer linked to counterparts in the firing rooms. The umbilical tower provided work platforms; swing arms that were disconnected automatically at liftoff; and distribution lines for propellant, pneumatic, electrical, and instrumentation functions. The highest swing arm, Number 9, 320 feet above the base connected with the Apollo spacecraft and was used by the astronauts to enter the command module. The base also provided hold-down arms that precluded motion of the vehicle after engine ignition until it was determined that all engines were operating satisfactorily. A rectangular opening in the launcher base allowed exhaust from the first stage engines to vent into a flame trench at the pad.

The launcher and the vehicle had to be moved from the VAB to the pad. After such concepts as barge transport, a rail system, and even pneumatic tired transporters and air cushion devices were considered and discarded, the choice was made of a crawler rolling on eight tracks that had a propulsion system similar to some used in strip mining. Two of these were procured. In addition to its transporting function, the crawlers could lift the entire stack to disengage it from the 22-foot pedestals in the VAB and lower it to similar pedestals at the pad after transport. The combined mass of the crawler, launcher, and unfueled Apollo Saturn was about 18 million pounds.

The highway for the crawlers to transverse with their burdens is the crawlerway, a two-lane road with a grass median to be straddled by

the crawler. This highway is not paved but constructed of materials that can bear the intended weight without permanent deformation. The actual surface is Alabama river rock that minimized friction on the crawler treads. About halfway between the VAB and Pad 39A, an extension of the crawlerway turns northeast and goes to PAD 39B.

Another major element was the Mobile Service Structure (MSS), a 410-foot, 10,500,000-pound structure designed to give 360° access to the space vehicle and outfitted with air conditioning, elevators, computers as well as television instrumentation, communications, and power systems. It was removed from the pad by the crawler about 7 hours before liftoff and placed at its park site along the crawlerway. It was mobile and was removed from the danger area before launch, so only one mobile service structure was built to service both pads.

The size of the Saturn V and Apollo components required a new look at delivering them to the launch site. Earlier programs delivered either by road or by transport aircraft. The first and second stages were transported by barge from MSFC in Huntsville, Alabama. The third stage, the instrument unit, and the Apollo spacecraft, were delivered in a specially modified aircraft, called the Guppy.

Air transported components landed at the Cape's Skid Strip and were transported overland to the VAB. The barge method required constructing, on MILA, a dock and turning basin near the VAB, inclusion of draw spans on bridges, constructing a lock between Port Canaveral on the Atlantic Ocean and the Banana River, and considerable dredging.

The KSC Industrial Area. In addition to the Complex 39A area, there was a need for an industrial area for much of the same purposes as the Cape industrial area. One important difference was that there were no hangars in the KSC industrial area; essentially all work on the vehicles themselves was done at Complex 39. There still remained the requirement for administration and data gathering facilities as well as for a Flight Crew Training Building and for a building to prepare the command, service, and lunar modules. The Operations and Checkout (O&C) Building, a multistoried structure with a high bay checkout area 100 feet high and 234 feet long and an adjacent low bay checkout area 251 feet long was constructed to fulfill this last requirement. Salient features in the high bay were two altitude chambers each 50 feet high and 30 meters in diameter, which allowed checking out the Apollo spacecraft in near vacuum. The O&C also had a large and more conventional portion separate from the checkout area but connected by above-ground access corridors. The north portion of the O&C contained offices, laboratories, a weather station, and astronaut quarters. The first NASA occupants of the KSC Industrial Area were members of the MSC's Florida Operations Group that moved much of its operation from Hangar S on the Cape to the O&C building in the fall of 1964, even before that group was part of KSC. Completion of other buildings in the industrial area, including the Headquarters Building, the Central Instrumentation Facility, a Training Auditorium and the Base Operations building, followed soon after.

Apollo Operations. Even while all this preparation for the eventual Moon landings was going on at KSC, work on the project was proceeding on the Cape at Complexes 34 and 37. Orbital launches of boiler plate or dummy Command and Service Modules (CSMs) were conducted as early as 1964 by Saturn 1 vehicles and continued through July 1965. Suborbital tests of CSMs were conducted using Saturn 1B vehicles in 1966. The success of all of these tests led up to preparations for the first manned launch of a CSM from Complex 34 using the Saturn 1B vehicle AS (for Apollo Saturn) 204 and CSM 012. The 27 January 1967 fire in the spacecraft during a simulated countdown took the lives of Astronauts Grissom, White, and Chaffee. Modifications of hardware and procedures were made, which culminated in a successful orbital launch of SA 205 carrying a redesigned CSM 101 with astronauts Schirra, Eisele, and Cunningham. This was the last manned launch from the Cape, and Complexes 34 and 37 were deactivated.

The history of the Apollo Program with its successes, especially the accomplishment of the first manned lunar landing within President Kennedy's schedule and its difficulties, including the disastrous AS-204 spacecraft fire and the harrowing flight of Apollo 13, is well known and is covered elsewhere. See also **Apollo Lunar Missions**. The launch of Apollo 11 on 16 July 1969, which culminated in the first manned lunar landing and successful return to Earth, is shown in Fig. 9 and 10.

Fig. 9. The Apollo 11 Command/Service Module (CSM) are being mated to the Saturn V Lunar Module Adapter. (*courtesy of NASA*).

Fig. 10. The Apollo 11 Saturn V space vehicle lifts off with astronauts Neil A. Armstrong, Michael Collins and Edwin E. Aldrin, Jr., at 9:32 a.m. EDT July 16, 1969, from Kennedy Space Center's Launch Complex 39A. (*courtesy of NASA*).

Skylab. The next challenge for KSC was Skylab, a program that would demonstrate that humans can exist in space for long periods and carry out useful scientific and applications tasks. The first launch would orbit the Skylab itself, and three succeeding launches would propel crews of three men to the orbiting workshop where they would transfer to Skylab and live and work there for periods increasing from 28 to 59 to 84 days,

before returning in their command and service modules. KSC facilities were modified for checkout of the workshop which replaced the Saturn third stage in the stack. The flights to the workshop did not require the power of the Saturn V; a Saturn 1B would suffice. At one time, it was planned to make these launches at Complex 37 on the Cape which had already supported the Apollo 7 manned launch in 1967. However, an ingenious plan to launch these missions (and the subsequent Apollo-Soyuz Test Program (ASTP) mission) from Complex 39 was devised and allowed deactivating Complex 37 years earlier than once planned at a considerable saving in money and manpower. See also **Space Stations**.

The solution was the construction of a steel pedestal, humorously called the "milk stool," 127 feet in height atop which the much shorter Saturn 1B would be placed on a mobile launcher allowing some of the Saturn V and Apollo access arms to be used. The mission concept called for the launch of Saturn V with the workshop on one day and the launch of the Saturn 1B with the first Skylab mission crew on the next. This of course required that launch crews at KSC would have to prepare two launch vehicles at the same time and operate two complexes simultaneously. Plans were made to do this, and KSC was ready to launch the crew on 15 May 1973, the day after the workshop was launched. The experience in rendezvous and docking first demonstrated in Gemini and used extensively in Apollo also came into play here, as did the requirement for relatively short launch windows to accomplish rendezvous and docking. However, serious problems arose with the workshop during ascent, and it was necessary to delay the Saturn 1B launch while personnel at MSFC and JSC worked on ways to salvage the mission. These were quickly accomplished, and the Saturn 1B with the first crew of three in their CSM was launched on 25 May 1973 on a 28-day mission.

Figure 11 shows the Skylab 2 stack atop the milk stool and mobile launcher on Pad 39B. The Mobile Service Structure, propelled by the crawler, is approaching the Saturn 1B vehicle. Skylab 3 was launched on 28 July on a 59-day flight. The program concluded with the third mission, launched on 16 November and splashdown occurred on 8 February 1974 after an 84-day flight.

Fig. 11. The Skylab vehicle on the "milk stool" on Pad 39B on 11 January 1971. The work stands on the Mobile Service Structure are clearly seen as it is propelled to the prelaunch position by the crawler (*NASA photo*).

Apollo-Soyuz Test Program. KSC then turned its attention to the Apollo–Soyuz Test Program (ASTP) which was a joint program between the Soviet Union and the United States for rendezvous and docking of a Soyuz, which would be launched first, (Fig. 12) and an Apollo CSM and joint flight of the two docked spacecraft. This called for using another Saturn 1B and Apollo CSM. Liftoff of the Apollo with three astronauts aboard took place on 15 July 1975 (Fig. 13). The U.S. portion of the successful mission was terminated by splashdown of the Apollo command module on 24 July 1975.

Fig. 12. The Soyuz spacecraft and launch vehicle are installed on the launch pad at the Baikonur complex in Kazakhstan. Baikonur is the world's largest space center. This launch was part of the Apollo-Soyuz Test Project (ASTP), a cooperative space mission between the United States and the USSR. The goals of ASTP were to test the ability of American and Soviet spacecraft to rendezvous and dock in space and to open the doors to possible international rescue missions and future collaboration on manned spaceflights. The Soyuz and Apollo crafts launched from Baikonur and the Kennedy Space Center respectively, on July 15, 1975. The two spacecraft successfully completed the rendezvous and docking on July 17th. While the Soyuz craft returned to Earth on July 21st, the Apollo craft stayed in space another 3 days, landing on July 24th in the Pacific Ocean. ASTP was a success, as not only did crews accomplish the rendezvous and docking, but they also performed in-flight intervehicular crew transfers and various scientific experiments. ASTP proved to be significant step toward improving international cooperation in space during the Cold War. (*courtesy of NASA*).

With the launch of ASTP, KSC entered a period of almost 8 years with no launches at Complex 39. Although there were no launches, it was a period of intense activity preparing the center for the Space Shuttle program.

Space Shuttle. The Space Shuttle program, which is described in detail elsewhere, featured a reusable Spacecraft called the Orbiter, boosted into space by three rocket engines in the Orbiter and by two large solid rocket boosters which would be jettisoned after burnout, recovered, and reused. After solid rocket separations, the Orbiter would continue on to orbit using its own engines which consumed liquid oxygen and liquid hydrogen from a huge external tank (ET) which would be jettisoned after engine burnout. The Orbiter would then continue to achieve the desired orbit by using its own onboard thrusters. After the mission was completed, the Orbiter would use thrusters to decelerate from orbital velocity and land like an airplane, although without any engines running. See also **Space Shuttle**.

The mobile launch concept was carried over to the Space Shuttle, so the mobile launcher crawlers, crawlerway VAB, LCC, and the two pads were destined to be used with the new program, even though some required considerable modification. Because the orbiters were to be reusable, a 15,000-foot landing strip, eventually called the Shuttle Landing Facility (SLF), was required. The Orbiters had to undergo considerable refurbishment after return to KSC, so a two-bay building called the

Fig. 13. The Apollo Soyuz Test Project Saturn IB launch vehicle thundered away from KSC's Launch Complex 39B at 3:50 p.m. Aboard the Apollo Command Module were ASTP Astronauts Thomas Stafford, Vance Brand and Donald Slayton. The astronauts will rendezvous and dock with a Soyuz spacecraft, launched this morning from the Baikonur launch facility in the Soviet Union, carrying Soviet cosmonauts Aleksey Leonov and Valerly Kubasov. (*courtesy of NASA*).

Orbiter Processing Facility (OPF) was needed for the refurbishment and for necessary modifications for the next mission, as well as for the initial preparations of each Orbiter as it came on line. Some payloads for Shuttle missions were installed in the OPF. Figure 14 shows the SLF, the VAB, the LCC, the OPF, and part of the crawlerway.

Fig. 14. An aerial view of the Launch Complex 39 area shows the Vehicle Assembly Building (center), with the Launch Control Center on its right. On the west side (lower end) are (left to right) the Orbiter Processing Facility, Process Control Center and Operations Support Building. Looking east (upper end) are Launch Pads 39A (right) and 39B (just above the VAB). The crawlerway stretches between the VAB and the launch pads toward the Atlantic Ocean, seen beyond them. At right is the turning basin where new external tanks are brought via ship. (*courtesy of NASA*).

An interesting change of nomenclature, emphasizing the Orbiter's reusability, had occurred with the advent of the Shuttle. Vehicles that were used only once, like the Delta, the Atlas Centaur, and the Titans, were now called "expendable," as opposed to the reusable Shuttle. See also **Launch Vehicles: U.S. Expendable**. Heretofore, all launch vehicles, even those used in the manned programs, were in fact expendable. Whether or not the fact that the terms "manned" and "unmanned" were now politically incorrect was involved in the name change is not clear. KSC, however, went to the extent of renaming its Unmanned Launch Operations Directorate the Expendable Launch Vehicles Directorate.

Modifications of the mobile launcher included removing the umbilical tower, reconfiguring the openings in the base to accommodate the different solid and liquid engine configurations, adding two tail service masts to handle connections between the launcher and the orbiter, and adding a hold-down/release mechanism to allow analyzing the liquid engine performance before igniting the solids. A number of modifications were made to the VAB; the most important was the modification of the low bay area to a checkout area for the solid rocket segments and nose cones to prepare them for stacking on the modified mobile launcher in the high bay cells.

The process of stacking started with transporting the mobile launcher into one of the high bay cells with the crawler. The two solid motors were then assembled segment by segment on the launcher. The external tank was then attached to the two solid motors. Last the Orbiter was rolled over to the VAB transfer aisle on its own landing gear, hoisted into position, and attached to the ET. After VAB operations were complete, the crawler returned and transported the entire stack of two SRBs, the ET, and the Orbiter to one of the two pads for final checkout and launch (Fig. 15 and 16). The fact that the SRBs were the basis of the stack, added to the presence of SRB segments in the VAB at almost all times, precluded the use of the office space in the VAB, as contrasted with the Apollo setup where ordnance was installed just before rollout.

Fig. 15. The Space Shuttle Discovery completes the final Earth-bound portion of its journey into space, leaving the Vehicle Assembly Building on the slow trip to Launch Pad 39B. (*courtesy of NASA*).

At the pads, the modifications included changes in the flame bucket to match the penetrations of the mobile launcher necessitated by the new motor configuration. A fixed service structure (FSS) mounted on the pad surface replaced the tower on the launchers. Among the features on the FSS are the Crew Access Arm, through which the crews enter and exit the Shuttle — ingress and egress in NASA parlance and the so called "Beanie Cap" which is positioned above the ET and draws off the vented gases from the cryogenic propellant tanks.

Attached to the FSS is the Rotating Service Structure (RSS) that rotates about a large hinge on the FSS allowing it to interface with the Orbiter

Fig. 16. Aerial view showing Space Shuttle Columbia at Launch Pad 39B following rollout from the Vehicle Assembly Building; Columbia is being prepared for Mission STS- 75. (*courtesy of NASA*).

Fig. 17. Takeoff of the 747 Shuttle Carrier Aircraft (SCA) with the Space Shuttle Columbia mated atop from Palmdale, California. (*courtesy of NASA*).

when required and to rotate to the retired position as launch approached. The RSS provides some protection from the elements for the Orbiter and, more importantly, contains a Payload Changeout Room (PCR) that allows access to the payload bay and allows installing payloads at the pad rather than in the OPF much earlier in the preparation process. Eventually, most users opted to install payloads at the pad, allowing for shorter times in the field for spacecraft crews and less unattended times for the spacecraft.

Modifications were also necessary to facilities away from Complex 39. The O&C building in the industrial area was modified to check out payloads that would be flown repetitively and that would usually be installed in the OPF. These payloads were sometimes called horizontally processed payloads. The most prominent of these was Spacelab, a facility that fits into the Shuttle payload bay and was built in Europe by the European Space Agency (ESA). Although final assembly and checkout of Spacelab before delivery to KSC was accomplished in Bremen in the Federal Republic of Germany, many of the components were manufactured in plants located in other ESA member countries.

An interesting product of the Shuttle era at KSC was the acquisition of a NASA "navy." As mentioned earlier, the solid rocket boosters were designed to be recovered, refurbished, and reused. After booster separation, parachutes were deployed, and the burnt out rockets descended to the ocean surface, where they would be located and towed back to a new dock behind Hangar AF on the Cape by two specially designed ships, the Liberty and Freedom leased by NASA. They were taken into the hangar, disassembled, and put into condition for rail shipment back to the factory for refurbishment for a subsequent flight.

Shuttle Operations at KSC. The first Orbiter named "Columbia" arrived at the KSC SLF on 24 March 1979. It had ridden piggyback from its California manufacturing plant atop a specially modified 747 aircraft called the Shuttle Carrier Aircraft (SCA). See Fig. 17. The two vehicles were then towed to another new KSC facility called the Mate/Demate Device (MDD) which was capable of lifting the Orbiter from the attach fittings on the 747 and, after the 747 had been moved away, of lowering it to the surface on its own landing gear. (The MDD can also reverse the process of lifting an Orbiter from the surface to the back of a 747, which has been done when Orbiters have been returned to the factory for major modifications and upgrades.) Columbia was then towed to the OPF to begin launch preparations. The other three original Orbiters were "Challenger," "Discovery," and "Atlantis," all named for ships famous for exploration. An earlier model with no engines was named "Enterprise" and was used for approach and landing tests at Edwards, for vibration tests at MSFC, and as a pathfinder for the new facilities at KSC. After the Challenger was destroyed, an additional Orbiter called "Endeavor" joined the fleet.

Columbia arrived at KSC with considerably more factory style work yet to be accomplished, mostly in the installation of the thermal protection tiles on areas of the Orbiter that would be susceptible to extreme heating during reentry. The original estimate was that about 25% of the approximately 31,000 tiles still needed installation. New tests that raised concern about the capability of many already installed tiles resulted in the removal of thousands of these tiles. This situation severely increased the amount of work to be done at KSC and resulted in substantial delays. Indeed, a second bay of the OPF was turned into a virtual production facility for tiles.

Meanwhile, other components were arriving at KSC. A pathfinder ET had arrived by barge in March. The flight ET arrived on 6 July 1979, and the first of the three Orbiter engines arrived on 10 July. The first solid rocket motor segments arrived in September.

The Orbiter finally was towed from the OPF to the transfer aisle of the VAB on 24 November 1980 after some twenty months in the OPF. In the VAB, it was mated to the ET and the SRBs already on the launch platform. See Fig. 18. On 29 December 1980, the crawler picked up the stack, and by evening the first Space Shuttle was on its launch pad, ready for preflight operations of the first shuttle mission, called STS-1 (for Space Transportation System). Unlike all other U.S. manned spaceflight programs, whose early launches were accomplished without a human crew, the first launch of Columbia was to be piloted by two astronauts. John Young, veteran of two Gemini flights and two Apollo flights, was the commander, and Robert Crippen, who had no previous space experience, was the pilot. On 12 April 1981, after a 20-second flight readiness firing on 20 February and an aborted countdown on 10 April, the first Space

Fig. 18. A vantage point high atop the Vehicle Assembly Building (VAB) shrinks the size and scale of the orbiter Columbia as it is rolled from the Orbiter Processing Facility to the VAB. During the working days it spends inside the huge building, Columbia will be mated to the external tank/twin solid rocket booster assembly, and then rolled out to Launch Pad 39A. In the VAB, the SPACEHAB Double Modules will be installed in the orbiter's payload bay and final launch preparations will get under way. (*courtesy of NASA*).

Shuttle lifted off on a mission of 2 days and 6 hours, terminated by a successful landing on a dry lake bed runway at Dryden Flight Research Center at Edwards Air Force Base in California.

A 300-man crew from KSC was stationed at Edwards to service the Orbiter and prepare it for return to KSC aboard the SCA two weeks later. An MDD like that at KSC had been constructed at Edwards for use in the Approach and Landing Test of the Enterprise and to facilitate delivery of the Orbiters from their relatively nearby production facilities in Palmdale.

On its first flight Columbia carried no payload *per se*. It did, however, carry extensive instrumentation called Development Flight Instrumentation (DFI) to measure the Orbiter's environment and performance. The second, third, and fourth flights of Columbia were primarily additional flight tests, but each of the STS-2 and STS-3 missions included a payload for NASA, and the STS-4 mission included a payload for the Air Force.

STS-5, using Columbia, was the first operational mission. It successfully carried into low Earth orbit two commercial communications satellites each with two solid motors, one for achieving a geosynchronous transfer orbit after being separated from the orbiter bay and a smaller one for circularizing the orbit to geostationary. The launch of STS-5 took place on 11 November 1982.

STS-6, the first flight of the second Orbiter, Challenger, carried a larger communications satellite and a different solid motor. It, too, was successful.

On the tenth STS flight, Challenger concluded another commercial spacecraft delivery mission, and the first Orbiter landed at the SLF on 11 February 1984. (The NASA nomenclature system for designating missions was changed starting with this mission, which was called STS 41-B, rather than STS-10.)

Mission 41-D, the twelfth mission, marked the introduction of the third Orbiter, Discovery, into the fleet on a 6-day satellite delivery flight launched on 30 August 1984. The fourth Orbiter, Atlantis, made its first flight in October 1985 carrying a Department of Defense payload as Mission STS 51-J, the twenty-first launch.

By the end of 1985, the STS had successfully accomplished 23 missions with a variety of mission objectives. The launch rate had increased with the addition of new Orbiters, from two in 1981, to three in 1982, to four in 1983, to five in 1984, and to nine in 1985. One successful mission had been flown in early January 1986, when disaster and tragedy struck the program with the destruction of Challenger soon after launch as Mission 51-L on 28 January 1986.

The Challenger loss, and the actions NASA took as a result, caused a significant hiatus in the launch of shuttles. The launch of Discovery on the STS-26 satellite delivery mission occurred more than 32 months later on 29 September 1988. (The nomenclature of missions had reverted to the former system.) By the time flights were resumed, several important policy changes had been made. No shuttle launches would be made at Vandenberg, commercial spacecraft would not be flown on shuttles, and no new DoD missions would be manifested on the Shuttle.

As a result, after resumption of flight, the launch rate did not continue to increase as had been planned, and the mark of nine per year has not been exceeded, even though an additional Orbiter, Endeavor, joined the fleet and made its first flight as STS-49 in September 1992. Parenthetically, the designation as STS-49 does not mean that it was the forty-ninth flight; STS numbers were now assigned with the manifesting of the mission, and the flights did not necessarily occur in that order. For instance, STS-28 was flown after STS-29 and STS-30, all in 1989.

Shuttle Payload Processing. The Shuttle would carry two principal kinds of payloads reusable and attached like Spacelab and deployable, typified by communications satellites. Even that distinction is not absolute because the deployables require cradles, erection devices, and separation systems which were not deployed but remained in the payload bay and had to be removed before the next flight.

In the beginnings of the Shuttle program, the term "cargo" was frequently used to describe the complement of experiments, satellites, attached payloads, and airborne equipment used to elevate and separate deployable payloads carried on a given Shuttle flight. A payload could be either a part of the cargo or, in the case of Spacelab, possibly the entire cargo. Gradually, as the program matured, this distinction between cargo and payload became blurred and though there are still references to cargo, the terms tend to be essentially interchangeable, and the term payload is more common.

Spacelab, a so-called attached payload, was installed in the cargo bay and remained there throughout the mission. It could be flown in either a manned or unmanned configuration. In the manned configuration, it consisted of a pressurized module outfitted with experiments and connected with the crew compartment of the Orbiter by a tunnel. Once the Orbiter and Spacelab were in orbit, the mission and payload specialists could enter the Spacelab through the tunnel and perform the planned experiments; similarly when the flight was nearly complete, the Spacelab crew secured the experiments, left through the tunnel, and went through deorbit, reentry, and landing in the crew compartment. The unmanned version consisted of a number of pallets containing experiments, which also stayed in the bay during flight, but which did not require hands-on attention. Any operation of the instruments could be accomplished from the aft flight deck of the Orbiter.

Most spacecraft that were intended to be deployed from the Orbiter are processed in some of the same facilities on KSC and on the Cape that had been used for the unmanned programs. One of these facilities, Building AO on Cape Canaveral, contains a large clean room that was used extensively to prepare planetary spacecraft. Most of these payloads were assembled into a cargo in the Vertical Processing Facility, a building that was originally constructed in 1964 as the Pyrotechnic Installation Building for Apollo spacecraft components. It had been previously used with the name Spacecraft Assembly and Encapsulation Facility 1 (SAEF-1) for planetary spacecraft and even housed the sterilization facility mandated to keep the Viking landers from contaminating Mars.

Payloads have historically been processed using two general philosophies. One is the host mode whereby the resident agency, usually the project providing the launch vehicle, provides facilities, services, and coordination functions with the Range and itself to a payload team that will be at the launch site for a relatively short time, sometimes called a launch campaign. The visiting project team will check out the payload for itself, depending on a coordinator and a team from the launch vehicle project, called the Launch Site Support Manager (LSSM) and the Launch Site Support Team (LSST), to see that its needs are fulfilled and, equally important, that it does not run afoul of Range and vehicle project rules and regulations, particularly in the area of safety. This host mode has been used by NASA's Unmanned Launch Operations Directorate (later renamed Expendable Vehicles Directorate) in the conduct of the Delta, Atlas Agena, Atlas Centaur, and Titan Centaur programs. It is appropriate for launch vehicle projects that launch a variety of spacecraft.

An alternate mode is more appropriate for a payload project that has a number of similar spacecraft. In this case, launch site personnel are delegated the task of performing the actual checkout, of course, subject to the requirements of the payload project. This method has been used on the Mercury, Gemini, and Apollo programs.

The Space Shuttle program has used both methods. Repetitive payload programs such as Spacelab were handled by resident NASA personnel. Generally deployable satellites that include a number of significantly different configurations are treated in the host mode. LSSMs were generally assigned in either case.

Payload processing was certainly not a new thing at either the Cape or at KSC, but the advent of the STS, its reusable delivery method, and the concept of reusable payloads brought about a new look to the process.

The International Space Station and KSC. The construction of the International Space Station (ISS) placed new requirements on KSC and resulted in the erection of a new facility at KSC, the Space Station Processing Facility (SSPF). The building contains processing bays, an airlock, control rooms, laboratories, logistics areas, office space, and a cafeteria. After the construction of the SSPF had begun, a decision was made to perform leak checks on pressurized modules of the International Space Station at KSC. One of the altitude chambers in the O&C building which had been used in the Apollo, Skylab, and ASTP programs was refurbished and turned over to ISS operators in 1999. These altitude chambers were deactivated after the ASTP mission in 1975, but they remained in the building unused because there was no requirement for them for Space Shuttle payloads and because removing them would have been very expensive and disruptive.

The new SSPF has been used for the prelaunch checkout of segments of the ISS and will continue to support the program with checkout of other segments of the ISS, experiments, and resupply items that will be transported on the Shuttle throughout the life of the ISS.

Accommodating the Public. The John F. Kennedy Space Center Multiple Property Submission is located on the east coast of Florida approximately midway between Jacksonville and Miami. The Kennedy Space Center Visitor Complex is open every day of the year (except Christmas Day and certain launch days) from 9:00 am to 5:30pm. For further information please call 321-449-4444 or visit www.kennedyspacecenter.com.

NASA has been aware of the requirement in its charter to keep the public informed of its activities. From its beginning, it has given the press information about and access to launches and other major events. In addition, KSC and other centers operate Visitors Centers, where the public is allowed to view exhibits and actual space hardware. These are normally located outside the gates in areas for which no credentials or passes are required. One of the features at the KSC Visitor Center is the Rocket Garden, which includes full size replicas (in some cases actual surplus flight hardware) of space launch vehicles of the past. A full size replica of a shuttle orbiter can be toured, and full scale exhibits of the external tank and the solid rocket boosters can be viewed. Also at KSC, there is the additional feature of bus tours throughout the center that allow the public, for a fee, to ride through the center and to some NASA sites on Cape Canaveral with the option of stopping at certain sites, such as the SSPF observation gallery, an observation tower from which one can see the entire Complex 39, and a Saturn V Apollo building devoted to Apollo, Skylab and ASTP. Within this building is actual Saturn V and Apollo hardware displayed horizontally with the stages and spacecraft elements separated. The KSC Visitor Center, which is operated by a concessionaire, consistently ranks among the top tourist attractions in Florida.

The Air Force, which faces a different set of security concerns, has also accommodated the public with its Air Force Space and Missile Museum. The museum is located within the boundaries of the Cape at deactivated Complex 26, the complex from which America's first Earth satellite was launched. The blockhouse is used for a display area, and many missiles and space vehicles are erected on the grounds in a Rocket Garden similar to its namesake at the KSC Visitor Center. It includes early ballistic and aerodynamic missiles in addition to some space launch vehicles. Admission is free, but operational and safety concerns limit visiting hours. Adjacent to the Air Force Museum is the deactivated Complex 5/6, the site of the Mercury Redstone launches. A Mercury Redstone and a Jupiter C are displayed in their gantries and can be viewed on drive-through tours of this facility.

Wallops Flight Facility

NASA Goddard Space Flight Center's Wallops Flight Facility, located on Virginia's Eastern Shore (Fig. 19). The complex allows for flight and rocket tests, and is associated with NASA's Goddard Center, located on three separate sites, and totaling 6,200 acres (25 km^2). Most of the facilities are at the Main Base, including a research airport with two runways, aircraft hangars, assembly buildings, tracking station antennas, and research labs.

Wallops Island houses the launch range, a battery of launch pads where over 14,000 launches have taken place since the opening of the installation in 1945. Many of the launches are sounding rockets, which are expendable data recording and measuring rockets, launched to study a specific aspect of the atmosphere or space. Wallops Mainland, located across from Wallops Island, has an array of tracking stations for satellites and rockets launched in the area.

Established in 1945 under NASA's predecessor, the National Advisory Committee for Aeronautics (NACA), Wallops is one of the oldest launch sites in the world. Our support of scientific research and orbital and suborbital payloads places us at the center of NASA's space and Earth sciences.

Built to conduct aeronautical research using rocket-propelled vehicles, Wallops launched its first rocket on July 4, 1945. Since then, we have fulfilled our mission with the launch of more than 14,000 rockets.

Over the years, our launch range has grown to include six launch pads, assembly facilities and state-of-the-art instrumentation. In addition, our mobile launch facilities enable our scientists and engineers to launch rockets around the world. The science dictates the launch site; we provide the expertise and instrumentation to launch, track, acquire data and recover the payload.

Wallops philosophy-then and now-is to provide a fast, low-cost and highly flexible response to meet the needs of America's aerospace technology community and science researchers. In addition to supporting NASA's bright stars-Project Mercury, Project Gemini, Project Apollo, and the Space Shuttle missions-we have a proud history of partnering with a diverse customer base to support and launch small projects that contribute significantly to Earth and space science.

Fig. 19. Located on Virginia's Eastern Shore, the Wallops Island Flight Facility shown in this aerial view began as an auxiliary flight research station associated with the Langley Aeronautical Laboratory in 1945. Its remote barrier-island location on the Atlantic coast made it ideal for testing aircraft models and launching small rockets. As the space program evolved, it became one of the agency's mainstays for launching sounding rockets carrying scientific experiments. In the 1980s, however, a proposal emerged to close Wallops as a way of reducing NASA's operating costs. Instead, NASA managers decided to incorporate the facility into the Goddard Space Flight Center because the latter already was closely linked with the facility because Goddard had a sounding rocket division that relied on Wallops for launch, range, tracking and data support. In 1982, Wallops Island Station became the Wallops Island Flight Facility managed under the "Suborbital Projects and Operations" directorate at Goddard. (*courtesy of NASA*).

History. 1945–1957: Pilotless Aircraft Research Station. For our first 12 years, Wallops helped provide a foundation for aerodynamic and heat transfer research. Our high-speed aeronautical launch site used rockets to propel unmanned aircraft models. This facility enabled researchers to overcome the limited capabilities offered by the wind tunnels of the day. See Figs. 20, and 21.

1958–1974: Wallops Station. 1958 marked the birth of NASA and the civilian space program. At Wallops, researchers developed components of the human space program, such as capsule escape techniques, maximum pressure tests and recovery systems. Wallops led the way in range support for research in re-entry and life-support systems, Scout launch vehicles and mobile research projects. See Fig. 22.

1957–1981: Wallops Flight Center. While continuing to act as a launch site for suborbital and orbital vehicles, Wallops expanded its horizons to include Earth studies of ocean processes and used our research airport for runway surface and aircraft noise reduction studies.

1982–1996: Wallops Flight Facility. After consolidating with the Goddard Space Flight Center in 1982, Wallops Flight Facility became NASA's primary facility for suborbital programs. Our customer base diversified to include more commercial users for our research airport, tracking facilities and launch range. We continued to support academic and government programs and projects using sounding rockets, balloons and scientific aircraft to facilitate research of the Earth, all regions of the atmosphere and the near-Earth and space environment. See Fig. 23.

1997–2005: Wallops Flight Facility. Wallops continues to meet the needs of the U.S. aerospace program. Our Mission 2005 Strategic Plan, part of NASA's reorganization for the next century, will keep us in the mainstream of NASA's mission. Our can-do philosophy and ability to support NASA-sponsored, commercial and academic projects will help ensure our stability and vitality.

Fig. 20. Technician Durwood Dereng prepares to pull the external-power plug from an E17 drag-research model at Wallops, September 8, 1950. (*courtesy of NASA*).

Fig. 21. Technician Durwood Dereng measures elevation of double Deacon booster prior to launch of RM-10 research model at Wallops, February 6, 1951. (*courtesy of NASA*).

Recognized as a role model for pioneering productive and innovative government, industry and academic partnerships, Wallops will continue to serve as a key facility for operational test, integration and certification of NASA and commercial next-generation, low-cost orbital launch technologies.

Fig. 22. Little Joe on launcher at Wallops Island. Little Joe was a major project for Langley. It was a test of the escape and recovery systems on the Mercury spacecraft. (*courtesy of NASA*).

Fig. 23. The four-stage Black Brandt shown here blasting off from a launch pad at the Wallops Island Flight Facility in rural Virginia is at 66 feet (20 meters), the tallest of NASA's 13 sounding rockets. These rockets can carry scientific payloads of various weights up to 1,213 lbs. (550 kg) to altitudes from 30 miles (48 km) to more than 800 miles (1,287 km). Researchers like to use sounding rockets because they offer an inexpensive means for conducting space, microgravity and Earth science research and have proven to be invaluable test beds for new technologies. The Wallops facility conducts about 35 launches per year. (*courtesy of NASA*).

Wallops Missions, Programs and Projects. Sounding Rocket. For over 40 years, the NASA Sounding Rocket Program (NSRP) has been one of the primary vehicles for space and earth science research. The program has provided important and often critical data to support the scientific community, NASA's orbital space programs, the Department of Defense, other Government agencies, and the international space community. NSRP's more than 2,500 missions have significantly added to our scientific knowledge in galactic astronomy, solar physics, planetary atmospheres, high-energy physics, and other disciplines. These low cost, quick response experiments remain vital to NASA's mission. http://www.wff.nasa.gov/code810/.

Scientific Balloons. Wallops launches an average of 25 scientific balloons each year. Balloons are launched routinely from the National Scientific Balloon Facility in Palestine, Texas and the Scientific Balloon Flight Facility in Ft. Sumner, New Mexico. Balloons also can be launched from temporary sites. In the past, balloon campaigns have been conducted from Canada, Australia, New Zealand, Antarctica, Alaska and Sweden. Balloons have been used for decades to conduct scientific studies. While the basics of ballooning have not changed, balloon size has increased and their dependability has improved greatly. The Wallops Flight Facility manages the NASA Balloon Program, which offers capabilities and benefits for scientific research that cannot be duplicated by other methods. http://www.wff.nasa.gov/code820/.

Aircraft. The Aircraft Office at Wallops provides for the operation, maintenance, configuration control, and mission support of assigned aircraft. The Aircraft Office has responsibility for 3 NASA-owned and operated aircraft, the Wallops Airport and the Agency Low Altitude Airborne Science Program. The NASA owned aircraft include the 4-engine turboprop, heavy-lift, P-3 Orion aircraft which supports LAASP; a 2-engine turboprop, 9-passenger Beechcraft-200 aircraft to support Agency mission management; and a currently un-sponsored, 4-engine turboprop, C-130 aircraft. The Aircraft Office enables scientific research by procuring and managing airborne assets to support NASA Earth Science Enterprise missions. The Aircraft Office currently has responsibility for the P-3, a commercial Twin Otter aircraft lease and is working with teams to develop low altitude UAV capabilities. http://www.wff.nasa.gov/code830/.

Range and Mission Management. The Range and Mission Management Office (RMMO) serves as the principal source of project management support for WFF flight projects and operations. In addition, RMMO is responsible for overall management of the WFF Test Range and mobile campaigns, including scheduling of resources, and coordination with external organizations such as other government agencies, commercial entities, and international organizations. RMMO manages the Wallops Test Range facilities, including operational areas supporting the research airport and the launch range. RMMO project managers provide high quality project management for all classes of flight projects and missions conducted by Wallops Flight Facility. Typical activities include formulation, design, implementation, and operational leadership of all mission areas. RMMO project managers are supported by safety, engineering, procurement, facilities and administrative support from multiple WFF organizations. Together, RMMO project teams deliver on the WFF promise to "Take science to new heights." http://www.wff.nasa.gov/code840/.

Educational Flight Projects Office. The Educational Flight Projects Office (EFPO) team members are "Explorers Inspiring Explorers". The goal is to provide hands-on flight experiences to students of all ages on all NASA carriers and to provide opportunities for students everywhere to become a part of the NASA team. http://www.wff.nasa.gov/efpo/.

Ground Network. The Ground Network (GN) Project is responsible for managing the development and operations of NASA's sub-orbital, low, and mid-earth orbiting spacecraft supporting ground systems. These systems provide spacecraft flight projects with tracking, telemetry and command services required to control and maintain spacecraft health and safety, as well as the science data collection interfaces required to achieve mission objectives. The GN Project manages the performance of systems planning, systems engineering, requirements analysis, design, implementation, integration, testing, and sustaining engineering of ground network services, including software, hardware, and security. http://scp.gsfc.nasa.gov/gn/.

The Western Flight Facilities

Vandenberg Air Force Base. Vandenberg Air Force Base which is often referred to by its workers as America's quiet launch site, is located at 34.7 degrees north latitude, at a spot on the rugged Central California coast in Santa Barbara County, where the shoreline runs east and west. Because of this unique geography, rockets launched from Vandenberg can fly nearly due south and not cross over land until they reach Antarctica. This is ideal for launches to polar orbit, because spent rocket stages or failed launches pose no threat to inhabited land. Vandenberg has therefore been the launch site for numerous reconnaissance and Earth observation satellites that require polar orbits. Vandenberg is headquarters for the 30th Space Wing. The 30th manages Department of Defense space and missile testing, and placing satellites into polar orbit from the West Coast, using expendable boosters (Delta II, Pegasus, Taurus, Minotaur, and Titan IV.) The wing is in a state of transition as it moves to the Evolved Expendable Launch Vehicles, the Atlas V and Delta IV. Wing personnel also support the Service's Minuteman III and Peacekeeper Intercontinental Ballistic Missile Force Development Evaluation programs. Future activities include operational missiles to provide missile defense for the western United States.

The 30th Space Wing is also home to the Western Launch and Test Range (WLTR). The WLTR begins at the coastal boundaries of Vandenberg and extends westward to the Marshall Islands, including sites in Hawaii on Oahu and Molokai. Operations involve dozens of federal and commercial interests.

The wing is organized into launch, operations, mission support and medical groups. The wing's staff agencies include chaplain, command post, comptroller, equal employment opportunity, Heritage Center, history, inspector general, manpower, military equal opportunity, plans and programs, protocol, public affairs, safety, site activation task force office, small and disadvantabed business office, staff judge advocate, and treaty inspections.

History. The spot where Vandenberg is located was occupied by Native Americans of the Chumash tribes before being acquired by Mexican ranchers and later white settlers in the 19th century. It was a sleepy, occasionally storm-battered, section of the coast northwest of the city of Santa Barbara used primarily for farming and cattle grazing. The primary large town was Lompoc (pronounced "lom-poke"), located inland from the sea protected from storms by a low mountain range. The only real excitement for the area for decades was the occasional shipwreck, culminating most dramatically with the beaching of seven U.S. Navy destroyers in 1923 at Honda Point. In World War II the U.S. Army needed to establish a new training facility and acquired a large swath of land north of Point Conception because it was isolated. The Pacific Rail Line ran up the coast and provided easy access to Los Angeles and San Francisco. The Army opened Camp Cooke in 1941 and used it to train infantry, tank crews, and other soldiers. Cooke was closed in 1945 and reopened in 1951 during the Korean War. It was then closed down again at the end of the war and the land rented to local farmers.

In 1956, a couple of Air Force officers assigned to the WS-117L reconnaissance satellite program flew to Cooke to check it out as a possible site to conduct operational training for ICBM launches as well as future reconnaissance satellite launches. Although the Atlas ICBM was going to be tested at Cape Canaveral, the head of the ballistic missile program, Brigadier General Bernard Schriever, wanted a facility closer to his headquarters in Los Angeles where Air Force crews could train to launch the missiles over the Pacific Ocean. Camp Cooke was perfect. The Air Force acquired the northern parts of the base, but the U.S. Navy acquired some territory as part of the Naval Missile Facility, Point Arguello (NMFPA).

Air Force personnel and civilian contractors quickly set about reopening many of Camp Cooke's old buildings, pulling boards from windows and chasing rattlesnakes from corners. They also began pouring concrete at several launch pads near the ocean. The first pad was originally Complex 75-3, but in 1966 was renamed Space Launch Complex 1 — abbreviated SLC-1 and referred to as "Slick 1." A launch complex usually consisted of a reinforced concrete blockhouse where the launch crew sat, one or more wooden buildings for tools and equipment, a bathroom and cafeteria for launch personnel, and usually two or more launch pads. (The SLC

designations will be used hereafter, although some of the pads originally had different designations.)

The first Thor intermediate range ballistic missile (IRBM) was launched from Vandenberg on December 23, 1958. See Fig. 24. It was successful and was followed a month later by the first attempted Discoverer launch, which was actually a cover for the CORONA spy satellite program. This launch attempt ended in a dud when a "sneak circuit" in the Agena upper stage nearly caused an explosion. The attempt was nicknamed "Discoverer Zero" by the launch crews who learned valuable lessons from the failure. A month later, on February 28, 1959, they tried again with another rocket and satellite named Discoverer 1. Discoverer 1 consisted of an Agena A upper stage fitted with instruments but no operational payload and mounted atop a Thor rocket. The initial launch was successful, but the satellite was never detected in orbit. The Air Force had already issued a press release calling the launch a success and therefore the service stuck to its story despite increasing doubt among those who worked on the project as to whether the spacecraft had ever reached orbit. Most of those involved in the launch now believe that Discoverer 1 fell on Antarctica.

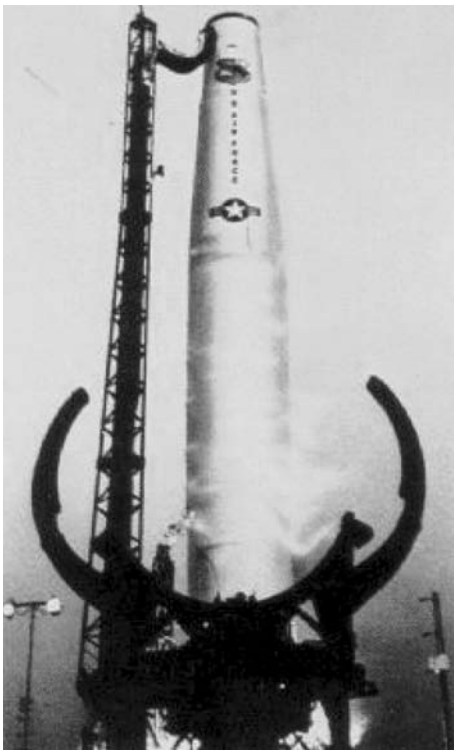

Fig. 24. The first Thor intermediate range ballistic missile- launch from Vandenberg AFB, December 16, 1958. (*USAF photo*).

In 1958, Cooke was formally renamed Vandenberg Air Force Base, after an early commander in chief of the Air Force, General Hoyt Vandenberg. The Air Force quickly built more Thor launch pads, SLC-2E (East) and SLC-2 W (West). Over the next few years it quickly began adding Atlas missile test and rocket launch pads as well as various Atlas silos. Each of these facilities had different requirements. Rocket launch pads were above ground and required equipment to keep the payload cool and provide electricity and payload monitoring. They had towers to run connections for fuel, electricity and air conditioning to the Agena upper stages and the payloads. Although extensive, many Vandenberg launch pads tended to be simpler and smaller than those built at Cape Canaveral, the country's primary launch site, located in Florida. In contrast to the rocket pads, the missile launch silos were underground and had no requirements to support the payload. They were used for operational training — a regular launch crew based around the United States would be selected to travel to Vandenberg to launch a missile out over the Pacific Ocean toward distant Kwajelein Atoll.

SLC-3 was the first Atlas launch complex and was the site of numerous launches of Samos spy satellites and later the KH-7 GAMBIT high-resolution satellites. SLC-4, which was also used for Atlas launches, was refurbished and in 1966 became the first Titan launch complex. Its two pads SLC-4 W and SLC-4E, were heavily used for launching KH-8 GAMBIT satellites. SLC-5 became operational in 1962 with the launch of its first Scout rocket. SLC-3 and 4 are still in operation, whereas SLC-5 was closed down in the mid 1990s. SLC-10, another Thor pad, was used to train Strategic Air Command anti-satellite missile teams and later became the site of numerous weather satellite launches. It is preserved as a National Historic Site.

Vandenberg also sprouted numerous additional support facilities, most notably Cooke Tracking Station, which is more popularly known on the base as Big Sky Ranch. Several other launch tracking facilities are also located on the base. The development of the Titan ICBM program led to the creation of numerous launch pads as well as silo complexes. The advent of the Minuteman ICBM program led to the development of a number of additional underground silos to the north of the main facility, an area known as North Base.

In 1964, the Naval Missile Facility, Point Arguello, became part of Vandenberg. Two years later the launch pads were renamed. Vandenberg was extremely busy during this time, with an average of two rocket or missile launches per week at its peak. At this time the Air Force also began to significantly expand the base by acquiring the Sudden Ranch to the south, where it began constructing its most notorious facility, SLC-6.

In 1972, Vandenberg was selected as the West Coast Space Shuttle launch and landing site. Space Launch Complex 6 (SLC-6, pronounced as "Slick Six"), originally built for the abandoned Manned Orbiting Laboratory project, was extensively modified for Shuttle operations. Over $100,000 were spent on the new space shuttle modifications. Two new flame ducts were added for the SRBs, and a payload changeout room, a payload preparation room, a new launch tower, and the Shuttle Assembly Building were added for it. SLC-6 was nearly ready for its first Shuttle launch, targeted for October 15, 1986 (STS-62A) when the *Challenger* disaster grounded the program and set in motion a chain of events that led to the cancellation of all West Coast Shuttle flights. It has since been rebuilt to support polar-orbit satellite launches by the new Delta IV (Heavy) launcher.

The West Coast operation would have contrasted with that at the Kennedy Space Center by creating the orbiter stack directly on the launch pad, rather than assembling it and then moving it — three movable buildings on rails would be used to assemble the Shuttle orbiter, external tank and SRBs. These buildings were designed to protect the cluster from high winds in the area.

Operations Group (30 OG). The 30th Operations Group (30 OG) commands and controls the Western Range and directs range resources in support of space launches, missile test launches and aeronautical and space surveillance operations. 30 OG also operates and maintains base communication systems and provides direct support for range operations, maintenance and modernization and sustainment efforts. To accomplish this nationally critical mission, the group relies on the combined efforts of our standardization/evaluation team and six diverse squadrons: 30th Operations Support Squadron, 30th Space Communications Squadron, 2 d Range Operations Squadron, 30th Range Management Squadron, 30th Weather Squadron and 76th Helicopter Squadron.

Launch Group (30 LCG). The 1st Air & Space Test Squadron has over 30 years of experience as a test organization for missile weapons systems and space launch vehicles.

1 ASTS is the ONLY full service Air Force Developmental Test and Evaluation organization for missiles, launch vehicles and payload/launch vehicle integration.

They specialize in the reuse of deactivated ICBMs for a variety of new missions, to include space and target launch. 1 ASTS was originated as the 6595th Missile Test Group under Air Force Materiel Command. In the early 1990s, the group was renamed as the Test Integration and Launch Division and came under the newly formed SMC/CU, a division of the Space and Missiles Systems Center in Los Angeles. In 1995, the division became part of SMC Det 9, at Vandenberg AFB, California. In December 2003, Det 9 became the 30th Launch Group and reorganized underneath the 30th Space Wing at Vandenberg, and Det 9 Test Integration and Launch Division (TEV) was renamed 1st Air and Space Test Squadron.

Initially, TEV provided for ballistic missile and reentry system test support. TEV gained an outstanding track record of test and evaluation

achievements in support of the DoD. Today 1ASTS also performs test and integration functions for experimental space systems, space launch vehicles, targets and interceptors (National and Theater Missile Defense).

The 4th Space Launch Squadron The 4th Space Launch Squadron (4 SLS) was activated 1 December 2003 to lead the Air Force's Evolved Expendable Launch Vehicle (EELV) program on the west coast. The squadron's Delta IV (Boeing) and Atlas V (Lockheed-Martin) launch vehicles provide the nation's sole medium/heavy lift capability to polar orbit. Insight into EELV operations enables the squadron's essential mission of providing continuous risk assessment and mission assurance for the 30th Space Wing and the Space and Missile Systems Center. The 4 SLS is a blended organization comprised of military, government civilians, and contractors working together to bring a vision to life... 100% mission success; one professional launch team defending the U.S. through assured access to space. See also **Launch Vehicles: U.S. Expendable**.

Mojave Spaceport. The Mojave Spaceport (IATA: MHV, ICAO: KMHV), also known as the Mojave Airport and Civilian Flight Test Center, is the first facility to be licensed in the United States for horizontal launches of reusable spacecraft. It was certified as a spaceport by the Federal Aviation Administration on June 17, 2004. It is favored for these purpose as, due to its proximity to the Edwards Air Force Base, the airspace is restriced from ground level to an unlimited height.

The Mojave airport is also known as a storage location for commercial airliners. Numerous large Boeing, McDonnell Douglas, Lockheed, and Airbus aircraft owned by major airlines are stored at Mojave. Some aircraft reach the end of their useful lifetime and are scrapped at Mojave, while others are refurbished and returned to active service. Not all the aircraft are in need of repair and some are only being stored for a short time.

Mojave Spaceport has been a test site for several teams in the Ansari X Prize.[1] Most notably; it is the test launch site for SpaceShipOne, developed by Scaled Composites, http://www.scaled.com/projects/tierone/, which conducted the first privately-funded human spaceflight on June 21, 2004. Other groups based at the Mojave Spaceport include XCOR Aerospace, http://www.xcor.com/, Orbital Sciences Corporation, http://www.orbital.com/, Interorbital Systems, http://www.interorbital.com/, and the now-defunct Rotary Rocket.

[1] The Ansari X Prize (formerly the X Prize) was a US$10,000,000 prize, offered by the X PRIZE Foundation, for the first non-government organization to launch a reusable manned spacecraft into space twice within two weeks. It was modelled after early 20th-century aviation prizes, and aimed to spur development of low-cost spaceflight. The prize was won on October 4, 2004, 47th anniversary of the Sputnik 1 launch, by the Tier One project using the experimental spaceplane SpaceShipOne.

The contest winner was to be the first team to launch a piloted spacecraft, carrying at least three crewmembers (or one human pilot and payload equivalent to two more), to an altitude of at least 100 kilometers (328,100 ft or 62.14 mi), and then repeat the feat using the same spacecraft within two weeks. Reaching orbit was not a goal, and so all the competitors aimed to make suborbital flights only. The spacecraft were permitted to land at the same site that they launched from. The 100 km target is the boundary of space as defined by the Fédération Aéronautique Internationale.

The two competitive flights were required to be made by the same vehicle. With the exception of propellant, no more than 10% of the vehicle could be replaced between flights; the rest of the vehicle must be reused. Even NASA's Space Shuttle falls short of this performance requirement, since it takes much more than two weeks to ready a given shuttle between flights. However, the space shuttle is an orbital, rather than sub-orbital spacecraft. The vehicle must be intact and theoretically reusable after the second flight, and the crew must return unharmed.

Altitudes achieved were measured by three separate systems. There was a flight recorder, referred to as the "gold box", carried on each competitive flight, and two separate radar systems were used. Official altitudes were determined by a compromise between the three systems.

Teams were forbidden to accept government funding for their efforts. Private sponsors were acceptable, however.

SPACE PROCESSING. The idea of processing materials in space originated at the NASA Marshall Space Flight Center (MSFC) during the Apollo program as the confluence of several different and essentially unrelated disciplines. Engineers responsible for propulsion systems needed to understand the behavior of liquids in tanks of orbiting stages. This led to the study of fluid mechanics in low gravity, where liquid behavior is dominated by interfacial forces. The need for welding and brazing in space was recognized for the eventual building of large space structures. Thermal designers considering the use of phase-change materials for thermal control of spacecraft were also interested in understanding how materials solidify in the virtual absence of gravity. A group of solid-state physicists, searching for new superconducting mechanisms, became interested in producing fine *in situ* dispersions of semiconductors in metals and performed the first low gravity monotectic alloy solidification experiments using the MSFC drop tower.

Because the residual accelerations resulting from atmospheric drag and gravity gradient effects in low earth orbit are typically on the order of 10^{-6} times earth-gravity, the term microgravity generally is used to describe this acceleration environment. Because by the mid-1990s the space shuttle had been operational for more than a decade, a large number of microgravity experiments were conducted on various flights. Several microgravity-emphasis missions, in which the shuttle was flown in an attitude that minimized acceleration disturbances, were also flown to accommodate experiments that were exceptionally sensitive to accelerations. The more academically oriented experiments designed to address fundamental issues of materials processing are sponsored by the NASA Office of Microgravity Science and Applications; experiments designed to address issues of more direct interest to industrial research are sponsored by the NASA Office of Space Access and Technology (formerly the Office of Commercial Programs).

Materials Experiments in Space

Protein Crystal Growth. By the mid-1990s, the protein crystal growth experiments produced the most spectacular results of all the space processing experiments. The importance of x-ray crystallography as a mechanism for determining three-dimensional structure of complex macromolecules has placed new demands on the ability to grow large (ca 0.5 mm on a side), highly ordered crystals of a vast variety of biological macromolecules in order to obtain high resolution x-ray diffraction

data. There are numerous difficulties encountered in attempts to grow macromolecular crystals of biological interest, and the ability to grow such crystals of sufficient size and quality has become an important step for advancement in this field. The difficulties encountered prompted some investigators to consider growing protein crystals in reduced gravity. The first protein growth experiment in reduced gravity was carried out in 1983 on Spacelab 1; crystals of lysozyme and β-galactosidase grew substantially larger in space than in ground control experiments.

The first U.S. protein crystal growth experiment under reasonably well-controlled conditions was carried out in September 1988 on a space transportation system (STS-26), the first shuttle flight after the Challenger accident. The γ-interferon sample and the porcine elastase sample grew much larger than the ground control samples. The isocitrate lyase sample grew as discrete prisms, whereas the ground control crystals always grew dendritically. Crystals of all three of these proteins exhibited significantly higher x-ray diffraction resolution than any produced on Earth. This was true even when some of the smaller space-grown crystals were compared with larger Earth-grown crystals.

Following STS-26, there have been many other attempts to grow a variety of protein crystals in space. Considered as a whole, these experiments have produced a mixed set of results. In some cases the space experiments yielded no crystals or produced crystals that were inferior to those grown on Earth. However, there have been a number of cases in which the space-grown crystals were larger and better ordered than the best ever grown on the Earth.

Solution Growth of Small-Molecule Crystals. At least some of the advantages obtained from growth of macromolecular crystals in microgravity appear to carry over to the growth of small-molecule crystals. Triglycine sulfate (TGS) crystals were grown from solution on Spacelab-3 and again on IML-1 using a novel cooled sting method. Supersaturation was maintained by extracting heat through the seed, which was mounted on a small heat pipe, and in turn was attached to a thermoelectric device. By growing under diffusion-controlled transport conditions, it was hoped it would be possible to avoid liquid–vapor inclusions. These inclusions are the most common types of defect in solution-grown crystals and are believed to be caused by unsteady growth conditions resulting from convective flows.

Typically, TGS crystals are grown on ⟨001⟩ oriented seeds, because growth on the ⟨010⟩ face tends to be nonuniform and multifaceted. However, in the absence of convection, growth on the ⟨001⟩ seeds on Spacelab-3 was mostly around the periphery of the seed. Therefore, seeds with a natural ⟨010⟩ face were cut from a polyhedral TGS crystal for the experiments on IML-1. The crystal was grown in space with a 4 °C undercooling, which produced a growth rate of 1.6 mm/d. Even though this is somewhat larger than typical growth rates (because of the limited time available) the quality of the space-grown crystal was extremely good. Growth was very uniform and the usual growth defects in the vicinity of the seed that form during the transition from dissolution to growth, known as ghost of the seed, were notably absent.

Vapor Crystal Growth. For materials that lend themselves to physical or chemical vapor transport, growth from the vapor offers some attractive alternatives to growth from the melt. Growth can take place at temperatures considerably lower than the melting point, thus avoiding some of the higher temperature problems associated with melt growth. Several crystal growth experiments on the shuttle have produced provocative results that are not at all understood, e.g., growth of unseeded GeSe crystals by physical vapor transport using an inert noble gas as a buffer in a closed tube on STS-7. In the ground control experiment, many small crystallites formed a crust inside the growth ampul at the cold end. The flight experiment produced dramatically different results; the crystals apparently nucleated away from the walls and grew as thin platelets that eventually became entwined with one another, forming a web that was loosely contained by the ampul. Even more striking was the appearance of the surfaces of the space-grown crystals. These were mirror-like and almost featureless, exhibiting only a few widely spaced growth terraces. By contrast, the crystallites in the ground control experiments conducted under identical thermal conditions had many pits and irregular closely spaced growth terraces.

Test of Dendritic Growth Models. The microgravity environment provides an excellent opportunity to carry out critical tests of fundamental theories of solidification without the complicating effects introduced by buoyancy-driven flows. This advantage was used to carry out a series of experiments to elucidate dendrite growth kinetics under well-characterized diffusion-controlled conditions in pure succinonitrile (SCN). Dendrite tip velocities were measured as a function of undercooling over a range from 0.05–1.5 K. Comparing these measurements with ground-based measurements, it was possible to show that effects of convection are more significant at the smaller undercoolings and are still important up to undercoolings as large as 1.3 K. Even in microgravity, a slight departure in the data was noted at the smallest undercooling, which was attributed to the residual acceleration of the spacecraft. These data also allow the determination of the scaling constant important in the selection of the dynamic operating state, which the present theories have been unable to provide.

Electrodeposition. Electrodeposition experiments in reduced gravity have produced some intriguing results. An early experiment on the German TEXUS rocket, using higher current densities than can normally be used on Earth, reported the deposition of amorphous Ni on Au substrates. In a series of experiments on the Consort Rocket, it was possible to repeat this result.

SPACE RADIATION. According to NASA's Critical Path Roadmap, (http://criticalpath.jsc.nasa.gov.) the most critical biomedical risks of space habitation are (*1* carcinogenesis caused by radiation, (*2*) loss of bone mass or density, (*3*) poor psychosocial adaptation, and (*4*) clinical manifestations of trauma or acute medical problems. Because of the unique problems and the potential long-term consequences, radiation is frequently considered the most serious of these for long-duration space missions, and cancer is the major risk followed by damage to the central nervous system. Radiative hazards in space have been discussed in depth by a Task Group of the National Research Council along with overall research strategies.

The term radiation in the present context refers specifically to directly and indirectly ionizing radiation, including X rays, gamma rays, neutrons, ions, and other somewhat esoteric particles such as muons and pions. Radiation is a natural part of our environment on the surface of Earth. We are constantly being bombarded with radiation from our own Sun and from outer space. In fact, X rays and gamma rays are part of the electromagnetic spectrum to which we are exposed daily that includes infrared radiation (heat), visible light, and ultraviolet radiation as well as higher energy X rays and gamma rays. Radioactive elements also are naturally present in essentially all of the materials that surround us as well as those of which we are composed. Biological organisms in general, and humans in particular, have adapted to the normal radiative environment at Earth's surface and certainly have even benefited from the radiation. At the same time, those radiations also initiate biological damage ranging from sunburn to cancer. Earth's atmosphere and its magnetic field act as excellent radiative shields by reducing the levels of radiation. As we go farther away from Earth's surface into orbit or toward outer space, the radiative level generally increases in intensity and changes in the types and energies of the radiation. It is known that the radiative dose rates for personnel in space are significantly higher than on Earth's surface. We have had little experience with regard to the biological consequences of healthy people exposed to these types of radiation for protracted periods of time. Our best estimates indicate, however, that the additional exposure

to higher energy radiation beyond that on Earth's surface or above the present allowable limits for radiation workers could result in significant risks of cancer or other serious diseases. See also **Radiation**.

Because of higher level of exposures and the potential for long-term negative consequences, radiation has been categorized as the worst biomedical risk of long-duration space missions. At the same time, using an appropriate programmatic strategy and focused research, the risks of radiation in space should be reduced to levels comparable to or less than those of other hazards.

Radiative Fields

Individuals in orbit around Earth or on space missions are subjected to three major sources of radiation: (*1*) particles trapped in Earth's magnetic field, (*2*) radiation emanating from solar events, and (*3*) galactic cosmic rays. Each of these radiative fields has unique distributions of particle types and energies at fluence rates (number of particles per unit area) of varying intensity, but generally higher than those at Earth's surface.

Solar Events. The Sun, operating largely as a result of nuclear fusion, is the major source of energy in our solar system. Although the rate of energy from the Sun is relatively constant, anomalous activities arise locally and stochastically, and these events can be major sources of radiation, especially higher energy protons. Figure 1 shows distributions of protons emanating from an exceptionally intense solar event as a function of time and the energy of the protons. Note that the fluence was delivered during an extended period of several hours. These protons can penetrate significantly and can produce substantial biological damage if left unchecked. They have, however, relatively low energies, so appropriate shielding can significantly reduce the doses and, presumably, the biological consequences. Additionally, although the occurrence of a specific solar event is somewhat stochastic, the number of such occurrences per unit time is cyclic, and the period is about 11 years. So the cyclic nature of solar events is something that may be used to minimize exposure. However, the fluence rate of galactic cosmic rays actually decreases during maximum solar activity, so the best scenario for minimum exposure is not necessarily during solar minimum.

Galactic Cosmic Rays. Galactic cosmic rays generally originate from activities within our galaxy during millions of years. As a group, these particles have the most energetic radiation and, therefore, are the most penetrating and the most difficult to shield. They consist primarily of protons and, to a lesser amount, helium ions; only a small fraction of ions has higher atomic numbers. The probability per logarithmic interval in kinetic energy per nucleon, $kEf(E)$, as a function of the kinetic energy E for four ions is given in Figure 2. These particles have the highest energies of space radiation and have modal values of about 1 GeV (1 GeV is 10^9 electron volts, where an electron volt is the energy gained by one electron accelerating through a potential of one volt). The energetic ions with atomic numbers greater than that of helium are frequently called HZEs, i.e., heavy ions (H) with high atomic numbers (Z) and high energy (E).

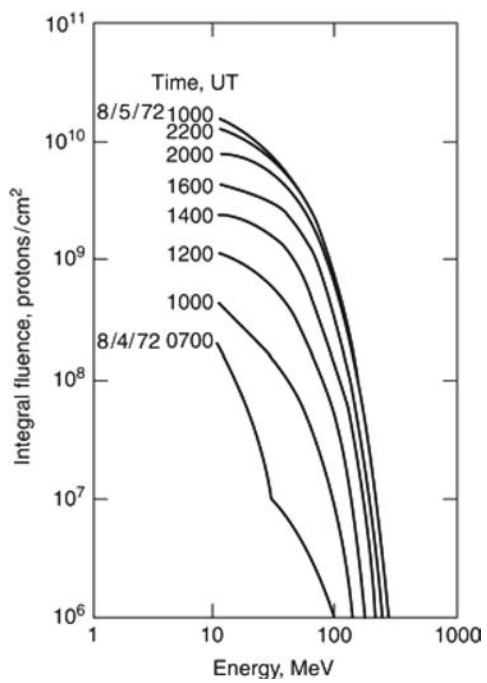

Fig. 1. The proton fluence as a function of time and energy of a solar event in August 1972 (*courtesy of National Council on Radiation Protection and Measurements*).

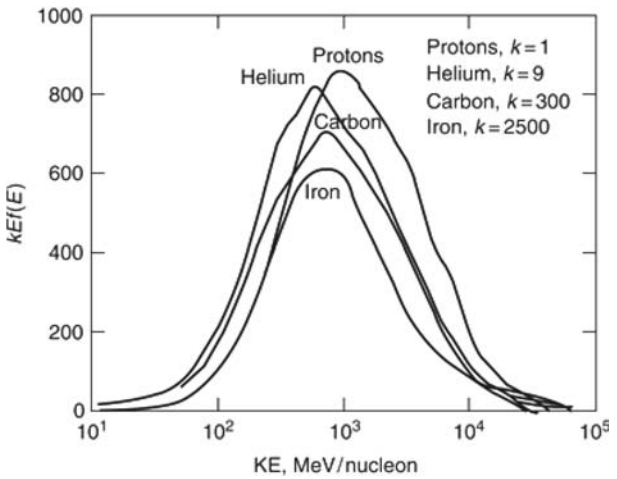

Fig. 2. The differential probability per logarithmic interval in kinetic energy per nucleon, $kEf(E)$, as a function of the kinetic energy E for four ions. $f(E)$ is the linear differential probability for a particle of kinetic energy E. k is the scaling factor given in the legend. In this representation, the area under the curve between two values of E is proportional to the number of particles in that interval (courtesy of National Council on Radiation Protection and Measurements).

Radiation on the Moon and on Mars

The radiative levels on the surfaces of both the Moon and Mars are reduced by their partial directional shielding and, in the case of Mars, the shielding provided by the Martian atmosphere. In both cases, the radiative fields are expected to be between those observed on Earth's surface, where its thickest atmosphere and greatest mass are, and those of deep space. It is estimated that radiative doses on the Moon are about half as intense as those in outer space. The same estimates for the Martian surface are significantly lower than in free space or on the surface of the Moon. Although higher than at Earth's surface, they could be within acceptable ranges for radiation workers, especially if the existing regolith were used for shielding.

Estimation of Doses from Radiation

During the last two decades, our knowledge of the types of individual particles present in the different radiative fields to which astronauts are likely to be exposed and their variation in time has improved considerably as a result of dedicated research efforts throughout the world. Concurrently, data to determine the doses to which the astronauts would be exposed were also obtained. The net result is that estimates of exposure levels are significantly more accurate, compared with earlier values, as are the corresponding doses for likely situations in space.

Terminology. The dose D is the energy deposited by radiation per unit mass of the absorbing medium [1 joule/kg = 1 gray (Gy) or 100 ergs/g = 1 rad]. It is sometimes called physical dose or absorbed dose to differentiate this quantity from other related quantities such as dose equivalent.

The relative biological effectiveness (RBE) is the ratio of the dose from a reference radiation, usually X or gamma rays (γ), to the dose from the radiation being studied to produce the same level of biological response ($\text{RBE} = D_{\text{reference}}/D_{\text{studied}}$).

In health physics, the term radiative quality Q is used for risk assessments and to establish the relative risk from different types of radiation or different energies. The unit for radiative quality is sieverts per gray (Sv/Gy). Analogous to the RBE, Q is a factor by which the physical dose is multiplied to obtain the dose equivalent to that of the

reference radiation, usually X or gamma rays. The RBE is generally used as a research quantity to express relative effectiveness, whereas radiative quality is more often used in a regulatory manner for risk assessments.

The dose equivalent D_{EQ}, then, is product of the physical dose and the quality factor for a specific type of radiation ($D_{EQ} = Q_F D$). Thus, it is the dose of the reference radiation which produces the same level of risk as the actual physical dose. The units are sieverts (Sv). The definition of dose equivalent intrinsically assumes that the physical properties of the dose D and the biological properties of the radiative quality Q are independent and multiplicative. Therefore, the relationship, further assumes that dose equivalent is linear with dose. None of these assumptions is necessarily true, and, therefore, Q is a function of dose, irradiative time, and other parameters.

Differences in biological response or risk of diseases for the same absorbed dose arise in part because particles of different energies, charge, or mass deposit energy differently as they traverse a given path length through the material. To quantify those differences, we define linear energy transfer (LET or L) as the energy lost by the particle per unit path length (MeV/m or keV/μm).

Dose and linear energy transfer are macroscopic quantities in the thermodynamic sense and, as such, apply only to large masses in equilibrium conditions. Many relevant biological processes take place at the cellular or molecular level. For these conditions, quantities such as dose or LET should not be applied because major errors result in some cases when this is inappropriately done. An entire field known as microdosimetry describes these microscopic and submicroscopic quantities and processes. To describe the stochastic process analogous to the macroscopic quantity LET defined in the previous paragraph and to differentiate between the macroscopic and microscopic processes, we define the quantity lineal energy y as the microscopic energy deposited per unit path length in units of keV/μm.

Doses from Environmental Sources. Radiation is an intrinsic and natural part of our environment. Radiation from the Sun is the major source of energy for Earth and has many positive consequences. At the same time, this same energy can produce undesirable consequences ranging from sunburn to cancer. Nevertheless, because we generally assume that average levels of exposure from natural sources are acceptable, these levels represent a good baseline for comparison. Table 1 lists typical sources of radiation and their contributions to exposures of the U.S. population, at a total dose equivalent of about 0.4 cSv. The actual dose is a strong function of elevation and location and can easily vary from this value by factors of two or more. Naturally occurring radon gases account for more than half of the dose equivalents, and cosmic radiation and other natural sources account for about a quarter of the dose equivalent. Medical applications and other man-made sources account for less than 20% of typical exposures.

TABLE 1. RECOMMENDED LIMITS ON DOSE EQUIVALENT

	ICRP	NCRP
Occupational		
Annual	5 cSv[a]	5 cSv
Lifetime (cSv)	—	Age[b]
Emergency	10 cSv	10 cSv
Public		
Annual (continuous)	0.1 cSv	0.1 cSv
Annual (occasional)	0.5 cSv	0.5 cSv

[a] 1 cSv = 100 crem = 1 rem.
[b] Age in years. (Reprinted (or adapted) from NCRP Report (or Commetary) No. 132, copyright year (1999), with permission from the National Council on Radiation Protection and Measurements).

Because the annual dose from natural sources hovers at about 0.3 cSv, it is not coincidental that the recommended upper limits for dose equivalents to the general public are typically between 0.5 and 0.1 cSv. Recommendations of two major institutions, the National Council on Radiation Protection and Measurements (NCRP) mentioned earlier and the International Commission on Radiation Protection are compared in Table 2. Occupational limits are generally allowed to be about a factor of 10 higher than those for the general population based on the strong stipulation that exposures should be kept *as low as* reasonably achievable, known as ALARA.

TABLE 2. ANNUAL EFFECTIVE DOSE EQUIVALENT[a]

Source	Persons exposed	Avg. annual dose equiv., cSv	Avg. annual dose equiv.In US pop., cSv[a]

[a] 1 cSv = 100 crem = 1 rem

Most of our data for medical complications that result from exposures to radiation higher than the natural background come from either medical diagnostics or treatments, accidental exposures, or observations of survivors of nuclear explosions. Several decades of work have gone into medical evaluations and analyses of these latter individuals, and these data form the major source of information about risks from environmental exposures. These data must be used with care, particularly in space applications, because the atomic bomb exposures were acute exposures of a specific population under extreme conditions. Other human results along with animal and cell studies have been used to extend these results to estimate risks for humans in space (see Table 3). Two excellent reports by the National Council on Radiation Protection and Measurements go into details of both the analyses and the application to radiative protection in space. For the present discussion, the most important single quantity for comparative purposes is the overall risk per unit dose equivalent. The value, even of that quantity, varies with gender, age, and biological end point. Generally, cancer is considered the single most likely risk from radiation exposures in space. The overall probability that an individual will develop cancer in the United States is 1 in 2 for males and about 1 in 3 for females. Typically, the risk factor in adults for fatal cancer from radiative exposure is about $4 \times 10^{-2}\,\mathrm{Sv}^{-1}$ (7, p. 137). Therefore, the recommended upper limits correspond to a fractional increase of a few percent in lifetime risk of fatal cancer.

TABLE 3. ESTIMATED DOSES FOR SPACE ACTIVITIES

Scenario	Radiation	Time	Dose, cSv[a,b]
Sea level	Various sources	1 yr	~0.4
Low Earth orbit	H+	90 d	~11
Med. Earth orbit	H+, e^-, HZE	90 d	~7
High Earth orbit	e^-, HZE	90 d	~7
Geo. Earth orbit	e^-, HZE	15 d	~8
Lunar mission	H+, e^-, HZE	88 d	~7
Mars mission	H+, e^-, HZE	3 yr	~100

[a] 1 cSv = 100 crem = 1 rem
[b] Does not include any dose from solar events

Doses and Dose Equivalents for Orbital and Interplanetary Missions. Two important aspects of the assessment of risks from radiation in space remain to be considered: the exposure levels from radiative fields in space and the corresponding risks from those exposures. To address the first issue, measured values of D_{eq} for previous space flights are plotted in Fig. 3. Except for the Apollo missions, these represent relatively short orbital missions compared with either the international space-station or interplanetary missions. Except for the geosynchronous Earth orbit, all of the scenarios result in dose equivalents in the neighborhood of roughly 0.1 cSv per day.

Estimates of True Risk and Associated Uncertainties. As the radiative fields in space environments have continued to be characterized with increasing certainty during the last two decades, we have been able to

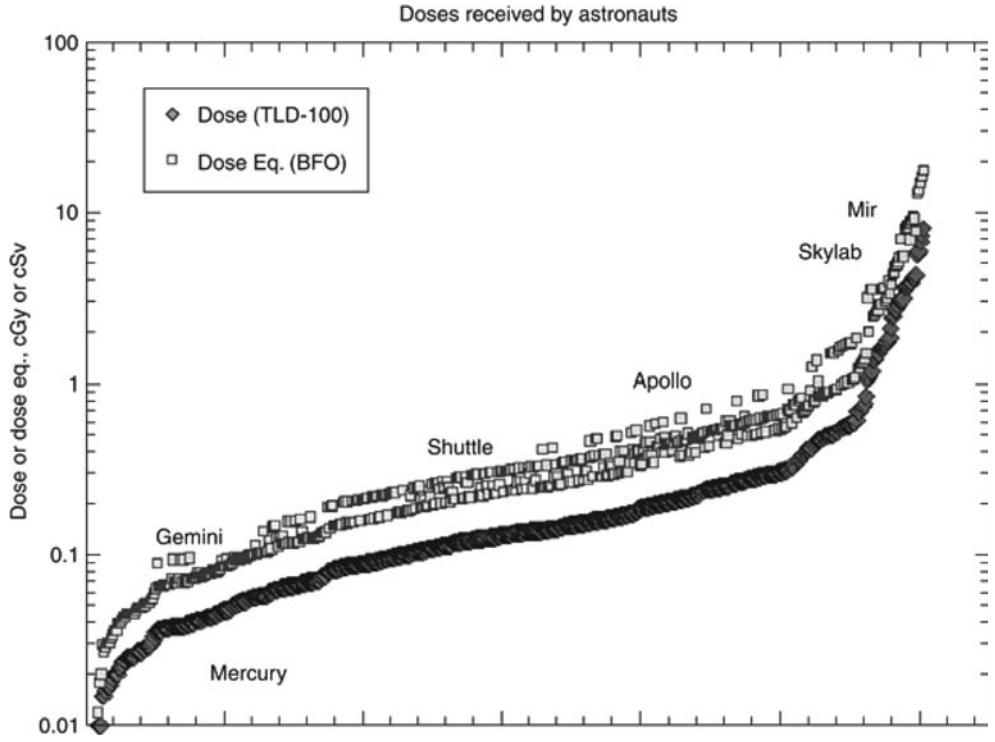

Fig. 3. The dose in centigrays and the dose equivalent for blood-forming organs (BFO) in centisieverts for individuals in space (*courtesy of NASA Johnson Space Center*).

proceed with estimates of the dose equivalents with increased confidence in the physics. However, the risk estimates continue to exceed established limits, and the errors of such analyses still remain at unacceptable levels for two major reasons:

1. Secondary particles: Although the primary spectra for galactic cosmic rays have been established with reasonable certainty, the variation in the radiative quality within a spacecraft remain both substantial and uncertain because of complex secondary reactions that produce neutrons and secondary charged particles.
2. Biological uncertainty in true risk: Dose equivalent may not represent the true risk of cancer and other diseases in a space environment. Because the particles responsible for radiative damage are more energetic and have greater mass than those encountered at Earth's surface, our experience with this type of radiative environment is severely limited.

Secondary Particles. Figures 4 and 5 present the frequency distribution $y^2 f(y)$ per logarithmic interval of lineal energy y for cobalt-60 gamma rays, 250-MeV protons, 250-MeV/nucleon heavier ions, and neutrons at several energies. In the early era of research on risks from radiation in deep space, it was thought that the high-energy heavier ions such as iron were the most biologically damaging and, therefore, the most significant despite their lower abundance. Although protons and helium ions are about a thousand times more abundant, they are sparsely ionizing, that is, have low LET. They were expected to have a biological effect equivalent to that of X or gamma rays. The higher lineal energies from heavier ions of the same energy per nucleon result from a higher ionization density along the tracks. The early conclusion of some researchers was that the increased ionization density or higher LETs of these heavier particles would result in their being biologically more damaging despite their lower abundance. Typical distributions of secondary particles for 800-MeV protons traversing silicon were calculated by J.F. Dicello et al. and others. The group of Miller et al.has been measuring the distributions of primary and secondary charged particles produced by energetic heavy ion beams. Although the primary energetic protons are themselves close to minimally ionizing, they produce an abundance of secondary particles, as they traverse the spacecraft or its occupants. These secondaries include an abundance of lower energy protons, neutrons, and ion recoils, and many can be at least

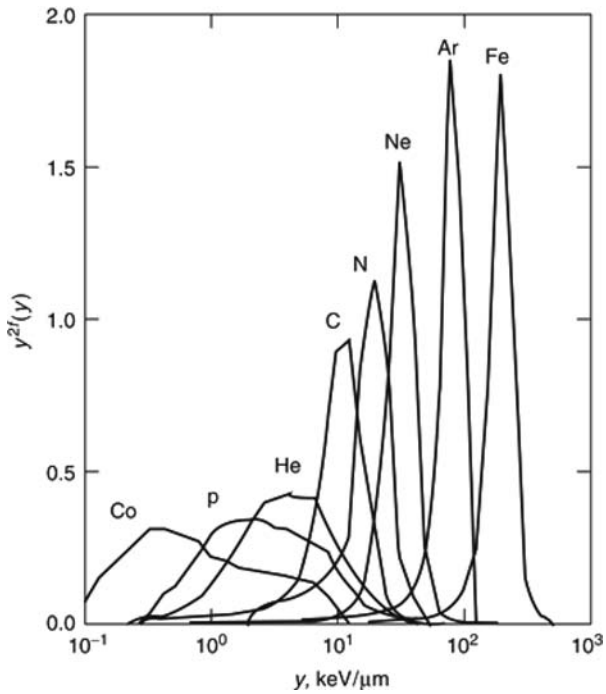

Fig. 4. The probability per logarithmic interval of lineal energy $y^2 f(y)$ as a function of lineal energy y for gamma rays from cobalt-60, protons of about 200 MeV initial energy, and heavier ions of about 600 MeV per nucleon (*courtesy of IEEE Trans. Nucl. Sci.*).

as highly ionizing as primary galactic cosmic rays and biologically as effective as primary HZE particles.

Based upon the microdosimetric analysis of the primary and secondary particles from galactic cosmic rays, Dicello proposed that primary protons, along with their secondary charged particles and neutrons, might be at least as effective biologically as heavy ions in producing biological damage. The relative doses and dose equivalents expected as a function of depth are presented in Fig. 6 and show that, as the primary protons enter the

spacecraft, they would rapidly produce secondaries and become major contributors to the dose equivalent at typical depths in a space vehicle. A major emphasis of current research is to choose materials that can minimize the number of primary HZE particles and also the substantial number of secondaries, particularly secondary neutrons. Despite the gradual change in the premise underlying the research and design, there is little biological data to evaluate any hypothesis.

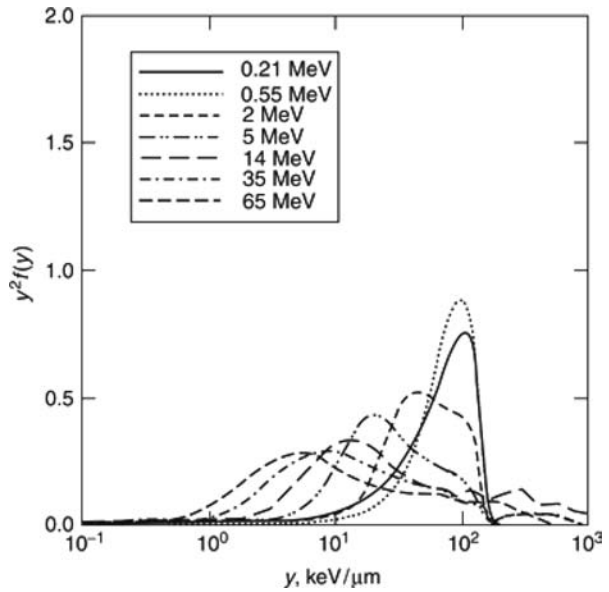

Fig. 5. The probability per logarithmic interval of lineal energy $y^2f(y)$, as a function of lineal energy y from external neutron beams of various specified mean energies (*courtesy of IEEE Trans. Nucl. Sci.*).

Biological Uncertainty in True Risk. Although the dose equivalent can be calculated with a reasonable degree of confidence, it remains a major issue as to how accurately the quality factors used to obtain dose equivalent from the physical dose truly represent the actual biological RBEs for cancer or other major diseases. The change in the quality factor as a function of LET remains somewhat arbitrary in radiative protection. We will adopt the relationship described in NCRP 132 and ICRP 60 as the defined relationship for regulatory purposes; however, note that this relationship may not necessarily provide either the correct functional dependency with dose or LET or the correct absolute values within acceptable limits of uncertainty. Historically, the relationship between the quality factor and the LET was based initially on animal studies at high doses and cellular end points, primarily *in vitro* survival. Although NASA and other agencies have carried out a life-sciences research program to address these specific issues, to date, only one comprehensive study of carcinogenesis for HZE particles, that of Alpen et al. and Fry et al., has been completed. Fry et al. estimated RBEs for the different particle types at the lower doses of interest for space applications by taking the ratio of the estimated initial slopes of the dose response curves. This group studied the prevalence of tumors that arise in the Harderian gland in the ocular system of mice as a function of particle type and energy. Some of the results are presented in Fig. 7. Their analysis of the results produced RBEs of 27 for iron ions and 4 for helium ions. More recently, Dicello et al. have been measuring the lifetime incidence of breast cancers that arise in a rat model from photons, protons, and iron ions. A large fraction of the animals is still alive, but preliminary results suggest RBEs somewhat lower than those observed by Alpen's group for the Harderian gland.

Countermeasures

Cucinotta et al. attempted to evaluate how well the relationship proposed by ICRP and NCRP conforms to existing data and how much uncertainty still exists in proposed scenarios. The result of one error analysis as a function of depth in aluminum is presented in Fig. 8. The range of the vertical bars represents the range of probabilities that cancers will arise

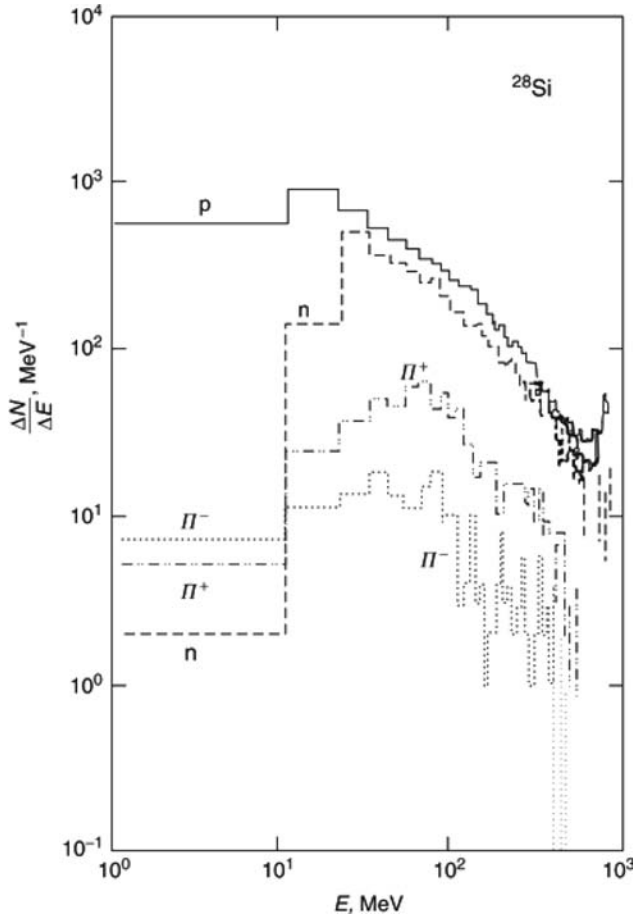

Fig. 6. Number of secondary protons, neutrons, and pions per unit energy interval arising from nuclear cascade processes of 800-MeV protons in silicon (*courtesy of Nucl. Methods Instrum.*).

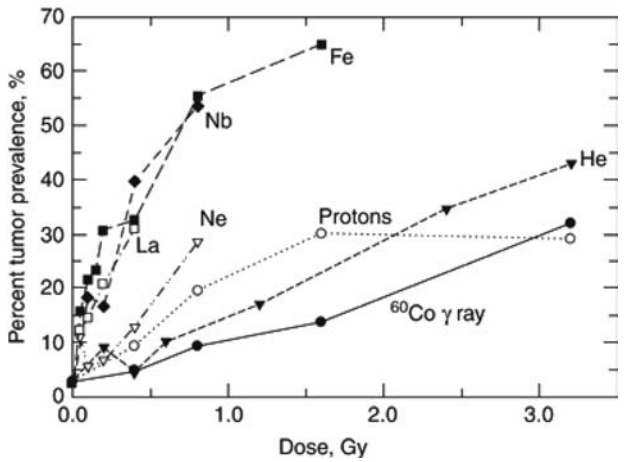

Fig. 7. Tumor prevalence vs. dose for selected particles (*courtesy of Advanced Space Research*).

from exposures in space that remain likely because of the uncertainties of the measurements and calculations. There is one major conclusion that might be drawn for this study. The uncertainties in the existing data suggest that about 80% of the risk uncertainties result from uncertainties in the quality factors, that is, uncertainties in the relative effectiveness of the different radiations in inducing fatal cancers or other serious diseases. This translates to uncertainty in *in vivo* biological responses, as it relates to human diseases, which further translates into risk factors for potential design criteria, as illustrated in Fig. 9. Cucinotta et al. conclude that the range in values likely for the probability for cancer is as much as a factor of five or more from the mean in specific regions.

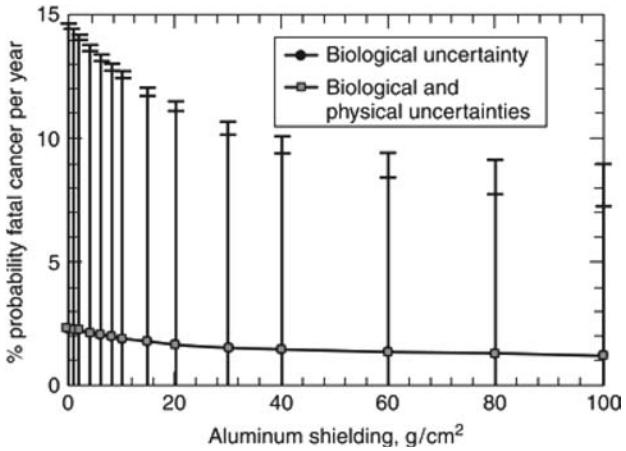

Fig. 8. Probability of fatal, cancer incidence as a function of Al shielding thickness (*courtesy of Radiation Research*).

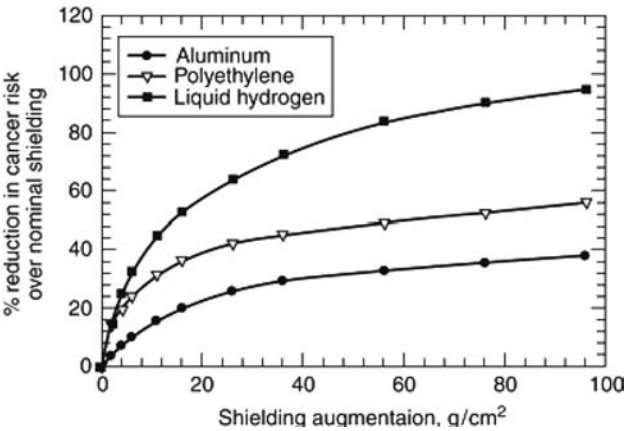

Fig. 9. Reduction in cancer risk over nominal shielding as a function of shielding augmentation (*courtesy of Radiation Measurements*).

Studies are in progress to determine optimal materials and combinations of materials that would reduce the dose equivalents within a spacecraft. Because of the potentially high levels of secondary neutrons, composite designs that include hydrogen-rich materials look particularly promising. Uncertainties in calculating the expected reduction in risk resulting from shielding and the material used for shielding are being reduced through current research to determine better the risks of carcinogenesis from the types of particles present in space. At the same time, research to examine pharmaceutical interventions that would reduce the consequences as well as the exposure are underway. Huso et al. have preliminary data to suggest that Tamoxifen® administered during the promotion and progressive stages of cancer can reduce the incidence of mammary cancers in rats. This approach has the appeal of being administered only after an exposure. Kennedy et al. and Lupton are examining less toxic dietary supplements to reduce cancer, and Vazquez is examining the effectiveness of drugs to reduce damage to the central nervous system.

Summary

The risk of cancer and other diseases arising from radiative exposures in space may be the major biomedical risk for missions of long duration because of the level of risk and the uncertainties of reducing such risks to acceptable levels. These risks arise primarily from exposures to galactic cosmic rays, particles from solar events, and particles trapped in Earth's magnetic fields, in decreasing order of potential significance. Considerable progress has been achieved in characterizing the physical characteristics of the primary radiative fields that surround Earth and are also present in space. Less progress has been made in determining the biological risk of cancer per unit exposure for the different types of radiation and for the probable time periods. Our best estimates suggest unacceptable levels of risk, although what constitutes an acceptable risk for missions beyond Earth's magnetosphere has yet to be defined. Research continues to make headway toward resolving the major issues, and few experts in the field doubt that safe interplanetary missions will be possible in the near future.

SPACE RESOURCES. Space resources consist of all of the useful materials, energy sources, and energy found in space. For practical purposes, this article focuses on those resources that may be accessible within the next 25 years, and for which large-scale demand is plausible. Therefore, the principal focus of this review is the bodies of nearby space: Earth's Moon, the planets Mercury and Mars, the two small Martian moons, Phobos and Deimos, and the near-Earth population of asteroids and comets.

Why Use Space Resources?

The cost of access to space is presently very high. To lift one kilogram (2.2 lbs) from Earth's surface into low Earth orbit costs about $10,000: a tonne of water aboard a space station represents an investment of nearly $10,000,000 in launch costs. Soft-landing one tonne of payload on the Moon costs about $100,000,000. A gallon of gasoline on the Moon would cost $400,001–$1 to purchase the gas on Earth and $400,000 to deliver it to the Moon.

Such a pricing system seems intuitively absurd: is there no better way to make intrinsically cheap, common, and highly desired materials available in space at affordable prices? How could we do better than launching them from Earth? Certainly any source of water, life-support materials, or propellants already present on the Moon or Mars would be enormously attractive. Even if it cost us $100 to extract or manufacture a liter of propellants on the surface of another planet, that amount would represent a 99.9% cost reduction, compared to transporting those propellants from Earth. We could then carry out the same mission for 0.1% of the propellant cost of launching the propellants from Earth — or move 1000 times as much payload for the same cost. To exercise this option, we require a scientifically, technically, and economically sound extraterrestrial source of propellants. This principle also applies to other commodities that are intrinsically cheap and in great demand in space, such as metal construction materials for building large space structures.

In recent years a number of suggestions have been offered regarding economic exploitation of the energy and material resources in nearby space. Among the resources proposed for exploitation are

1. solar energy, from space-based photovoltaic cells (Solar-Power Satellites or lunar power stations), via microwave transmission of power to antennae on Earth, to provide clean, cheap energy in vast amounts;
2. oxygen extracted from lunar or asteroidal rocks and minerals for use in life-support systems and as the oxidizer for rocket engines departing from the Moon;
3. the isotope helium-3, a constituent of the atmospheres of Uranus and the other giant planets and a very minor constituent of lunar regolith, for use as clean fusion fuel on Earth;
4. water from near-Earth asteroids, Martian permafrost, or lunar polar ice deposits for use in life support and rocket propellants;
5. metals, especially ferrous-metal alloys, for use in space construction; and
6. precious and strategic metals for importation to Earth.

As these examples suggest, the most important single motivation for space resource use is the recognition that large-scale future activities in near-Earth space may be made far less expensive by using materials that are already in space and that therefore need not be launched at great expense out of Earth's gravity well. But this is not the only motivation. A second important benefit of using space-derived energy and resources is the enormous positive environmental impact of off-loading energy-related mining, drilling, and shipping and large-scale energy production from Earth's surface. Return of valuable commodities to Earth merits third priority.

Many material resources found in space, especially on the Moon and Mars, would be used locally (i.e., within the gravity well of the body from which the resource was mined) to support unmanned and manned exploration or to fuel vehicles returning to Earth. Because of the substantial gravity fields of Mars and the Moon and the consequent high energy cost of landing and takeoff, as well as the low quality of their proven mineral resources, profitable export of materials from such massive bodies is far less feasible than local use: neither of these two bodies is well suited to export materials for use in other locations. For these logistical reasons and because of their great resource richness and diversity, near-Earth asteroids have emerged as the most attractive nearby sources of space-derived materials for export (especially, for return to near-Earth orbits).

The realization that these space resources may have enormous economic impact has stimulated considerable technical and economic interest. Two technical volumes on space resources have appeared in recent years, *Space Resources* [McKay, and Duke Ref.] and *Resources of Near-Earth Space* [Lewis, Matthews, and Guerrieri Ref.]. A popular overview of space resources based on these technical studies appears in *Mining the Sky* [Lewis Ref.]. A series of conference volumes containing papers on space resources, based on the proceedings of the biennial Princeton High Frontier Conferences and entitled *Space Manufacturing* (volume numbers I to XIV), has been published by the American Institute of Aeronautics and Astronautics. The technical literature on space resources is otherwise very widespread and difficult to research; it often appears in contractor reports, limited-circulation conference proceedings, and government publications. For this reason, using the volumes mentioned as introductions to the literature and as a source of citations to original publications is highly desirable.

The Resources of the Moon. The best single source for information on the physical and chemical properties of the Moon is the *Lunar Sourcebook* [Heiken, Vaniman, and French Ref.]. See also **Moon (Earth's)**.

The Moon is in orbit around Earth at a mean distance of 384,400 km (238,855 miles) from Earth's center. Its orbit has an eccentricity of 0.055 and an inclination of 5.142° relative to the ecliptic that allows excursions of the Moon to as far as 28.7° north or south of the terrestrial equator. The Moon is airless and utterly devoid of liquid water. Its radius is 1738 km and its mass is 1/81.3 times the mass of Earth. Its surface gravity is 0.165 Earth gravities, and its escape velocity is 2380 $m\,s^{-1}$.

The Lunar Rocks. The Moon is largely covered by heavily cratered highlands that are rich in the calcium aluminosilicate mineral, anorthite ($CaAl_2Si_2O_8$), one of the two defining constituents of terrestrial plagioclase feldspar. The Moon is so severely depleted in alkali metals that the complement of sodium plagioclase (albite; $NaAlSi_3O_8$) normally found on Earth is reduced to a minor component on the Moon. The most common highland rock type is anorthosite, a rock dominated by anorthite. The second most abundant mineral in these rocks is generally a low-magnesium pyroxene, and olivine is also present. These rocks, the ferroan anorthosites, are among the most ancient rocks on the Moon and date back at least 4.4 Ga (billion years before the present).

The second most abundant highland rocks are magnesium-rich and compositionally diverse. They have plagioclase contents that range to nearly zero in dunite, which is nearly pure olivine rock. Olivine-plagioclase rocks are called norites, and pyroxene and Ca-poor plagioclase rocks are classified as gabbros or norites. Many of the Mg-suite highland rocks also date to before 4.4 Ga.

An unusual lunar highland rock type that contains enhanced abundances of potassium (K), the rare-earth elements (REE), and phosphorus (P), found only as small chips in the regolith, has been named KREEP. In major-element chemistry, KREEP is a basalt. As on Earth, the rare earths concentrate strongly in phosphate minerals. Gamma-ray spectroscopy conducted from lunar orbit during the Apollo program tentatively identified the KREEP source region on the edge of the Mare Imbrium basin, based on the enhanced gamma emission from high concentrations of K, U, and Th. These data have recently been confirmed and refined by a gamma-ray spectrometer on the Lunar Prospector mission.

Chemical analyses of representative lunar igneous rocks show that most have silica abundances that are near the low end of the terrestrial range; they usually have less than 50% by weight of SiO_2, within the range of terrestrial basalts. Materials from the lunar lowlands, which cover about 25% of the near side of the Moon, are typically basaltic in composition.

However, lunar basalts differ from terrestrial basalts in that the lunar rocks have alkali metal abundances that are several times lower and titanium abundances that are several times higher than the usual terrestrial examples. Because the very high titanium abundance is accounted for by large amounts of ilmenite ($FeTiO_3$), the iron abundance is also abnormally elevated in lunar basalts relative to terrestrial basalts.

We find a range a range of textures, from the most fine-grained lunar basalts, which cooled rapidly upon extrusion as lava flows onto the surface of the Moon, to coarser grained basalts that crystallized more slowly and completely in a more protected (often intrusive) environment beneath the surface, forming volcanic sills or dikes or the bottoms of thick lava flows. Extruded basalts often show abundant vesicles, essentially bubbles inflated by magmatic gases such as hydrogen or CO, which unfortunately have long since diffused away.

Liquids of lunar basalt composition have very low viscosities and therefore are poorly suited for building tall volcanic structures about their magma vents. They are, however, ideal for making lava tubes, which may later drain and collapse to make features that look like the lunar rilles. These basaltic liquids have densities of only about 3.0, compared to about 3.3 for the solidified basalt. The observed bulk density of the Moon is only 3.34.

Lunar Minerals of Interest as Resources. Only seven minerals are ever found in abundances greater than about 1% in lunar rocks (Table 1). These include pyroxene $(Ca,Fe,Mg)SiO_3$; calcic plagioclase $(Ca,Na)(Al,Si)_4O_8$, close to anorthite composition; ilmenite ($FeTiO_3$); olivine $(Mg,Fe)_2SiO_4$; pyroxferroite $CaFe_6(SiO_3)_7$; and two polymorphs of silica (SiO_2), cristobalite and tridymite.

Pyroxene compositions in lunar rocks trespass into regions of the pyroxene quadrilateral not previously populated by other solar system materials. Some lunar pyroxenes are fairly standard augites, but others (often the outer layers of normal augite crystals) range far into the ferrosilite corner of the quadrilateral, perilously close to pure $FeSiO_3$, which is thermodynamically unstable with respect to its component oxides. This new material crystallizes in the triclinic system, unlike monoclinic augite, and hence is given a new mineral name, pyroxferroite. Pigeonite, which is low in calcium, is also present in smaller amounts.

Feldspars are present as an unusually calcium-rich plagioclase (from about 60% up to 99% anorthite) and a potassium feldspar. The K-spar, which has a sanidine structure, is crystallized in very small amounts out of the residual melt in rapidly crystallized basalts.

Given the low silica content of most lunar rocks, the presence of small amounts of olivine is hardly surprising. Olivine is well approximated by a solid solution of Mg_2SiO_4 (forsterite; fo) and Fe_2SiO_4 (fayalite; fa). Most lunar olivine is fairly iron-rich ($fa_{20}-fa_{50}$), but virtually pure fayalite is sometimes observed. Fayalite, unlike pure ferrosilite, is thermodynamically stable. Many lunar basalts are close to or above silica saturation and often contain a few percent of cristobalite or tridymite or even a trace of quartz.

Ilmenite occurs in basalts at abundances from a few percent to more than 20%. There is an important difference in oxidation state between terrestrial ilmenite, which is a solid solution of $FeTiO_3$ and Fe_2O_3, rich in ferric iron, and lunar ilmenite. Ferric iron is absent from lunar igneous rocks, and in fact small amounts of metallic iron are often found in lunar basalts. The ferric mineral FeOOH, ubiquitous in trace amounts in lunar samples, is an alteration product produced by the attack of terrestrial atmospheric water vapor on lunar lawrencite ($FeCl_2$).

Metallic iron in lunar rocks, generally found in association with troilite, is nearly pure iron and contains less than 1% nickel. The molar ratio of metal to troilite always lies close to the eutectic composition for an Fe–FeS melt. On rare occasions, tiny traces of metallic copper are also found in association with the metal and troilite in basalts.

By contrast, metallic iron found in the regolith and in the shock-lithified microbreccia contains up to 30% Ni and 1% Co. The metal in the basalt seems to have been made by reduction of FeO during melting, whereas the regolith metal is clearly dominated by asteroidal debris. This view is reinforced by the common occurrences of traces of cohenite (Fe_3C) and schreibersite [$(Fe,Ni)_3P$], both common accessories of meteoritic metals, in association with Ni-bearing metal in the regolith and breccias.

TABLE 1. SELECTED NATIVE LUNAR MINERALS

	Metals	
Kamacite	Fe,Ni (<6% Ni)	a[a]
Taenite	Fe,Ni (>6% Ni)	a
	Sulfides	
Troilite	FeS	a
	Oxides

K-spar		a
Orthoclase	$KAlSi_3O_8$	
Sanidine	$KAlSi_3O_8$	
Pyroxferroite	$CaFe_6(SiO_3)_7$	m
Zircon	$ZrSiO_4$	a

[a] M: major mineral (>10% in some rocks); m; minor mineral (1 to 10% in some rocks); a: accessory mineral (always <1%).
[b] S.S. Solid solution.

Several interesting oxide minerals besides ilmenite are also found on the Moon (Table 1). Rare spinel, nearly stoichiometric $MgAl_2O_4$, has been found in breccias, chromite $FeCr_2O_4$ has been found within regolith nickel-iron particles of apparent asteroidal origin, and ulvospinel, nearly stoichiometric Fe_2TiO_4, has been found in trace amounts exsolved from or replacing ilmenite. Other titanates include armalcolite [$(Fe,Mg)Ti_2O_5$], usually found within ilmenite grains, and perovskite $CaTiO_3$ that contains high concentrations of rare-earth elements, in the late-crystallizing component of the coarser basalts. Rutile TiO_2 and both baddeleyite (ZrO_2) and zircon ($ZrSiO_4$) are also found in tiny quantities.

Few elements serve as important markers of the oxidation state of lunar material. We have seen lunar basalts lie close to the Fe–FeO buffer. Sulfur is fully reduced to sulfide (indeed, almost exclusively as troilite), and carbon is found as meteoritic carbide. Phosphorus, which is found as coexisting phosphide and phosphate in some meteorites, is found in accessory amounts in lunar basalts as apatite [$Ca_5(PO_4)_3X$]. Fluorapatite (X=F) seems to be more common, but chlorapatite (X=Cl) has also been

reported. Hyroxylapatite (X=OH) has not been found. Small amounts of an amphibole that contains fluoride instead of hydroxyl have also been reported. Whitlockite [$Mg_3(PO_4)_2$] that has very high concentrations of rare earths (to about 10%) has also been found as a component of KREEP.

The Lunar Regolith. The lunar regolith, the crushed debris layer that covers the surface, is extremely complex. It is dominated by the products of violent cometary and asteroidal impacts on lunar igneous rocks and on the regolith itself. Rocks of all sizes, from house-sized boulders down to tiny rock chips and dust that contains only one or a few mineral grains, are mixed together with tiny glass droplets, similar to small chondrules, and with dust composed of very finely crushed grains. Impacts in the regolith have produced rocks, called microbreccias, that are essentially shock-lithified samples of the lunar regolith. Eclectic mixtures of smaller particles are often also found welded together by melt glass from later impacts. These welded, highly heterogeneous lumps are called agglutinates. In some places, the lunar regolith has been reprocessed so thoroughly that it has been mostly converted into agglutinates. Agglutinate-rich regolith samples are said to be *mature*.

Polar Volatiles on the Moon and Mercury. Lunar polar ice was apparently first envisioned as a resource by American rocket pioneer Robert H. Goddard in his student notebooks that date from 1908–1910. Harrison Brown and co-workers at Cal Tech in the early 1950s presented a simple quantitative argument for the preservation of ice from water-bearing impactors by recondensation in the lunar polar regions. These calculations were extended in the 1960s by James A. Arnold at UCSD, whose calculations stimulated considerable interest among both theorists and builders of spacecraft instrumentation.

The physical search for polar volatiles on the Moon and Mercury sounds at first like an exercise in futility. The problem is not just the expected very low abundance of volatiles in both bodies, but the logic of detection: the only places on the Moon and Mercury that are cold enough to permit trapping and long-term retention of volatiles (roughly 100 K for water ice) are permanently shadowed regions, such as crater bottoms, very close to the poles. Because the ice must be permanently shadowed to survive, it is always in the dark and cannot be photographed. Further, small, very cold regions on a generally very hot planet are difficult to detect in the infrared, where the long wavelengths of thermal infrared radiation degrade our spatial resolution and high fluxes from hot spots completely swamp the tiny fluxes from cold regions. The intensity of emitted thermal radiation from 600 K areas is greater than that from 100 K areas by a factor of $(T_{hot}/T_{cold})^4$, or about 1300:1. Temperatures below 110 K are necessary to keep the evaporation rate low enough to preserve water ice for billions of years.

The first probe of the polar regions of Mercury was an ingenious experiment carried out in 1991 by Martin Slade of the Jet Propulsion Laboratory and Bryan Butler and Duane Muhleman of Cal Tech. They used the 70-meter (230 ft) radar transmitter at Goldstone in the Mojave Desert to illuminate Mercury with monochromatic (single-frequency) radar pulses at a wavelength of 3.5 cm. Slade and his co-workers transmitted a right circularly polarized (RCP) radar signal that would reflect from a flat mirror-like surface with left circular polarization (LCP). The center of the disk of Mercury is essentially a flat, though rough, mirror, so there is a large intensity spike in the returned signal that has minimum time delay, zero Doppler shift (after allowing for the relative motion of the transmitter and the center of Mercury), and strong left-hand polarization. Extremely complex scattering from a very rough surface tends to depolarize the returned signal, which means a relative increase in the RCP component. When the Goldstone/VLA data were analyzed, a bright RCP component was found at zero Doppler shift and maximum range, which requires that it originate at a pole. Fortunately, Mercury's orbit is significantly tilted with respect to the plane of the ecliptic and affords observers on Earth frequent opportunities to see either pole. At the time of observation, the North Pole of Mercury was slightly tipped toward the observers and the South Pole was invisible, so the feature clearly must be associated with the north polar regions. Because the radar scattering properties observed for this feature are, so far as is known, unique to ice-covered surfaces, the strong implication is that Mercury has polar ice. Since these original observations, studies at different Earth–Mercury geometries have revealed that a similar feature is also present near the South geographic Pole. That area of anomalous reflection appears to be confined mostly to the floor of the large Chao Meng-Fu impact crater, which is centered at 87.5°S latitude.

Polar ice need not be exposed on the surface. Tens of centimeters of dry, porous dirt could overlie the ice without degrading the distinctive radar reflection signature of the ice. The thickness of the ice layer is poorly constrained by the observations. A few tens of centimeters or a few meters of ice would suffice to explain the observations, but a few kilometers of ice would be possible. Further, other materials besides water ice might possibly look the same.

Thermal modeling of the polar regions by David Paige and co-workers at UCLA shows that flat, unshadowed regions near the poles can be as cold as 167 K and that the observed cratering of the polar regions favors the existence of small, permanently shadowed enclaves inside craters that have large depth to diameter ratios. The craters that exhibit the highest depth to diameter ratios are simple bowl-shaped craters that have rim-crest diameters of 10 km or less. Unfortunately, because of the geometry of the Mariner 10 — Mercury encounters, our photographic (visible light) coverage of the polar regions has only an extremely narrow range of solar longitudes and leaves nearly half of the polar regions unimaged. The available coverage does, however, suggest areas that may be perpetually colder than 100 K, and even as low as 60 K. The coldest spot inside Saturn's orbit may be on Mercury!

The knowledge that ices can be stable in the Moon's and Mercury's polar regions is fascinating but does not by itself tell us the source of the volatiles that are condensed there. Outgassing from their interiors seems an unlikely source if these planets are made of volatile-poor, high-temperature condensate; however, the mass of ice required to explain the observations may be as low as a few cubic kilometers, an amount so small as to make it impossible to rule out the presence of that much intrinsic water in the planet. Further, cometary impacts during billions of years provide vastly larger fluxes of water onto both bodies than the amount required by the radar data.

Long-period comet impacts can be enormously energetic events. At Mercury's mean orbital speed of about $V_{orb} = 48\ km\,s^{-1}$, a low-inclination retrograde parabolic comet could encounter Mercury at a speed as high as $(1 + \sqrt{2})V_{orb}$, about $116\ km\,s^{-1}$, a kinetic energy density of $6.7 \times 10^{13}\ erg\,g^{-1}$. Mercury's escape velocity is only $4.3\ km\,s^{-1}$ (an escape energy of $9 \times 10^{10}\ erg\,g^{-1}$), so an impacting long-period comet carries enough energy to eject its own mass, plus more than 740 times its mass of Mercury's regolith, from the planet. This is not an efficient method of emplacing water on Mercury. Short-period comets, however, have average encounter speeds that are several times lower and have minimum encounter speeds of the order of $10\ km\,s^{-1}$. More important, extinct periodic comets (that have dust-insulated ice cores) and C-type planet-crossing asteroids may occasionally approach at velocities not much greater than escape velocity. Such impacts carry vastly less energy per gram and also have higher mean atomic weights in their fireballs, and hence expand more slowly. Thus water-bearing asteroids appear to be the most credible source of water and other volatiles on Mercury.

Unfortunately, our knowledge of the velocity distribution of Mercury-crossing asteroids is still very incomplete. Recent Spacewatch discoveries, mentioned later, show a surprising number of 10- to 500-m bodies in extremely Earth-like orbits of low eccentricity and modest inclination. The origin of this newly discovered class of bodies is not understood, and hence the likelihood of finding such a swarm of low-velocity bodies near Mercury cannot be assessed. Note also that, although there are many known Mercury-crossers among the near-Earth asteroid population, they represent an extremely biased set: all of them were discovered in the night sky from Earth and therefore must be in high-eccentricity orbits. Conversely, any low-eccentricity bodies that orbit near Mercury (or Venus) could not be discovered by present asteroid search techniques. Further, because all Mercury-crossing asteroids so far discovered must also cross Venus and Earth, they are strongly depleted in bodies whose inclinations are so low that they make frequent close approaches to these three planets.

One important implication of the discovery of polar ice on Mercury is that it suggested a similar phenomenon on the Moon. If there are massive quantities of polar volatiles on the Moon, both rocket propellants and life-support fluids could be manufactured readily on the lunar surface. Such a local source of propellants would greatly decrease the cost of launch operations from the Moon and possibly provide a source of propellant for

export to other locations in the Earth–Moon system, most of which are far more accessible from the lunar surface than from the surface of Earth.

The first evidence of the presence of lunar polar ice deposits came from the Clementine mission in 1994. See also **Clementine Mission**. The Radio Science experiment on this spacecraft took advantage of the observed "anomalous depolarization" of radio signals reflected from an ice surface, a phenomenon discovered in the course of radar studies of the icy Galilean satellites of Jupiter. The Clementine observations showed that when signals from the spacecraft transmitter are bounced at grazing incidence off the lunar poles, they were depolarized in the same way as those reflected from Europa, Ganymede, and Callisto — and the Mercurian poles. Although there is no convincing theoretical reason to link this phenomenon exclusively to water ice, it has not yet been shown that any other natural substance has the same effect. The data suggested that a small fraction of the surface area immediately adjacent to the lunar poles, possibly permanently shadowed crater bottoms, contains ice.

Clementine's indirect detection of ice set the stage for the much more specific neutron spectroscopy carried out by the Lunar Prospector spacecraft. This experiment is diagnostic for the presence of abundant hydrogen. Identification of the hydrogen-bearing material as water ice is inferential, but ice is the most abundant hydrogen compound in the Universe and has a vapor pressure compatible with the deduced latitudinal distribution of ice on the Moon (and Mercury). To a chemist, the exact molecular speciation of hydrogen is of enormous interest, especially because these hydrogen compounds are almost certainly of cometary or asteroidal origin. But to a chemical engineer, it hardly matters which ices are present: reacting any of them with FeO at high temperatures releases water in abundance. Lunar Prospector found ice deposits on crater floors near the poles with a total mass probably of the order of a billion tonnes (10^{15} grams). The ice is probably buried at a shallow depth in the regolith as interstitial ice, or permafrost, and partially fills the pore volume of the regolith. See also **Lunar Prospector Mission**.

Lunar Resource Exploitation

Many authors have suggested practical uses for lunar materials (Table 2). The simplest such use would be to employ regolith as radiation and micrometeoroid shielding for a lunar base. Using a sufficient power source, chemical processing of the regolith can also be attempted.

TABLE 2. RESOURCE TARGETS ON THE MOON

Product	Resource target	Process
Shielding	Regolith	Mechanical
Oxygen	Ilmenite	CO reduction
		H_2 reduction
		Methane/HC reduction
		H_2SO_4 dissolution
		Li/Na reduction
		Plasma reduction
	Mare regolith	H_2 glass reduction
		Magma electrolysis
		Strong base solution
		Carbon reduction
		Vapor pyrolysis
		HF dissolution
	Highland rock	Magma electrolysis
		Strong base solution
		Carbon reduction
Fe/Ni metals	Regolith	Magnetic separation
		Any reduction process
		Magma electrolysis
	Ilmenite	Any reduction process
Water	Regolith	Solar wind H release
	Polar ice deposits	Melting, distillation
Refractories	Regolith	Electrolytic residue
	Ilmenite	Any reduction process
Helium-3	Ilmenite	Heating, gas fractionation

The most frequently discussed lunar product is oxygen, liberated by reduction of oxides of iron and possibly other metals. This process naturally makes metals, especially iron, available as an ancillary product. Ferrous oxide, an abundant and easily reduced component of many lunar minerals (especially pyroxene [$(Mg,Fe,Ca)SiO_3$], olivine, [$(Fe,Mg)_2SiO_4$], and ilmenite ($FeTiO_3$) can be reduced at elevated temperatures by gaseous reagents such as hydrogen, carbon monoxide, and methane. The oxygen-bearing product, water vapor and/or carbon dioxide, can then be split electrochemically to release oxygen and reconstitute the original reducing agent.

In principle, it would be desirable to heat and process only chemically pure mineral separates. However, beneficiation, the process of separating high-grade mineral fractions, is difficult on the Moon for a number of reasons. First, "static cling" makes powders extremely sticky in the lunar vacuum and inhibits electrostatic or magnetic separation. Second, ilmenite-bearing rock chips have other minerals firmly bonded to the ilmenite, preventing clean separation. Third, mature regolith has been extensively processed into agglutinates, which weld together grains of disparate compositions. Fourth, the glassy component of the agglutinate is a mutual solution of many minerals that have been rendered inseparable by melting.

If ferrous metals are sought, ilmenite reduction is a logical technique: the process (ignoring dross and unreacted ilmenite) produces oxygen, iron, and the refractory oxide, rutile (TiO_2). Passing the iron through the gaseous carbonyl (Mond) process produces high-purity iron that is so free of defects that it resists corrosion as well as stainless steel.

Other processes for extracting oxygen, including high-temperature thermal decomposition of oxides, chlorination of ilmenite, whole-rock fluorination, and electrolysis of molten lunar material, also have attractive aspects but are not as well studied as hydrogen or carbon monoxide reduction. Of these, whole-rock schemes have the distinct advantage that they require only minimal physical processing and do not require beneficiation and sizing of selected minerals. They also share a disadvantage: any scheme that produces a variety of metals requires a much more complex chemical processing plant to turn the metals into useful products. Chlorination and fluorination processes also require very efficient recovery of the halogen reactants from a wide diversity of halide products.

Nonferrous metals are also abundant on the Moon. Titanium from the rutile by-product of ilmenite processing is an obvious possibility for extraction. Aluminum from anorthite and magnesium from pyroxenes and olivine should also be considered. Some authors have advocated using lunar calcium (also from anorthite) for making electrical wires and cables for outside use in an environment free of water vapor and oxygen.

Perhaps the easiest source of ferrous metals is simple magnetic extraction of native metal grains from the regolith. These grains have two origins: nearly pure metallic iron, produced by reduction of FeO by implanted solar-wind hydrogen during impact shock-heating, and asteroidal iron–nickel–cobalt alloys left behind by the explosion of asteroidal impactors. Like polar ice and helium-3, these materials owe their presence on the Moon to external sources of hydrogen and metals: none are native to the Moon.

The use of lunar polar ice may be very difficult. It is stable only in permanently shadowed areas, so it is not easy to use sunlight to evaporate or melt the ice. If there are permanently illuminated mountain peaks adjacent to the ice deposits, one could envision a manned lunar polar base occupying that choice location, feeding solar power to a mining operation on the crater floor. However, even given such a fortuitous geographical arrangement, schemes for installing and operating a base and mine under such extreme conditions are very daunting. The installation of base modules requires landing in incredibly rugged terrain atop a lunar peak. Mining operations would have to be conducted at a temperature below about 100 K, a temperature so low that most metals would be brittle, and in the presence of pervasive fine, highly abrasive lunar dust. Ice at such low temperatures is as strong as rock.

Polar ice is not the only possible source of volatiles on the Moon. Solar-wind-implanted volatiles, especially hydrogen and helium, are widespread, especially in the equatorial region. These gases are implanted as ions in the surfaces of grains exposed atop the lunar regolith. Old, mature regolith has accumulated far more gases than young, immature regolith, from 10 to as much as 50 ppm (parts per million) by weight. The highest solar-wind

gas concentrations are found in fine-grained ilmenite: it would be desirable to invent a beneficiation scheme that isolates ilmenite and screens out the largest grains. Unfortunately, mature regolith is very rich in agglutinates, which weld grains together irrespective of their composition, size, or gas content. Beneficiation of ilmenite or screening the ilmenite is impossible without thorough crushing to liberate individual grains. Further, the grains of greatest interest are so small that electrostatic "cling" makes it very difficult to separate them from grains of other sizes or compositions. Many simplified studies of ilmenite beneficiation have been reported; the most successful are those that least fit lunar conditions. The best recipe for success in liberating ilmenite is to separate magnetically, in air, a terrestrial ilmenite-bearing simulant free of agglutinates. But terrestrial ilmenite is a highly magnetic solid solution of iron oxides in ilmenite, not at all like lunar ilmenite. Success under such unrealistic conditions does not translate into success with unliberated, dust-like, slightly magnetic ilmenite in a vacuum.

The obvious method of extracting implanted hydrogen and helium is to heat the lunar material. It is reasonable that a feedstock containing 50 ppm of hydrogen could be heated efficiently so that 40 ppm of hydrogen is recovered. Then 25,000 tons of regolith must be heated per tonne of hydrogen recovered.

G.L. Kulcinski and his collaborators at the University of Wisconsin have suggested the recovery of solar-wind-implanted helium-3 from the lunar regolith for return to Earth for use as a clean fusion fuel with terrestrial deuterium. Near-perfect recovery of helium-3 from mature regolith would require heating 100,000,000 tonnes of regolith per tonne of helium-3 extracted. Based on extremely generous assumptions regarding helium-3 content, efficiency of gas extraction and recovery, beneficiation and sizing of ilmenite particles, heat reclamation from the baked regolith, sealing the ovens gas-tight in the presence of ubiquitous dust, and the ability of great quantities of complex mechanical equipment to survive autonomous operation in a dusty hard vacuum with diurnal temperature extremes of -200 to $+200\,^{\circ}\mathrm{C}$, the scheme can be made to turn a handsome profit. Although it is far too early to identify this scheme as practical and economically attractive, it is not too soon to contemplate realistic tests of components of this proposed system in lunar simulators and even on the Moon itself.

Logistical Considerations. Outbound missions from low Earth orbit (LEO) to the lunar surface have total propulsive velocity requirements of $3.0\ \mathrm{km\,s^{-1}}$ (from LEO nearly to escape velocity) plus $0.7\ \mathrm{km\,s^{-1}}$ to match orbital speeds with the Moon and $2.4\ \mathrm{km\,s^{-1}}$ to decelerate the spacecraft to a soft landing on the lunar surface, a total of $6.1\ \mathrm{km\,s^{-1}}$.

Inbound missions from the lunar surface to a LEO Space Station require the same total velocity change; however, because the Space Station is so close to the top of Earth's atmosphere, the $3.0\ \mathrm{km\,s^{-1}}$ of braking required for the returning lunar vehicle to match speeds with the LEO Station can be provided by aerobraking, the controlled passage of the space vehicle, with an appropriate heat shield, through Earth's upper atmosphere below the 100-km altitude level. The perigee of the resulting capture orbit, ranging from about 60–100 km, must then be lifted by an apogee burn to circularize the orbit at the same altitude as the LEO station. This maneuver typically requires $0.3\ \mathrm{km\,s^{-1}}$ velocity change a total propulsive change of $3.3\ \mathrm{km\,s^{-1}}$.

See also **Moon (Earth's)**.

The Resources of Mars

In addition to the general books on space resources suggested earlier, Martian resource exploitation is a major concern at the Case for Mars Conference series. The proceedings of these conferences are the basis of a series of books starting with *The Case for Mars*. A popular account of planning for future manned Mars missions, including Mars resource exploitation, is found in the book, *Islands in the Sky* [Schmidt, and Zubrin Ref.]

Because of its substantial escape velocity, Mars is even less suited for export of products than the Moon. Nonetheless, production of propellants on the Martian surface is highly attractive. Manned missions would also benefit greatly from extracting life-support materials, such as water, oxygen, nitrogen, and nutrients from local resources. A demand for volatiles naturally motivates a search for methods of extracting these materials from the Martian atmosphere, rather than from crustal minerals.

Materials Available on Mars. Geochemically, Mars is intermediate in properties between Earth and the Moon. The presence of a water-bearing carbon dioxide atmosphere on Mars enables a wide range of weathering reactions and products never found on the anhydrous, anoxic Moon. Solar ultraviolet photolysis of both carbon dioxide and water vapor provides a continuous weak supply of oxygen, which accelerates the weathering process and makes a variety of highly oxidized surface minerals, notably ferric oxides and oxysalts such as carbonates and sulfates. Much of the Martian surface has experienced the direct action of liquid water in the distant past. Clay minerals and hydrated salts are certainly widespread, possibly ubiquitous, components of the surface. Nitrogen, a minor constituent of the atmosphere, may also contribute small quantities of nitrate minerals by photochemical production of nitrogen oxides.

Primary igneous rocks on Mars have been spectrally mapped from Earth and from orbit. The discovery that the rare shergottite, nakhlite, and chassignite (SNC) achondritic meteorites contain adsorbed gases that have the distinctive chemical and isotopic signature of the Martian atmosphere has led to the general acceptance that they are fragments of the Martian crust that have been hurled into independent orbits around the Sun by asteroid or comet impacts on Mars. Calculations by Ann Vickery and Jay Melosh of the University of Arizona have shown that rock fragments from shallow depths in the regolith may be accelerated to escape velocity by the blast wave from such impactors. The SNC meteorites, of which more than a dozen have now been identified, are igneous rocks that contain elevated concentrations of ferrous iron and traces of weathering products characteristic of the Martian environment.

Direct chemical analyses of the Martian surface dirt have been carried out by the Viking landers and the Mars Pathfinder mission. The dirt is characterized by high sulfur and iron and low potassium and sodium contents. This combination of factors is best understood as the result of oxidative weathering and hydration of a relatively low-temperature (FeO- and sulfur-rich) primitive material, followed by leaching and partial removal of water-soluble salts. In addition, traces of weathering products have been found in several of the SNC meteorites. Along with smectite- and illite-like clays, these products include sodium and potassium chlorides; hydrated ferrous oxides; and carbonates, phosphates, and sulfates of calcium and magnesium, some of which carry water of hydration.

The Martian poles are covered with deep, probably permanent caps of dust-laden water ice, often covered by frosts of solid carbon dioxide ("dry ice"). Because of the orientation of the line of apsides of the Martian orbit relative to the direction of the polar axis, the seasons are not symmetrical between the Southern and Northern Hemispheres: the colder (southern) polar cap presently retains solid carbon dioxide all summer. Seasonal precipitation of solid carbon dioxide (dry ice) snow occurs at high latitudes and altitudes. Ultraviolet spectra of the poles reveal the presence of a tiny trace of ozone in the ice deposit. The ozone is a minor product of atmospheric photochemistry.

Manufacture of Propellants on Mars. The first use of Martian resources is likely to be to produce propellants to support unmanned or manned missions to the Martian surface, including use for both local mobility and for return to Earth (Table 3). In the longer term, manned missions may use native Martian materials to provide their requirements of air (oxygen and nitrogen) and water.

By far the most accessible and most easily "mined" resource on Mars is atmospheric carbon dioxide. Ash et al., first proposed that Martian carbon dioxide could be dissociated into carbon monoxide and oxygen by exposure to a hot (roughly 1000 K) zirconia membrane. By applying an electrical potential across the membrane, oxygen can be pumped selectively (as oxide ions), leaving a carbon dioxide/carbon monoxide mixture on one side and oxygen on the other side of the membrane. The net effect is to dissociate CO_2 via

$$CO_2 \longrightarrow CO + 1/2O_2$$

Liquefaction of CO and oxygen provides a propellant combination that has a specific impulse of about 284 seconds, limited by both the modest enthalpy of combustion of CO and the high molecular weight of the exhaust (carbon dioxide; MW = 44).

At high pressures and moderate temperatures, carbon monoxide can disportionate via

$$2CO \longrightarrow CO_2 + C(gr)$$

TABLE 3. RESOURCE TARGETS ON MARS

Product	Resource target	Process
Shielding	Regolith	Mechanical
Oxygen	Atmosphere	CO_2 cracking — ceramic membrane electrolysis
		CO_2 cracking — molten carbonate electrolysis
	Fe oxides; FeOOH	CO reduction
		H_2 reduction
	Water	Electrolysis
Fe metal	Regolith	Any reduction process, Magma electrolysis
Water	Atmosphere	Condensation
	Clays	Heating
	Permafrost/polar ice	Melting, distillation
Refractories	Regolith	Electrolytic residue
Nitrogen/Ar	Atmosphere	CO_2 removal

to precipitate graphite, after which the carbon dioxide can be cycled through the zirconia cell to yield more oxygen.

A variety of additional propellants can be synthesized in the presence of other elements. If hydrogen is available, then hydrogen can be burned with oxygen ($I_{sp} = 460$), or hydrogen can be used with carbon oxides to synthesize any of a variety of other fuels, including methane (CH_4), methanol (CH_3OH), ethanol (CH_3CH_2OH), and acetylene (C_2H_2). These fuels burn with oxygen to provide a lower specific impulse than hydrogen–oxygen but have the great advantage that they are noncryogenic. Some are liquid at the normal temperatures of the Martian surface. A discussion of schemes for integrating hydrogen with carbon-oxygen chemistry is found in Hepp et al.

Hydrogen gas is not found on Mars, so taking advantage of these options requires finding a source of hydrogen. The two most obvious alternatives are to transport liquid hydrogen to Mars from Earth or to extract hydrogen from Martian water. The former requires carrying liquid hydrogen for several months, far beyond present experience for space missions. Martian sources of water include atmospheric water vapor, water of hydration in surface clays and salts, permafrost (at latitudes greater than about 45°), and polar ice (above roughly 80° latitude). The atmosphere of Mars, even when saturated with water, is so cold that the water content rarely exceeds a few parts per million. Although processing a clean gas stream appears attractively simple compared to mining, the energy cost of removing so small a trace of water appears prohibitive. The most concentrated source of water is polar ice, but accessing that ice requires operating during local summer when solar energy illuminates and warms the polar cap above the winter temperature of 140 K.

Permafrost is so widespread on Mars that it may prove almost as attractive as polar ice; however, permafrost may be buried under 0.1 to several meters of relatively dry regolith. Removal of the overburden may be easy, but mining permafrost requires extreme care because permafrost is effectively an abrasive-ice composite material. Finally, we consider extracting water from heated regolith that contains hydrated salts and hydrated and hydroxyl silicates, which is apparently possible anywhere on Mars. This approach may be the most direct and simplest to implement.

The second most attractive atmospheric component for propellant production is nitrogen. Nitrogen, combined with a chemical source for hydrogen and the ubiquitous carbon dioxide, allows synthesizing ammonia (NH_3), hydrazine (N_2H_4), hydrazine derivatives, and the storable oxidizers nitrogen tetroxide (N_2O_4) and nitric acid (HNO_3).

Life-Support Materials on Mars. Water and oxygen have obvious direct application to life-support systems on Mars. Inert gases, especially nitrogen and argon, are also of considerable importance because of their use in admixture with oxygen to moderate the danger of fire. Together, nitrogen and argon make up about 5% of the Martian atmosphere.

Nutrients for plants and animals derive ultimately from inorganic materials. Beyond those materials already mentioned, chemically active nitrogen compounds such as ammonium and nitrate salts and phosphates deserve special mention.

Metals on Mars. Because of the high concentration of iron oxides in both Martian weathering products and primary igneous rocks, extraction of iron seems attractive (Table 3). The route to iron reduction could be either by carbon monoxide or solid carbon; the former is simpler and more practical. Carbon monoxide heated strongly with an iron oxide-hydroxide weathering product releases both carbon dioxide and water vapor and produces pure metallic iron:

$$2FeOOH + 3CO \longrightarrow 2Fe + 3CO_2 + H_2O$$

Recovery of water and cycling of carbon dioxide through a cracking device allows oxygen recovery and CO regeneration. Reaction of carbon monoxide with iron or iron oxides at about 200 °C and pressures of the order of 100 atmospheres produces a volatile iron carbonyl;

$$Fe_2O_2 + 13CO \longrightarrow 2Fe(CO)_5 + 3CO_2$$

These moderate temperatures can be attained by passive solar heating without requiring electrical heating. The gaseous iron pentacarbonyl can then be passed over a heated surface at about 200 °C (392 °F) and 1 atm pressure to decompose it quantitatively into high-purity metallic iron and gaseous carbon monoxide. This is a form of *chemical vapor deposition*. Iron deposited in this way is so pure that it has the corrosion resistance of stainless steel.

No other metal should be as readily extractable as iron. The very existence of aluminum ores appears improbable; indeed, if the SNC meteorites are representative, even plagioclase feldspar may be of low abundance locally. Titanium ores are also not established. The iron titanate mineral ilmenite, found in high concentrations in several lunar mare basins, is a minor or trace mineral in SNC meteorites. Chromite is also found in trace amounts. Other sulfides occur in minor or trace amounts, too low for reasonable economic exploitation, but suggesting the possible presence of undiscovered sulfide ore bodies on Mars.

It is important to note that existing data on Mars are of insufficient resolution and sensitivity to confirm or reject the presence of ore outcroppings of other economically useful materials. Hydrothermal deposits, either active or extinct, are almost certainly present. Therefore, ore mineralization must be considered a very real possibility. However, without knowledge of the nature and location of these ores, it is scarcely possible to suggest methods of use. It must suffice to point out that volatiles and iron, as discussed earlier, meet our most pressing local needs. Ancient sedimentary deposits might also provide calcium and magnesium carbonates, which suggest the possibility of manufacturing "Marscrete", or Martian concrete, using carbonates that have been kilned to drive off carbon dioxide and make lime (CaO).

Logistical Considerations for Mars Missions. The total velocity requirement for outbound trips (from the LEO Space Station to the surface of Mars) is only 4.8 $km\,s^{-1}$, compared to 6.1 $km\,s^{-1}$ for missions from LEO to the lunar surface. The reason for the advantage enjoyed by Mars is that aerobraking for arrival at Mars is possible, and permits the dissipation of hyperbolic orbital energy without significant propellant consumption. The penalty paid for this liberation from heavy propellant use is that a heavy aerobrake heat shield must be carried.

The escape velocity of Mars, 5.4 $km\,s^{-1}$, is the mean of the escape velocities of Earth (11.2 $km\,s^{-1}$) and the Moon (2.4 $km\,s^{-1}$). Single-stage-to-orbit launch vehicles, which are marginally feasible on Earth, are highly appropriate for takeoff from Mars. Because the most likely destination for a vehicle that departs from Mars is Earth and the entire impulse for injection into an Earth-intercept solar orbit can be delivered at launch while still deep in Mars' gravity well, summing velocity requirements is incorrect: energy conservation gives a return velocity requirement of 7.8 $km\,s^{-1}$ for Earth intercept, compared to 3.0 $km\,s^{-1}$ for aerobraked return to Earth or LEO from the Moon. The returning Mars vehicle must then use aerobraking either to descend to Earth's surface or to capture into Earth orbit.

Because of the relatively high escape velocity, it is probable that, aside from scientific samples and curios, export of Martian materials would be unprofitable.

See also **Mars**.

The Martian Moons, Phobos and Deimos

The Martian moons are dark, irregularly shaped bodies whose characteristic dimensions are of the order of 10 km (6.2 miles) and masses of the order of 10^{18} grams (one trillion tonnes). Their orbits bracket Mars-synchronous orbit, so that Phobos passes from west to east across the Martian sky, whereas Deimos moves in the opposite direction. The masses and densities of these small satellites, measured by the Viking Orbiter spacecraft in the late 1970s, show that they are little more dense than ice and about half the density of even the least dense rocky meteoritic materials. Spectroscopic studies of the Martian moons have long suggested that they are very similar to the class of meteorites known as carbonaceous chondrites. Carbonaceous chondrites are black because of the pervasive presence of both tarry organic polymers and the iron oxide mineral, magnetite. They contain up to 6% of organic matter and up to 20% chemically bound water in the form of clays and hydrated salts. Spectroscopic studies in 1994, however, found that, unlike carbonaceous meteorites, Phobos and Deimos show no sign of the presence of water-bearing minerals.

One of the oddities of the Martian satellite system is its dynamic environment: the two satellites are so deep in the Martian gravitational field that most of the debris excavated from them by impacts remains in orbit about Mars. The debris fan from each impact quickly settles into a thin, dense dust disk in the equatorial plane, where it is eventually reaccreted by the two moons at low relative speeds. In the Asteroid Belt, for comparison, debris is injected into independent orbit around the Sun. It is dispersed over a vast volume of space and is subjected to severe disturbing forces from radiative pressure and gravitational perturbations, so that there is no reasonable probability that it will be reaccreted by the body from which it originated — or any other asteroid. Therefore, the surfaces of Phobos and Deimos, more than any asteroid, consist of materials ejected and strongly shock-heated in many generations of previous impacts. The surface material, not surprisingly, is very dry. But the surfaces of these bodies do not tell us whether their interiors are rich in water. The low observed density likewise is ambiguous evidence because it could be affected either by a large abundance of water ice or by pervasive fracturing of the interior: the insides of Phobos and Deimos may be full of both ice and vast systems of cracks and voids.

Utilization schemes for Phobos and Deimos clearly must await determination of their water content. If water is present and abundant, both satellites would become highly attractive as sources of propellants for use within the Mars system and for return to Earth.

Logistically, because of their low surface gravities, Phobos and Deimos are both more accessible for outbound soft-landing missions than the Moon. Return missions from Phobos and Deimos to Earth intercept require a very small velocity change to escape from the satellite, a larger ΔV to escape from Mars into heliocentric orbit, and another substantial ΔV to lower the perihelion distance of that orbit to 1 AU. The total ΔV for return to Earth intercept (aerocapture) is 2.88 $\mathrm{km\,s^{-1}}$ from Phobos and 2.55 $\mathrm{km\,s^{-1}}$ from Deimos. To get off Phobos and drop down into the atmosphere of Mars for an aerobraked landing requires only 0.56 $\mathrm{km\,s^{-1}}$ and a Mars landing from Deimos needs only 0.4 $\mathrm{km\,s^{-1}}$. Thus return to a Space Station orbit about Earth from either of the Martian moons is easier than a comparable return from Earth's Moon (assuming aerobraking in each case). The principal penalty for Phobos and Deimos return missions is the approximately 9-month travel time back to Earth.

The Near-Earth Asteroids

Asteroids as Threats and Opportunities. Recent developments in the astronomical search for near-Earth asteroids and in geological studies of impact features on Earth and other planets have presented us with a disturbing vision of the threat of disaster visited upon Earth by the impact of a near-Earth asteroid or comet. A technical overview of these issues can be found in the book *Hazards due to Comets and Asteroids* and in a popular discussion based on that volume. A quantitative treatment of impact hazards, based on the results of extensive and detailed Monte Carlo simulations of centuries of impact events on a populated Earth, has recently appeared. These studies show that, if a large asteroid, one massive enough to threaten human civilization, is now on a course to collide with Earth 100 years from now, then that body would almost certainly be one that we have not yet discovered: to date, we have found only about 10% of all kilometer-sized bodies that cross Earth's orbit. These data also show that virtually all such large bodies can easily be discovered within the next few decades by a systematic, globally coordinated search and characterization program that costs less than a single small space mission. Using such a search program to give us adequate warning of a threatened asteroid impact, we would then have ample time to design, build, test, and deploy an effective defense against the threat.

That same search and characterization program, however, provides an exceptional opportunity. Many of the most dangerous asteroids have orbits that are remarkably accessible from Earth: they cross or graze Earth's orbit about the Sun and can be reached, orbited, and landed upon more readily than any other body in the solar system. Fully a quarter of the near-Earth asteroids of all classes are easier to land on than the Moon: a given booster rocket could soft-land a larger payload on any of these than it could on the Moon. Further, these bodies have such feeble gravity that departure from them to return to Earth is vastly easier than departure from the Moon. Return of samples from the near-Earth asteroid Nereus, for example, requires a departure speed as low as 60 meters per second (135 mph), whereas departure from the Moon to return to Earth requires a speed of about 3000 meters per second. The amount of energy (or propellant) required per ton of returned material is 2500 times as large for lunar missions as it is for Nereus missions. For this reasons, exportation of bulk materials from the Moon to Earth could make sense only for fabulously valuable materials.

Logistical Considerations. Because of the ease of returning asteroid-derived materials to Earth orbit, very large masses of materials may be moved. Logistical studies suggest that each ton of equipment launched from Earth to a near-Earth asteroid can return 100 tons of material to Earth orbit during the operational lifetime of the vehicle. Thus, assuming a launch cost of less than $500 per pound from the surface of Earth and using a 100:1 leverage factor, materials such as propellants or metals could be made available in Earth orbit for a few dollars a pound. The materials needed for future space transportation and construction would then be comparable in expense to those used in high-quality residential construction here on Earth.

In addition to these very favorable energy and logistical considerations, asteroids are attractive targets for a wholly different reason: they are rich in "cheap" materials, such as water or steel, that are of great value and utility in space but outrageously expensive to launch from Earth. Further, the large majority of near-Earth asteroids contains high concentrations of extremely valuable precious and strategic metals, such as platinum, osmium, iridium, rhenium, and palladium, and semiconductor components such as germanium, gallium, arsenic, antimony, tellurium, and indium. The Earth-surface market value of this fraction is roughly $10,000 per pound, and the concentration of platinum, for example, is higher in the average NEA than in the best known terrestrial ore deposits. Experiments now underway in the laboratory of Prof. Henry Freiser at the University of Arizona, funded by a visionary private foundation that is interested in commercial development of space, are seeking simple, effective means to extract and separate many of these valuable resources from meteorites that are authentic samples of asteroids.

The idea of extracting asteroidal materials for commercial use is not new: As early as 1903, the great prerevolutionary Russian rocket visionary, Konstantin Tsiolkovskii, proposed exploiting asteroid resources. The father of practical rocketry, the American physicist Robert Goddard, wrote in a 1918 essay entitled The Ultimate Migration, of interstellar ships made from asteroids conveying our remote descendants away from the death throes of the Sun. The idea of mining asteroids was so visionary that Goddard sealed his manuscript away in an envelope labeled "Special formulas for silvering mirrors," where it languished unread for more than 60 years. Goddard's reticence is understandable: the technologies required to carry out such ambitious schemes did not exist then, whereas critics and mockers incapable of understanding his ideas were legion. But today, this dream can be made a practical reality by applying the technology of the year 2000.

The keys to successful importation of materials from space are lower launch costs, careful choice of exploitation targets to favor those that are most accessible and have the richest resource concentrations, and minimizing the complexity of the operations to be undertaken by mining and extraction vehicles to rely on artificial intelligence, not human

presence. The question how to lower the cost of access to space from about $5000 per pound to a few hundred dollars per pound is also an old one. Exactly a century ago, Tsiolkovskii wrote a science fiction novel in which the first successful manned venture into space was carried out in the year 2000. . . by a consortium of industrialists, scientists, and technologists funded by what can only be described as venture capital. Today, we see nearly two dozen companies, funded by venture capital and equipped with exciting ideas and the most modern aerospace and electronic technology, competing to lower the barriers in the way of massive development of space.

The NASA Near-Earth Asteroid Rendezvous mission — Shoemaker (Near Shoemaker), renamed in honor of Gene Shoemaker), which arrived at the asteroid Eros in 2000 for a prolonged study of its surface, has already returned a wealth of data on the physical and chemical properties of that asteroid. Early data strongly suggest that the common S-type asteroids are chemically closely similar to ordinary chondritic meteorites, the most common class falling on Earth. X-ray and gamma-ray analytical experiments are planned to continue compositional mapping of Eros for many months.

The Space Development Corporation's much-discussed Near-Earth Asteroid Prospector mission (NEAP) is merely the first example of attempts to privatize space activities. For planning purposes, it is assumed that NEAP is a mission to the asteroid Nereus. NEAP, although confined to a role as a science platform to fly NASA-funded instruments at low cost and to sell data gathered by privately funded instruments to NASA, can be regarded as an authentic prospector — a searcher for useful resources. The leading candidate instruments for the first mission are an alpha-proton X-ray spectrometer and multispectral imaging for global physicochemical mapping of the surface. The NEAP spacecraft bus can also accommodate several small experiments, such as a rover, that could be soft-landed on the surface of the asteroid after the primary mapping mission is complete. A second step would be to land processing experiments on the surface of an asteroid and demonstrate small-scale production of water or metals. Because return of materials from so many NEAs is exceptionally easy, both virgin surface samples and processed materials may be automatically returned to Earth more easily than samples could be returned from the Moon (a technique the Soviet Union that demonstrated successfully on the unmanned Luna 16, 20, and 24 missions in the 1970s).

Given the accessibility of NEAs and the diversity of their resources, some idea of the amount of available resources is in order. Perhaps the first example of note is the metallic near-Earth asteroid called Amun. This asteroid is about 2,000 meters (1.24 miles) in diameter. If it were to strike Earth, it would deliver a devastating blow of 10 million megatons (10 teratons) of TNT, several thousand times the explosive power of a nuclear world war. Amun, the smallest known metallic asteroid of the several dozen known, contains several times as much metal as the entire amount of metals mined and processed during the history of humankind. A conservative estimate of the market value of this asteroid is $5 trillion. See also **Near-Earth Asteroid Rendezvous Mission**.

Resource Richness and Diversity. The entire NEA population, which has very diverse chemical and physical properties, contains vastly more material than Amun. An estimate of the overall composition of the NEA population is shown in Table 4. It is not difficult to estimate how much of each of a wide variety of commodities, such as water, carbon, nitrogen, metals, and phosphorus, is required in circulation to maintain one average human at present-day North American, Western European, or Japanese levels of affluence. From these figures, we may estimate how many people could be supported indefinitely by the resource wealth of the NEA population, assuming a fully recycling regime powered by the Sun. According to Table 4, the number is probably close to 14 billion people. Nitrogen, principally in its role as a fire-suppressing diluent of atmospheric oxygen, appears to be the limiting resource. One of the most remarkable lessons of Table 4 is that the proportions of materials needed by civilized human beings is similar to the proportions in asteroids.

But the NEAs are only a small part of the picture. Most NEAs follow orbits that take them out to the heart of the Asteroid Belt, between the orbits of Mars and Jupiter, at aphelion. Thus a processing unit landed on a typical NEA will get a free round trip to the Belt and back on each trip around the Sun (typically, once every 3–5 years).

TABLE 4. RESOURCES OF THE NEAR-EARTH ASTEROIDS[a]

Commodity	Mass among 10^{15} g	Per capita inventory, g/person	Population sustainable by NEA resources, billion people
Silicate	2500	140,000,000	17.8
Ferrous metals	300	20,000,000	30.0
Fe in oxides	300		
Cement	60	10,000,000	6.0[b]
Industrial CaO		2,000,000	30.0
Phosphates	10	2,000,000	5.0[c]
Water	300	10,000,000	30.0
Carbon	100	1,000,000	100.0[d]
Nitrogen	10	700,000	14.0[e]
Sulfur	60	1,200,000	50.0
Sulfides	150	1,200,000	125.0

[a] The Near-Earth asteroid population is a renewable resource that replaces itself about every 30 million years. Note that the only true "consumable" in this fully recycling system is solar power.
[b] Cement is of dubious utility in space, except for wholly internal (non-vacuum-tight) construction.
[c] Phosphate fertilizer usage on Earth is predicated upon toleration of massive loss in runoff from fields. In a 100% recycling regime, the required inventory could easily be 10 times smaller.
[d] Carbon inventories assume 1000 g of plant carbon per gram of human carbon.
[e] Nitrogen inventories assume 1000 m^3 of habitat volume per person.

In the likely order of development, water is the first asteroidal resource worthy of attention. Its uses as a propellant and as a life-support material are obvious. Second in order would be native ferrous metal alloys, whose major components, iron and nickel (and possibly cobalt), would be retained in space for constructing space-based facilities such as solar power satellites. The rare and very valuable precious metals and semiconductors in asteroidal metal alloys are worth returning to Earth. Dr. Jeffrey S. Kargel has explored the effects of large-scale importation of these materials from space on the market size and prices of these commodities on Earth. He concludes that prices will decline less rapidly than the rate of supply increase because of new uses stimulated by lower prices.

The potential customers for the materials that remain in space include government agencies that need propellants for injection into geosynchronous orbit, for orbital stationkeeping, or for departure from Earth's gravity well, such as both unmanned and manned Mars missions. In addition, civil traffic bound for geosynchronous orbit would be an important market for propellants. Metals would be of use for constructing and shielding large structures, of which the most obvious commercial example would be Solar Power Satellites. But this entire scenario depends on a stable and rational legal and regulatory system in which investors will have reasonable assurance that the fruits of their ingenuity and investment will not be arbitrarily obstructed, or even confiscated. We return to this issue later.

Proposed System Architectures. There are two central questions regarding the exploitation of asteroidal resources. First, there are the propulsive energy constraints imposed by the geometry of the orbit of the target asteroid. Outbound ΔV requirements from reference orbits such as LEO (a circular orbit at 300–600 km altitude, compatible with future space stations) have been calculated for almost every known near-Earth asteroid. In general, the typical NEA of interest has a perihelion close to or within Earth's orbit. Many NEAs have aphelia in the asteroid belt. The best candidates have low orbital inclination, perihelia (or, in the case of Atens, aphelia) very close to 1.00 AU, and low eccentricities. Outbound ΔVs (from LEO to landing on the target asteroid) as low as 3.2 km/s are allowed by theory, but in practice bodies whose outbound ΔVs are less than about 4.2 km/s are so vulnerable to perturbations and capture by Earth that their populations are depleted. About 15% of all NEAs have outbound ΔVs that are less than the ΔV requirement for missions from LEO to a soft landing on the Moon (6 km/s). Return from many NEOs requires ΔVs less than 1 km/s; several lie below 0.4 km/s. The best known return ΔV is 0.06 km/s from Nereus (1982 DB). By comparison, return to Earth intercept from the lunar surface requires roughly 4 km/s, depending on where the launch site is on the Moon.

Second, there is the choice of location for the space base in near-Earth space from which missions depart and to which they return with their

cargoes. In a study of opportunities for missions to the Mars system, Benton Clark argued that the most suitable base for long-term, round-trip use would be in highly eccentric Earth orbit. A typical base orbit might have a perigee of several thousand kilometers, beyond the heart of the Van Allen radiation belts, and an apogee of 40,000 to as much as 400,000 km (roughly the orbit of the Moon). Both aerobraking and propulsive capture require that the hyperbolic excess velocity be lost as close to Earth as possible and the perigee be about 100 km. A small apogee burn can then lift the perigee safely out of the atmosphere. From such an orbit, the velocity required for escape from Earth is extremely modest, and from such an orbit, it is easy, by a brief apogee burn, to drop the perigee down to the top of the atmosphere either for return to Earth or for an engine burn to escape Earth at maximum efficiency.

See also **Asteroid**.

Solar Power from Space

In recent years, debate concerning the greenhouse effect, global warming, fossil fuel burning, and the environmental impact of mining and transporting fossil fuels has focused increasing attention on alternative sources of electrical power. The desire is for cheap, clean, abundant future energy supplies motivates consideration of solar power.

There are several ways in which solar power may be made available on Earth. The first and most obvious option is constructing solar voltaic cell "farms" in locations on Earth's surface where the total insulation is highest. Earth-surface solar cell arrays are subject to the day–night cycle; atmospheric attenuation of sunlight by Rayleigh scattering and by cloud opacity; shadowing by windblown dust (an especially common phenomenon in areas that have the most reliable solar illumination); or by smoke, haze, or volcanic aerosols, and damage by wind, snow and ice loads, hail, lightning, and flying objects.

An obvious alternative is to locate the solar cell arrays in space, where performance (watts of electrical power per square meter of collector area per year) can be 2 to 10 times higher than on Earth's surface. The principal drawbacks of space-based solar collectors are the initial cost of launch and the necessity of beaming the power down to receiving antennae on Earth as microwave power. The choice of the orbit of the solar cell array has an important influence on system performance. The easiest orbits to achieve (low Earth orbit; LEO) usually have a 50% duty cycle due to passage through Earth's shadow and also traverse the 300 to 1000-kilometer altitude range where the probability of collision with orbital debris is high. Higher orbits have greater installation costs and less opportunity for service but better exposure to the Sun and a more favorable debris environment. Most point designs of Solar Power satellites (SPS) assume that they will be installed in geosynchronous orbit. Large-scale reliance on SPS constellations would entail installing approximately 5×10^4 km^2 of solar collectors in the geosynchronous belt, where they would far outshine the brightest stars.

An interesting variant of the SPS concept that would avoid the light pollution problem is David R. Criswell's scheme of building solar-power collectors on the Moon, using lunar resources for collector construction. This approach saves the cost of lifting most of the mass of the SPS system from the Earth.

SPS constellations in Earth orbit could also benefit greatly from using nonterrestrial materials. A recent NASA study showed that SPS are close to being economically viable, even with Earth launch ("uphill" transport) of all of their components. Any scheme that derives the most massive, low-tech SPS components from nonterrestrial metals (brought "downhill" to Earth orbit) holds promise of making them highly competitive economically.

Some words are also in order regarding the environmental impact of space resource use. In general, any industrial activity that can be offloaded from Earth eases the environmental burden on Earth's biosphere. An enormous proportion of Earth's environmental troubles are related to mining, refining, transporting, and using fossil fuels. National policies aimed at reliance on solar power satellites mitigate all of these problems, simultaneously making the United States the world's largest exporter of energy and energy technology and extending the usefulness of our limited petroleum reserves far into the future by dedicating crude oil to petrochemical production, not combustion. Finally, such an approach reduces or eliminates American dependence on foreign sources of crude oil.

Long-Term Prospects

For logistical and programmatic reasons, the most attractive locations for resource extraction are the near-Earth asteroids, the Moon, and the Mars system, including Phobos and Deimos. But, in the longer term, other options may be considered. As mentioned earlier, Mercury's polar ice deposits provide a potential source of propellants for a sample return mission. Venus, by reason of its enormous atmospheric pressure (92 atmospheres), scorching surface temperatures (750 K, or about 900 °F), highly corrosive atmosphere (containing gaseous hydrochloric and hydrofluoric acids and clouds of sulfuric acid droplets), and high escape velocity (10 kilometers per second), is among the most unattractive locations in the solar system, similar to Dante's vision of Hell.

Near-Earth asteroids typically reach the heart of the Asteroid Belt at aphelion. Any equipment riding on an NEA is transported out to the main Belt every few years. It is easy to envision a device riding on a water-bearing NEO out to the Belt, manufacturing propellants from the water as it goes, and using that water to transfer from the NEO to a convenient Belt asteroid. Such a transfer is energetically no more difficult than returning to Earth. Emplacing equipment on Belt asteroids in this manner is logistically more complex than landing on an NEO but not more demanding from a propulsive or launch-weight perspective. In effect, systematic exploitation of the NEO population makes access to the main Belt easy.

The mineral riches of the Asteroid Belt are almost beyond comprehension (Table 5). The asteroids that reside in the Belt make up a very large population, roughly 40,000 bodies larger than a kilometer in diameter, and the total mass is roughly a million times as large as the total mass of the NEA population at any one time. Table 5 summarizes the total amount of resources available in the Belt in a manner similar to the NEAs treated in Table 4. The conclusions are staggering: the materials available in the Asteroid Belt would maintain indefinitely a human population of at least 10,000,000 billion people — about one million times the maximum carrying capacity of Earth. Assertions that we are running out of resources reckon without twentieth and twenty-first century technology. The supply of resources available to a spacefaring humanity is effectively infinite. But there is no possibility of returning all that material to Earth (enough steel in the Asteroid Belt, for example, to build a steel-frame building 8,000 stories tall covering all the land area of Earth), nor is there any possibility of accommodating so many people on one planet. The bulk of these resources would be used in space.

Beyond the Belt, in two extensive clusters located on the orbit of Jupiter, 60° ahead of and behind Jupiter, are the Trojan Asteroids. The total mass of material in these two vast clouds is probably several times the total

TABLE 5. RESOURCES OF THE ASETROIDS BELT[a]

Commodity	Mass among 10^{21} g	Per capita inventory, g/person	Population sustainable by NEA resources, billion people
Silicates	2500	140,000,000	17,800,000
Ferrous metals	300	20,000,000	30,000,000
Fe in oxides	300		
Cement	60	10,000,000	6,000,000[b]
Industrial CaO		2,000,000	30,000,000
Phosphates	10	2,000,000	5,000,000[c]
Water	300	10,000,000	30,000,000
Carbon	100	1,000,000	100,000,000[d]
Nitrogen	10	700,000	14,000,000[e]
Sulfur	60	1,200,000	50,000,000
Sulfides	150	1,200,000	125,000,000

[a] Assumes full recycling and full reliance on solar power.
[b] Cement is of dubious utility in space, except for wholly internal (non-vacuum-tight) construction.
[c] Phosphate fertilizer usage on Earth is predicated upon toleration of massive loss in runoff from fields. In a 100% recycling regime, the required inventory could easily be 10 times smaller.
[d] Carbon inventories assume 1000 g of plant carbon per gram of human carbon.
[e] Nitrogen inventories assume 1000 m^3 of habitat volume per person.

mass of the Belt. At the same distance from Earth are the satellites of Jupiter. The largest four, the Galilean satellites Io, Europa, Ganymede, and Callisto, lie so deep in Jupiter's gravity well and so far inside its intense radiation belts that they are demanding destinations for even flyby spacecraft. The four small inner satellites are in an environment that is essentially not survivable. The two families of small outer satellites, however, are dynamically and probably even chemically indistinguishable from the Trojan asteroids. Saturn also has several small, remote satellites. But the great distance of these bodies from any plausible site of demand for their resources and the very low light levels at such great distances from the Sun (27 times less at Jupiter than at Earth) argue against any short-term economic significance.

The gas-giant outer planets, Jupiter, Saturn, Uranus, and Neptune, offer astronomical quantities of attractive resources situated at the bottom of very deep gravity wells. The easiest of the giant planets to land on and return from, Uranus, is at the very limit of the capability of single-stage nuclear rockets. But if high-performance liquid- or gas-core nuclear rocket engines, or fusion rockets, can be built, then the helium-3 fusion fuel resources of their atmospheres would become accessible to Earth. Uranus alone contains enough helium-3 to support a population of 10 billion people at present-day North American or European consumption levels for more than 10^{15} years, or to support a million times as many people from now until the Sun dies of exhausting its hydrogen fuel.

JOHN S. LEWIS, University of Arizona, Tucson, AZ

SPACE SCIENCE MISSIONS: EARTH. From our vantage point above the Earth, we can view Earth as a whole system, observe the results of complex interactions, and begin to understand how our planet and star are changing. Working with its domestic and international partners, NASA provides accurate, objective scientific data and analysis to advance our understanding of Earth system processes.

Learning more about these processes will enable improved prediction capability for climate, weather, and natural hazards. By studying the Earth as a system and employing an end-to-end strategy to assure that all the information, understanding, and capabilities derived from its research are fully realized, NASA is striving to develop a scientific understanding of the Earth System and its response to natural or human-induced changes.

The Nation now has a system of spacecraft with the ability to characterize the current state of the Earth system. In the years ahead, NASA's fleet will evolve into constellations of smart satellites that can be reconfigured based on the changing needs of science and technology. From there we envision an intelligent and integrated observation network composed of sensors deployed in vantage points from the subsurface to deep space. This "sensorweb" will provide on-demand data and analysis to a wide range of end users in a timely and cost-effective manner. This observation system will have many practical benefits for scientific research, national policymaking, and economic growth.

Current Missions

Acrimsat. The purpose of the Active Cavity Radiometer Irradiance Monitor III (ACRIM III) instrument is to study total solar Irradiance from the Sun. The ACRIM III package is flying on a spacecraft called ACRIMSAT. The spacecraft was launched on December 20, 1999 as a secondary payload on a Taurus launch vehicle from the Western Test Range, Vandenberg Air Force Base, CA. ACRIM III, third in a series of long-term solar-monitoring tools built for NASA by the Jet Propulsion Laboratory, will continue to extend the database first created by ACRIM I, which was launched in 1980 on the Solar Maximum Mission (SMM) spacecraft. ACRIM II followed on the Upper Atmosphere Research Satellite (UARS) in 1991. ACRIMSAT data will be correlated with possible global warming data, ice cap shrinkage data, and ozone layer depletion data. It is theorized that as much as 25 percent of the Earth's total global warming may be solar in origin due to small increases in the Sun's total energy output since the last century. By measuring incoming solar radiation and adding measurements of ocean and atmosphere currents and temperatures, as well as surface temperatures, climatologists will be able to improve their predictions of climate and global warming over the next century. See also **Earth Observing System (EOS)**.

The ACRIMSAT mission is funded by NASA through the Earth Science Programs Office at Goddard Space Flight Center. The ACRIMSAT Project Office at the Jet Propulsion Laboratory (Pasadena, CA) manages the design, fabrication, and test of the ACRIM III instrument and manages the subcontract for the ACRIMSAT spacecraft being built by Orbital Sciences Corporation. The ACRIM III data products will be available through the Langley EOS Data Analysis and Archive Center. See also http://acrim.jpl.nasa.gov/mission.html

Aqua. Aqua was launched on May 8, 2002, and has six Earth-observing instruments on board, collecting a variety of global data sets. Aqua was the first member launched of a group of satellites termed the Afternoon Constellation, or sometimes the A-Train. The second member to be launched was **Aura**, in July 2004, the third member was **PARASOL**, in December 2004, and the fourth and fifth members are **CloudSat** and **CALIPSO**, in May 2006. Expected upcoming missions are **OCO** and **Glory**, with the placement of Glory not yet determined. Once completed, the A-Train will be led by OCO, followed by Aqua, then CloudSat,

CALIPSO, PARASOL, and, in the rear, Aura. See also **Earth Observing System (EOS)**.

NASA's commitment to studying the Earth as a global system continues with the Aqua spacecraft (originally called EOS PM-1). Aqua represents a key contribution by NASA to the U.S. Global Change Research Program. Aqua carries six state-of-the-art instruments in a near-polar low-Earth orbit. The six instruments are the Atmospheric Infrared Sounder (AIRS), the Advanced Microwave Sounding Unit (AMSU-A), the Humidity Sounder for Brazil (HSB), the Advanced Microwave Scanning Radiometer for EOS (AMSR-E), the Moderate Resolution Imaging Spectroradiometer (MODIS), and Clouds and the Earth's Radiant Energy System (CERES). Each has unique characteristics and capabilities, and all six serve together to form a powerful package to observe the Earth's oceans, atmosphere, land, ice and snow covers, and vegetation, providing high measurement accuracy, spatial detail, and temporal frequency. This comprehensive approach to data collection enables scientists to study the interactions among the four spheres of the Earth system — the oceans, land, atmosphere, and biosphere.

Aqua, Latin for "water," is named for the large amount of information that the Aqua spacecraft will collect about the Earth's water cycle. In particular, the Aqua data will include information on water vapor and clouds in the atmosphere, precipitation from the atmosphere, soil wetness on the land, glacial ice on the land, sea ice in the oceans, snow cover on both land and sea ice, and surface waters throughout the world's oceans, bays, and lakes. Such information will help scientists improve the quantification of the global water cycle and examine such issues as whether or not the cycling of water might be accelerating.

In addition to information about the water cycle, Aqua will also provide information on many additional elements of the Earth system. For instance, Aqua will enable studies of the fluxes of radiation from the Sun and from the Earth that combine to constitute the Earth's radiation balance. It will also enable studies of small particles in the atmosphere termed "aerosols" and such trace gases in the atmosphere as ozone, carbon monoxide, and methane. The trace gases each have a potential contribution to global warming, whereas the aerosols are more likely to have a cooling effect. Aqua will also provide observations on vegetation cover on the land, phytoplankton and dissolved organic matter in the oceans, and the temperatures of the air, land, and water. All of these measurements will have the potential to contribute to improved understanding of the changes occurring in the global climate and the role of the interactions among the various elements of the climate system.

One of the most exciting of the potential practical benefits likely to derive from the Aqua data is improved weather forecasting. Aqua will carry a sophisticated sounding system that will allow determination of atmospheric temperatures around the world to an accuracy of 1° Celsius in 1-km-thick layers throughout the troposphere, the lowest portion of the atmosphere. The troposphere extends to an altitude of about 10–15 km, depending on location, and contains most of the global cloud cover. The anticipated 1° Celsius accuracy far exceeds current accuracies from satellite observations and, in conjunction with the moisture profiles also obtainable from the Aqua sounding system, will offer the potential of improved weather forecasting. NASA is working with the U.S. National Oceanic and Atmospheric Administration and the European Center for Medium-Range Weather Forecasts to facilitate the incorporation of the Aqua data in their weather forecasting efforts.

Aqua is one of a series of space based platforms that are central to NASA Earth Science, a long-term study of the scope, dynamics and implications of global change. Aqua is a joint project of the United States, Japan, and Brazil. The Aqua program is composed of Aqua and other spacecraft (including Terra and Aura) and a data distribution system (ESDIS, and Mission Operations Center Implementation Team). Multidisciplinary teams of scientists and researchers from North and South America, Asia, Australia and Europe will put this data to work. See also **Earth Observing System (EOS)**.

Aura. (Launched July 15, 2004) The Aura satellite hosts a suite of scientific instruments designed to make the most comprehensive measurements ever undertaken of atmospheric trace gases. Aura's objective is to study the chemistry and dynamics of the Earth's atmosphere with emphasis on the upper troposphere and lower stratosphere (0–30 km) by employing multiple instruments on a single satellite. The satellite's measurements enable scientists to investigate questions about ozone trends, air quality changes and their linkages to climate change. These observations provide accurate data for predictive models and provide useful information for local and national government agencies. See also **Aura Mission**.

Parasol (Polarization & Anisotropy of Reflectances for Atmospheric Sciences Coupled with Observations from a Lidar). Parasol is the second microsatellite in the Myriade series developed by CNES. It is carrying a wide-field imaging radiometer/polarimeter called POLDER (Polarization and Directionality of the Earth's Reflectances), designed in partnership with the LOA atmospheric optics laboratory in Lille (CNRS-USTL). POLDER is designed to improve our knowledge of the radiative and microphysical properties of clouds and aerosols by measuring the directionality and polarization of light reflected by the Earth-atmosphere system.

Launched by an Ariane 5 G+ (December 2004) from Europe's spaceport in Kourou, French Guiana, Parasol has embarked on an expected two-year mission, flying in formation with Aqua and Aura (NASA), Calipso (NASA/CNES) and CloudSat (NASA/CSA) as part of the so-called A-Train (Fig. 1). These satellites, to be joined later by NASA's Orbiting Carbon Observatory (OCO) in 2008, will for the first time ever combine a full suite of instruments for observing clouds and aerosols, from passive radiometers to active lidar and radar sounders.

The PARASOL mission intends to characterize the radiative properties of clouds and aerosols by exploiting its complementarity with the other instruments in the A-Train formation, which include the CERES and MODIS radiometers on the AQUA satellite, the lidar on CALIPSO and the radar on CLOUDSAT.

The AQUA, CALIPSO and CLOUDSAT missions are intended to fulfill this purpose by collecting measures in different spectral domains (optical and microwave) accessibles to spatial observation, and by combining measures covering larges fields of view with punctual measures. PARASOL, with its ability to measure directional characteristics and light polarization reflectances from land surfaces, will complete the measures collected by the other missions.

The PARASOL mission purpose is to perform measurements of the polarized and multi-directional reflectances, on areas observed by the LIDAR on board CALIPSO as a priority.

The synergy between the AQUA, CALIPSO, CLOUDSAT and PARASOL missions imply three major constraints on this mission, which are:

> The orbit characteristics that are set to: a 705 km altitude; a 98,21° declination (AQUA) or a 98,08° declination (CALIPSO); and the equator time crossing which must be in concordance with the AQUA (13 h30) and CALIPSO time crossing (set between 14 h10 at the beginning of the mission and 12 h50 at the end),
> The launch, which must take place during the activity phase of the constellation other satellites,
> The synergies to achieve on the mission centers, for the orbit control as well as the scientific data processing.

Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO). (Launched: April 28, 2006). The CALIPSO satellite was developed to help scientists answer significant questions and provide new information about the effects of clouds and aerosols (airborne particles) on changes in the Earth's climate. Understanding these components will provide the international science community with a more comprehensive data set that is essential for a better understanding of the Earth's climatic processes. See also **Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO)**.

CloudSat. (Launched: April 28, 2006) CloudSat uses advanced radar to "slice" through clouds to see their vertical structure, providing a completely new observational capability from space. Earlier satellites could only image the uppermost layers of clouds. CloudSat is among the first satellites to study clouds on a global basis. It will look at their structure, composition and effects. This is a cooperative mission with Canada. CloudSat measurements have applications in air quality, weather models, water management, aviation safety, and disaster management.

The key observations are the vertical profiles of cloud liquid water and ice water contents and related cloud physical and radiative properties. The spacecraft payload consists of a millimeter-wave radar. CloudSat will fly

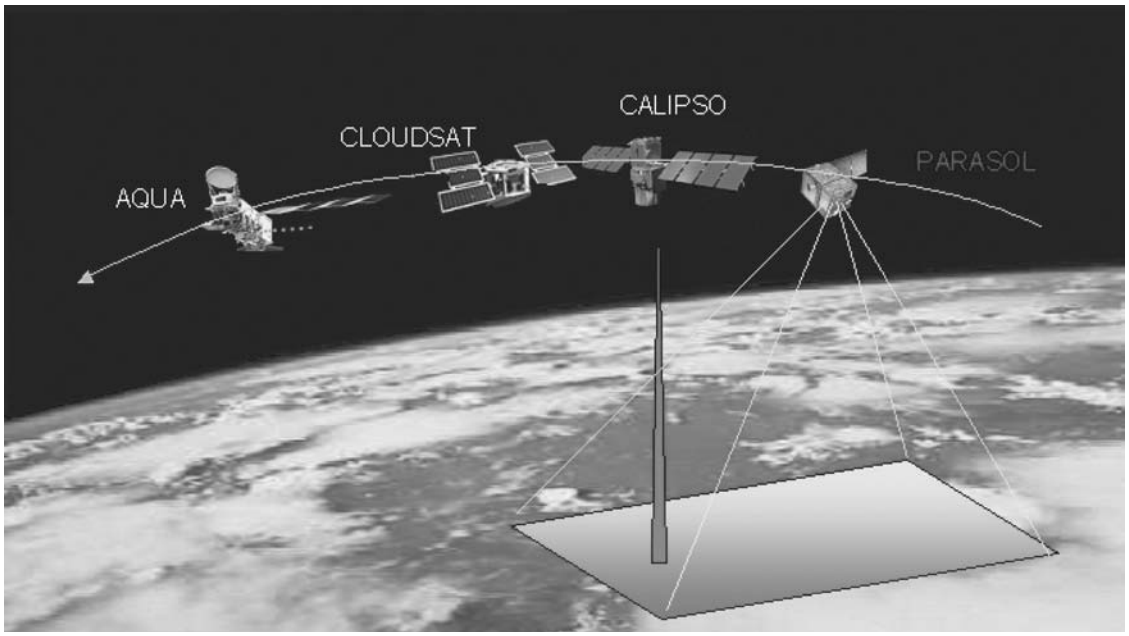

Fig. 1. A-Train formation.

in tight formation with the CALIPSO satellite carrying a backscattering lidar, and these two satellites will follow behind the Aqua satellite in a somewhat looser formation. The combination of data from the CloudSat radar with coincident measurements from CALIPSO and Aqua provides a rich source of information that can be used to assess the role of clouds in both weather and climate. See also **CloudSat**.

Gravity Recovery and Climate Experiment (GRACE). (Launched March 17, 2002) The primary goal of the GRACE mission is to accurately map variations in the Earth's gravity field over its 5-year lifetime. This will provide scientists from all over the world with an efficient and cost-effective way to map the Earth's gravity fields with unprecedented accuracy. The results from this mission will yield crucial information about the distribution and flow of mass within the Earth and its surroundings. See also **Earth System Science Pathfinder (ESSP) Program**.

Ice, Clouds, and Land Elevation Satellite (ICESat). Are the ice sheets that still blanket the Earth' poles growing or shrinking? Will global sea levels rise or fall? NASA has developed the ICESat mission to provide answers to these and other questions — to help fulfill NASA' mission to understand and protect our home planet. The primary goal of ICESat is to quantify ice sheet mass balance and understand how changes in the Earth' atmosphere and climate affect polar ice masses and global sea level. ICESat is also measuring the distribution of clouds and aerosols, as well as surveying land topography, sea ice, and vegetation cover.

Ice sheets are complex and dynamic elements of our climate system. Their evolution has strongly influenced sea level in the past and currently influences the global sea level rise that threatens our coasts. Ice streams that speed up, slow down, and change course illustrate their dynamic nature. Atmospheric factors cause snowfall to vary in space and time across their surfaces. In Antarctica, small ice shelves continue to retreat along the Antarctic Peninsula, and large icebergs are released from its largest ice shelves. In Greenland, the ice margins appear to be thinning and the inland parts of the ice sheet may be thickening. Surface melt water seeps into the ice sheets and accelerates their flow. Some of the factors controlling the mass balance of ice sheets, and their present and future influences on sea level, are just beginning to be understood.

The ICESat mission, part of NASA' Earth Observing System (EOS), was launched in January 12, 2003 from the Western Test Range, Vandenberg Air Force Base, CA. The Geoscience Laser Altimeter System (GLAS) on ICESat will measure ice sheet elevations, changes in elevation through time, height profiles of clouds and aerosols, land elevations and vegetation cover, and approximate sea ice thickness. Future ICESat missions will extend and improve assessments from the first mission, as well as monitor ongoing changes. Together with other aspects of NASA Earth science and current and planned EOS satellites, ICESat will enable scientists to study the Earth' climate and, ultimately, predict how ice sheets and sea level will respond to future climate change. See also **Earth Observing System (EOS)**.

JASON-1. (Launched December, 7, 2001) Jason is an oceanography mission to monitor global ocean circulation, improve global climate predictions, and monitor events such as El Nino conditions and ocean eddies. The Jason-1 satellite carries a radar altimeter, and it is a follow-on mission to the highly successful TOPEX/Poseidon mission, that measured ocean surface topography to an accuracy of 4.2 cm, enabled scientists to forecast the 1997–1998 El Niño, and improved understanding of ocean circulation and its effect of global climate. Jason-1 altimeter data is part of a suite of data provided by other NASA missions — the GRACE mission uses two satellites to accurately measure Earth's mass distribution, and the QuikSCAT scatterometer mission will measure ocean-surface winds. The Delta vehicle was shared with the Thermosphere, Ionosphere, Mesosphere, Energetics and Dynamics (TIMED) mission.

Since the oceans are so large, remote sensing from satellites has proved to be the only way to get global information about these vast, hard-to-measure expanses. Spaceborne altimeters, such as the Poseidon 2 instrument that Jason 1 carries, can calculate ocean heights to within centimeters.

The ocean and atmosphere transport heat from the equatorial regions toward the icy poles and the atmosphere sends heat through a complex, worldwide pattern of winds. As these winds blow across the oceans, they help drive the currents and exchange heat, moisture and gases with the water. While winds create daily, short-term weather changes, the oceans have a slower, much longer-lasting effect on climate. The powerful forces of wind and water combine to help regulate our planet's climate.

Accurate observations of sea-surface height and ocean winds provide scientists with information about the speed and direction of ocean currents and about the heat stored in the ocean that, in turn, reveals global climate variations. Jason 1 will help scientists in their quest to understand these global climate forces.

Weighing about 500 kilograms (about 1,100 pounds), Jason 1 is only one-fifth the weight of TOPEX/Poseidon. After launch, Jason 1 will enter orbit about 10 to15 kilometers (6 to 9 miles) below TOPEX/Poseidon's 1,337-kilometer-altitude (830-mile) orbit. During the next few weeks, Jason 1 will use its thrusters to raise itself into the same orbital altitude as TOPEX/Poseidon, and then move in close behind its predecessor, trailing by about 500 kilometers (300 miles).

The two spacecraft will fly in formation, making nearly simultaneous measurements. The science team will compare the data to make sure the instruments are calibrated exactly. This procedure is expected to take about

six months. Jason 1 will then assume TOPEX/Poseidon's former flight path, and the older satellite will move into a parallel ground track midway between two Jason 1 ground tracks. Jason 1's mission is designed to last three years.

Jason 1 carries five instruments: the Poseidon 2 altimeter, the spacecraft's main instrument, to measure altitude; a microwave radiometer to measure atmospheric water vapor; and three precision location-finding instruments.

Jason-1 completed its 5th year on orbit on 7 December 2006. From its vantage point 1,330 kilometers (860 miles) above Earth, this follow-on to the highly successful TOPEX/Poseidon mission has provided measurements of the surface height of the world's oceans to an accuracy of 3.3 centimeters (1.3 inches). With this milestone, Jason-1 surpasses both its primary and extended mission phases and continues to collect valuable ocean data for researchers and operational users worldwide.

Jason 1 is a joint project between NASA and France's Center National d'Etudes Spatiales. The U.S. portion of the mission is managed for NASA by the Jet Propulsion Laboratory, Pasadena, Calif. See also http://topex-www.jpl.nasa.gov/mission/jason-1.html.

LANDSAT 7. (Launched April 15, 1999, aboard a Delta II from the Western Test Range, Vandenberg Air Force Base, CA.). Landsat 7 systematically provides well-calibrated, multispectral, moderate resolution, substantially cloud-free, sun-lit digital images of the Earth's continental and coastal areas with global coverage on a seasonal basis. It covers the United States every 16 days. Operations were transferred to USGS in Fall 2000.

The Landsat Project is a joint initiative of the U.S. Geological Survey (USGS) and the NASA to gather Earth resource data using a series of satellites. NASA was responsible for developing and launching the spacecrafts, while the USGS is responsible for flight operations, maintenance, and management of all ground data reception, processing, archiving, product generation, and distribution.

The primary objective of the Landsat Project is to ensure a collection of consistently calibrated Earth imagery. Landsat's Global Survey Mission is to establish and execute a data acquisition strategy that ensures repetitive acquisition of observations over the Earth's land mass, coastal boundaries, and coral reefs; and to ensure the data acquired are of maximum utility in supporting the scientific objectives of monitoring changes in the Earth's land surface and associated environment.

Landsat is the longest-running project for acquisition of moderate resolution imagery of the Earth from space. The Landsat 1 satellite was launched in 1972; the most recent, Landsat 7, was launched in 1999. Landsat 7 is a 5000 pound-class satellite designed for a 705 km, Earth mapping orbit with a 16-day repeat cycle. Its payload is a single nadir-pointing instrument, the Enhanced Thematic Mapper Plus (ETM+). The ETM+ provides for an eight-band multispectral scanning radiometer capable of providing high-resolution image information of the Earth's surface. The ETM+ is designed to collect, filter and detect radiation from the Earth in a swath 185 km wide as it passes overhead. It produces approximately 3.8 gigabits of data for each scene, which is roughly equivalent to nearly 15 sets of encyclopedias at 29 volumes per set.

The instruments on the Landsat satellites have acquired millions of images. These images form a unique resource for applications in agriculture, geology, forestry, regional planning, education, mapping, and global change research. See also http://geo.arc.nasa.gov/sge/landsat/.

New Millennium Program Earth Observing-1 (NMP EO-1). The NMP EO-1 Earth Observing-1 (EO-1) is an advanced land-imaging mission that will demonstrate new instruments and spacecraft systems. EO-1 will validate technologies contributing to the significant reduction in cost of follow-on Landsat missions. Launched on a Delta 7320 from Vandenberg Air Force Base, California, November 21, 2000. EO-1 has a 1-year primary mission but was designed to operate for an additional year.

The NMP EO-1 mission includes three advanced land imaging instruments and five revolutionary cross cutting spacecraft technologies. The hyperspectral instrument is the first of its kind to provide images of land-surface in more than 220 spectral colors. The Hyperion will demonstrate the ability to perform detailed spectral mapping with high radiometric accuracy. In the future, an operational version of the Hyperion will allow complex land ecosystems to be imaged and accurately classified. The Advanced Land Imager (ALI) instrument yields almost four times better performance at only one-fourth the cost and weight of the Landsat ETM+. Finally the Linear Etalon Imaging Spectral Array/Atmospheric Corrector (LEISA/AC) is an infrared camera, which can be used to remove the effects of the atmosphere from surface pictures obtained by instruments such as the ALI on EO-1 and Landsat. This instrument will provide scientific return both in terms of improved imagery and hyperspectral sensing capabilities. It will also test a number of new technologies. Because the AC is small and adaptable to different spacecraft configurations, it is a bolt-on instrument, which can be attached to any future Earth imaging spacecraft. The three advanced imaging instruments will lead to a new generation of lighter weight, higher performance and lower cost Landsat-type Earth surface imaging instruments.

The future of Earth science measurements requires that spacecraft have even greater capabilities packaged in more compact and lower cost spacecraft. To this end, EO-1 tests, for the first time, five new technologies that will enable new or more cost-effective approaches to conducting science missions in the 21st Century. These are: the X-band Phased Array Antenna, used for downlinking data gathered by the EO-1 science instruments; Enhanced Formation Flying, an autonomous, onboard, relative navigation and formation flying control; the Pulse Plasma Thruster, used for fine attitude precision control; the Lightweight Flexible Solar Array, an advanced photo-voltaic solar array which utilizes a lightweight solar blanket and shockless, shapedhinge deployment mechanism to achieve two to three times the specific power over conventional solar arrays; and the Carbon-Carbon Radiator, which has superior thermal radiating properties over conventional materials. Future NASA spacecraft will be an order of magnitude smaller and lighter than current versions, and the EO-1 Mission provides the on-orbit demonstration and validation of several technologies to get us there. See also **New Millennium Program (NMP)**.

Quick Scatterometer (QuikSCAT). QuikSCAT mission is intended to record sea-surface wind speed and direction data under all weather and cloud conditions over Earth's oceans. QuikSCAT was initiated as a "quick recovery" mission to help reduce the ocean-wind vector data gap created by the loss of the NASA Scatterometer (NSCAT) on the Japanese Advanced Earth Observing Satellite (ADEOS), which ceased functioning when ADEOS failed on June 30, 1997. See also **Quick Scatterometer (QuikSCAT)**.

SeaWinds (ADEOS-II). (Launched December 14, 2002) The SeaWinds scatterometer is a specialized microwave radar that measures near-surface wind velocity (both speed and direction) under all weather and cloud conditions over Earth's oceans. This is a twin sister to the QuikSCAT sensor and flies on the Japanese ADEOS-II Spacecraft to provide similar observations beyond the QuikSCAT mission. The experiment is a follow-on mission and continues the data series initiated in 1996 by the NSCAT.

Winds over the ocean modulate air-sea changes in heat, moisture, gases and particulates, regulating the crucial bond between atmosphere and ocean that establishes and maintains global and regional climate. Measurements of surface wind velocity can be used in regional and global numerical weather models to improve our ability to predict weather. As the only remote-sensing system to provide accurate, frequent, high-resolution measurements of ocean surface wind velocities, under all weather conditions, scatterometers play an increasingly important role in oceanographic, meteorological and climatic studies.

SeaWinds is an active radar scatterometer. This scatterometer operates by transmitting high-frequency microwave pulses to the ocean surface and measuring the echoed radar pulses bounced back to the satellite. The scatterometer estimates wind speed and direction over the Earth's oceans at 10 meters (33 feet) above the surface of the water. The instrument collects data over ocean, land, and ice in a continuous, 1,800-kilometer-wide band, making approximately 400,000 measurements and covering 90% of Earth's surface in one day. SeaWinds can acquire hundreds of times more observations of surface wind velocity each day than can ships and buoys, and can provide continuous, accurate and high-resolution measurements of both wind speeds and direction regardless of weather conditions. This data is vital for global climate research, operational weather forecasting, and storm warning. It can also be combined with measurements from scientific instruments in other disciplines to understand mechanisms of global climate change and weather patterns.

ADEOS-II beams down SeaWinds-collected science data to ground stations operated by NASA and the National Space Development Agency

of Japan, which then relay them to scientists and weather forecasters. SeaWinds provides ocean wind coverage to an international team of climate specialists, oceanographers and meteorologists interested in discovering secrets of climate patterns and improving the speed with which emergency preparedness agencies can respond to fast-moving weather fronts, floods, hurricanes, tsunamis and other natural disasters.

SeaWinds (ADEOS-II) is a joint mission with the NASDA. The SeaWinds Project is managed for NASA by the Jet Propulsion Laboratory, a division of the California Institute of Technology.

Solar Radiation and Climate Experiment (SORCE). SORCE is a NASA-sponsored satellite mission that will provide state-of-the-art measurements of incoming x-ray, ultraviolet, visible, near-infrared, and total solar radiation. SORCE represents the merging of the EOS Solar Stellar Irradiance Comparison Experiment (SOLSTICE) and the Total Solar Irradiance Mission (TSIM). The measurements provided by SORCE specifically address long-term climate change, natural variability and enhanced climate prediction, and atmospheric ozone and UV-B radiation. These measurements are critical to studies of the Sun, its effect on our Earth system, and its influence on humankind.

Solar radiation is the dominant, direct energy input into the terrestrial ecosystem, and it affects all physical, chemical, and biological processes. The Sun provides a natural influence on the Earth's atmosphere and climate. In order to understand mankind's roles in climate change, the Sun's impact must first be understood.

SORCE measures the Sun's output with the use of state-of-the-art radiometers, spectrometers, photodiodes, detectors, and bolometers engineered into instruments mounted on a satellite observatory. The SORCE satellite orbits around the Earth accumulating solar data. Spectral measurements identify the irradiance of the Sun by characterizing the Sun's energy and emissions in the form of color that can then be translated into quantities and elements of matter. Data obtained by the SORCE experiment will be used to model the Sun's output and to explain and predict the effect of the Sun's radiation on the Earth's atmosphere and climate.

The SORCE spacecraft launched on January 25, 2003 on a Pegasus XL launch vehicle from the Eastern Test Range, Kennedy Space Center, FL. to provide NASA with precise measurements of solar radiation. It launched into a 645 km, 40 degree orbit and is operated by the Laboratory for Atmospheric and Space Physics (LASP) at the University of Colorado. It will continue the precise measurements of total solar irradiance (TSI) that began with the ERB instrument in 1979 and has continued to the present with the ACRIM series of measurements. SORCE will also provide the measurements of the solar spectral irradiance from 1 nm to 2000 nm, accounting for 95% of the spectral contribution to TSI. SORCE carries four instruments including the Total Irradiance Monitor (TIM), Solar Stellar Irradiance Comparison Experiment (SOLSTICE), Spectral Irradiance Monitor (SIM), and the XUV Photometer System (XPS). See also http://lasp.colorado.edu/sorce/.

Sounding Rockets. Sounding rockets take their name from the nautical term "to sound", which means to take measurements. Sounding rockets are used to study the Earth's upper atmosphere, ionosphere, and aurora. Also, since sounding rockets can get above the atmosphere, they are used to study astronomical targets in the ultraviolet and x-ray portions of the electromagnetic spectrum. NASA launches an average of 20 sounding rockets each year. See also **Sounding Rockets**.

Terra. (Launched December 18, 1999) Terra (formerly EOS AM-1) is the flagship satellite of NASA's Earth observing systems. Terra is the first EOS (Earth Observing System) platform and provides global data on the state of the atmosphere, land, and oceans, as well as their interactions with solar radiation and with one another. See also **Terra Satellite (EOS AM-1)**.

Tropical Rainfall Measuring Mission (TRMM). (Launched November 27, 1997) TRMM is a joint mission between NASA and the National Space Development Agency (NASDA) of Japan. TRMM is particularly devoted to determining rainfall in the tropics and subtropics of the earth. These regions make up about two thirds of the total rainfall on Earth and are responsible for driving our weather and climate system. TRMM will contribute to a better understanding of where and how much the winds blow, where the clouds form and rain occurs, where floods and droughts will occur, and how the winds drive the ocean currents. See also **Tropical Rainfall Measuring Mission (TRMM)**.

Future Missions

Aquarius. (Launch Date: September 5, 2009) Aquarius is a focused satellite mission to measure global sea surface salinity (SSS). Its instruments will measure changes in SSS equivalent to about a "pinch" (i.e., 1/6 of a teaspoon) of salt in 1 gallon of water. By measuring SSS over the globe with such unprecedented precision, Aquarius will answer long-standing questions about how our oceans respond to climate change and the water cycle. For example, monthly SSS maps will give clues about changes in freshwater input and output to the ocean associated with precipitation, evaporation, ice melting, and river runoff. Aquarius data will also be used to track the formation and movement of huge water masses that regulate ocean circulation and Earth's climate.

The mission will be led by principal investigator Dr. Gary Lagerloef of Earth & Space Research. Goddard Space Flight Center (GSFC) will build and calibrate the highly accurate radiometers that are crucial for the detection of ocean salinity. Jet Propulsion Laboratory (JPL) will design and build the scatterometer that helps to minimize measurement errors due to sea surface roughness. JPL will manage the mission until launch when GSFC assumes this duty. Data processing, dissemination, and archiving tasks will be shared between GSFC and JPL.

NASA will partner with the Argentine space program CONAE on the Aquarius mission, building on a successful long- standing relationship between NASA and Argentina. Multiple universities and corporate and international partners will be involved in the Aquarius mission.

Aquarius is named after the Water Bearer constellation because of its objective to explore the role of the water cycle in ocean circulation and climate. Aquarius will orbit the earth for at least three years, repeating its global pattern every 7 days. Within two months, Aquarius will collect as many sea surface salinity measurements as the entire 125-year historical record from ships and buoys, and provide measurements over the 25 percent of the ocean where no previous observations have been made. See also http://aquarius.gsfc.nasa.gov/.

Geostationary Operational Environmental Satellite (GOES) N Series — GOES N/O/P. (Launch Date: May 1, 2008) The Geostationary Operational Environmental Satellite Program (GOES) is a joint effort of NASA and the National Oceanic and Atmospheric Administration (NOAA). Currently, the GOES system consists of GOES-12 operating as GOES-East and GOES-10 operating as GOES-West. GOES-N/O/P are the next satellites in the series and are currently under development. GOES-N is scheduled to launch in 2006, GOES-O in 2007 and GOES-P in 2008. These spacecraft help meteorologists observe and predict local weather events, including thunderstorms, tornadoes, fog, flash floods, and other severe weather. In addition, GOES observations have proven helpful in monitoring dust storms, volcanic eruptions, and forest fires. The benefits that directly enhance the quality of human life and protection of Earth's environment include:

- Supports the search and rescue satellite aided system (SARSAT)
- Contributes to the development of worldwide environmental warning services and enhancements of basic environmental services
- Improves the capability for forecasting and providing real-time warning of solar disturbances
- Provides data that may be used to extend knowledge and understanding of the atmosphere and its processes

The next series, GOES-N/O/P has several new top-level capabilities. These include changing the weather facsimile service from analog to digital: expanded measurements for the space environment monitoring instruments; a new dedicated channel for the Emergency Managers Weather Information Network; and most importantly, a more stable platform for supporting the improved imager, sounder and x-ray imager instruments.

GOES-N/O/P provides weather imagery and quantitative sounding data used to support weather forecasting, sever storm tracking, and meteorological research. This is a reimbursable project for NOAA. NASA builds and launches the satellites. NOAA operates the satellites post commissioning and check-out period and uses the data in weather forecasts, disaster management, public health, and aviation safety.

The launch of the prototype Synchronous Meteorological Satellite, SMS-A, in May 1974 inaugurated the series of geosynchronous satellites that have provided systematic, continuous observations of weather patterns.

Following the launch of a second prototype, SMS-B, in February 1975, the GOES program was inaugurated. GOES imagery is commonly featured on many TV weather reports across the United States and the world. The GOES Program maintains 2 satellites operating in conjunction to provide observational coverage of 60% of the earth. The GOES satellite system has remained an essential cornerstone of weather observations and forecasting for over 25 years.

The GOES spacecraft serve as complementary satellites to the Polar Operational Environmental Satellite (POES) system. Where the GOES satellites provide near-term data from the continental United States and Hawaii, the polar-orbiting spacecraft provide full global data for short- and long-range forecast models, climate modeling, and various other secondary missions. See also **Geostationary Operational Environmental Satellite (GOES)**.

Global Precipitation Measurement (GPM). (Launch Date: June 1, 2013). GPM is a joint mission with the Japan Aerospace Exploration Agency (JAXA) and other international partners. Building upon the success of the Tropical Rainfall Measuring Mission (TRMM), it will initiate the measurement of global precipitation, a key climate factor. Its science objectives are: to improve ongoing efforts to predict climate by providing near-global measurement of precipitation, its distribution, and physical processes; to improve the accuracy of weather and precipitation forecasts through more accurate measurement of rain rates and latent heating; and to provide more frequent and complete sampling of the Earth's precipitation. GPM is envisioned to consist of a core spacecraft to measure precipitation structure and to provide a calibration standard for the constellation spacecraft, an international constellation of NASA and contributed spacecraft to provide frequent precipitation measurements on a global basis, calibration/validation sites distributed globally with a broad array of precipitation-measuring instrumentation, and a global precipitation data system to produce and distribute global rain maps and climate research products. See also http://gpm.gsfc.nasa.gov/.

Landsat Data Continuity Mission (LDCM). (Launch Date: July 11, 2011) LDCM is a joint NASA-United States Geological Survey (USGS) mission to extend the Landsat record of multispectral, 30-meter (98 foot) resolution, seasonal, global coverage of the Earth's land surface. The Land Remote Sensing Policy Act of 1992 directs NASA and USGS to assess various system development and management options for a satellite system to succeed Landsat 7. NASA and USGS are working together on the Landsat Data Continuity Mission (LDCM) to meet this goal, and to ensure continued collection of Landsat data. In addition to the primary goal of maintaining "data continuity with the Landsat system," the Land Remote Sensing Policy Act of 1992 set two additional goals for LDCM. They are to serve "the civilian, national security, commercial, and foreign policy interests of the United States," and to "incorporate system enhancements... which may potentially yield a system that is less expensive to build and operate and more responsive to users."

The 1992 Act expressed a preference for "private-sector funding and management". To that end, NASA and USGS pursued a private-public partnership for procuring LDCM data, and awarded study phase contracts to two commercial companies (DigitalGlobe and Resource21) during 2002. NASA cancelled the final Request for Proposal (RFP) on September 26, 2003, following an evaluation of the responses to the solicitation. NASA decided that awarding a contract was not in the best interest of the U.S. Government on the basis of proposal evaluations. Since that time, other options for implementing LDCM have been under consideration.

On August 5, 2004, a Request for Information (RFI) was issued to solicit information on innovative approaches for the development and incorporation of a new Operational Land Imager and also for a potential stand-alone mission. All the RFI documents can be found at this web site under procurement or at the NASA Acquisition Internet Service.

One of the key objectives of LDCM is to make all Landsat-type data available at affordable cost. This will enable the many different sectors of the population — farmers, school children, business leaders, scientists, state and federal governments and many others to continue to utilize this data for high quality research and applications. See also **Satellites (Scientific and Reconnaissance)**.

NPOESS Preparatory Project (NPP). (Launch Date: September 30, 2009) The NPOESS Preparatory Project (NPP) is a joint mission to extend key measurements in support of long-term monitoring of climate trends and of global biological productivity. It extends the measurement series being initiated with EOS Terra and AQUA by providing a bridge between NASA's EOS missions and the National Polar-orbiting Operational Environmental Satellite System (NPOESS) of the Integrated Program Office (IPO). See also **Earth Observing System (EOS)**.

Ocean Surface Topography Mission (OSTM). (Launch Date: June 15, 2008). OSTM will measure sea surface height to an accuracy of < 4 centimeters (< 1.5 inch) every ten days. Sea surface topography measured by satellite altimeters has numerous applications important to global environmental monitoring including predicting hurricane intensification, improving tide models, mapping deep ocean bathymetry, monitoring and forecasting El Niño Southern Oscillation, measuring the rate of global sea level rise, and charting surface currents. Applications: coastal zone management, disaster management.

OSTM is a cooperative effort between NASA, the National Oceanic and Atmospheric Administration (NOAA), the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) and the Center National d'Etudes Spatiales (CNES), the space agency of France. OSTM is a follow-on to Jason-1 and will provide continuity of ocean topography measurements beyond Jason-1 and TOPEX/Poseidon. See also **Earth Observing System (EOS)**.

Orbiting Carbon Observatory (OCO). (Launch Date: September 15, 2008). OCO provides space-based observations of atmospheric carbon dioxide (CO_2), the principal human-initiated driver of climate change. This mission uses mature technologies to address NASA's highest priority carbon cycle measurement requirement. OCO will generate precise global maps of the abundance of CO_2 in the Earth's atmosphere. Scientists will then analyze OCO data to improve our understanding of the natural processes and human activities that regulate the distribution of CO_2 in the atmosphere. See also **Orbiting Carbon Observatory (OCO)**.

Past Missions

Challenging Mini-Satellite Payload for Geo-scientific Research and Applications program (CHAMP). (Launched July 15, 2000) CHAMP will generate for the first time simultaneously highly precise gravity and magnetic field measurements over a 5 years period. This will allow us to detect besides the spatial variations of both fields also their variability with time. The CHAMP mission will open a new era in geopotential research and will become a significant contributor to the Decade of Geopotentials. It will perform the following three tasks: 1) Mapping of the Earth's global long to medium wavelength gravity field and temporal variations with applications in the geophysics, geodesy and oceanography; 2) Mapping of the Earth's global magnetic field and temporal variations with applications in geophysics and solar terrestrial physics; 3) Atmosphere/ionosphere sounding with applications in global climate studies, weather forecasting, disaster research and navigation.

CHAMP-derived data will serve as an ideal basis for a further refinement of modern satellite surveying methods and constructing digital terrain models covering large land and ice areas for remote sensing applications and for cartography. The evaluation of all three kinds of signals CHAMP will be observing will allow a complete and integrated modeling of the structure and dynamics of the Earth core and mantle. Such an improvement will strongly enhance studies concerning the structure and composition of the Earth's interior and will open new insights and application areas in geodesy, solid Earth physics and oceanography.

Within the next few years, a number of dedicated satellite missions will be available for gravity field determination from space (CHAMP, GRACE, GOCE). CHAMP is a cooperative project with Germany with NASA providing a GPS Blackjack Flight receiver built by the Jet Propulsion Laboratory (JPL). See also http://www.gfz-potsdam.de/pb1/op/champ/.

Earth Radiation Budget Satellite (ERBS). NASA's Earth Radiation Budget Satellite (ERBS) was designed to investigate how energy from the sun is absorbed and re-radiated by the Earth. Understanding this process helps reveal patterns in Earth's weather. One of the longest-running spacecraft missions to date, ERBS was launched on October 5, 1984 on the Space Shuttle Challenger and retired on October 14, 2005. The spacecraft was expected to have a two-year operation life, but ultimately, the mission

provided scientific data about the Earth's ozone layer for more than two decades.

What's more, ERBS observations have also been used to determine how human activities such as the use of chlorofluorocarbons (CFCs) and the burning of fossil fuels affect Earth's radiation balance. Data on the ozone layer provided by ERBS was key in the international community's decision-making process during the Montreal Protocol Agreement, which has resulted in a near elimination of CFCs in industrialized countries. It was ERBS data, in part, that led to the understanding that CFCs deplete atmospheric ozone concentrations.

The mission was part of the NASA's three satellite Earth Radiation Budget Experiment (ERBE), designed to investigate how energy from the Sun is absorbed and re-emitted by the earth. This process of absorption and re-radiation is one of the principal drivers of the Earth's weather patterns. Observations from ERBS are also used to determine the effects of human activities (such as burning fossil fuels and the use CFCs) and natural occurrences (such as volcanic eruptions) on the Earth's radiation balance. In addition to the ERBE scanning and nonscanning instruments, the satellite also carried the Stratospheric Aerosol Gas Experiment (SAGE II). The ERBS was the first of three ERBE platforms which would eventually carry the ERBE Instruments. Goddard Space Flight Center built the satellite and it was launched by the Space Shuttle Challenger in 1984. The second ERBE Instrument was aboard the NOAA-9 satellite when it was launched in January of 1985, and the third was aboard the NOAA-10 satellite when it was launched in October of 1986. Although the scanning instruments on board all three ERBE satellites are no longer operational, the nonscanning instruments are all presently functioning. See also http://asd-www.larc.nasa.gov/erbe/.

Geostationary Operational Environmental Satellite, I-M Series (GOES-M). GOES-M provides weather imagery and quantitative sounding data used to support weather forecasting, sever storm tracking, and meteorological research. This is a reimbursable project for NOAA. NASA builds and launches the satellites. NOAA operates the satellites post commissioning and check-out period and uses the data in weather forecasts, disaster management, public health, and aviation safety. See also **Geostationary Operational Environmental Satellite (GOES)**.

NOAA Polar Operational Environmental Satellites, (POES) Series K/L/M (NOAA-M). (Launched on June 24, 2002) NOAA-M broadcasts data directly to thousands of users around the world and continues to provide a polar-orbiting platform to support the environmental monitoring instruments for imaging and measurement of the Earth's atmosphere, its surface, and cloud cover. Observations include information about Earth radiation, sea and land surface temperature, atmospheric vertical temperature, water vapor, and ozone profiles in the troposphere and stratosphere. See also **Polar-Orbiting Environmental Satellite (POES)**.

SAGE-3 (Meteor). (Launched December 10, 2001) The Stratospheric Aerosol and Gas Experiment III (SAGE III) instrument is one of nine experiments on the Russian Meteor-3 M (1) spacecraft. It provides accurate, long-term measurements of ozone, aerosols, water vapor and other key parameters of Earth's atmosphere. These observations are crucial for providing a better understanding of how natural processes and human activities may influence our climate.

Since the 1950's, it has become increasingly clear that human activities are modifying the composition of the atmosphere on a global scale. As the result of industrialization, the concentration of carbon dioxide has increased by about 20% during this period. More recently, the stratospheric concentrations of chemically active gases containing chlorine, bromine, and fluorine have dramatically increased. These trends have created issues of global interest including global warming and declining levels of ozone (both globally and in the ozone "hole" in the Antarctic). It has become increasingly clear, however, that these processes do not occur independently of one another and can only be understood in the context of a global system. Accurate and precise measurements are needed to unravel complex and interactive relationships between chemical, radiative, and dynamical processes in the atmosphere, ocean, and on land. As a result, in 1991 NASA initiated a comprehensive program to understand the Earth's atmosphere, oceans, land, and cryosphere (ice and snow) as a single, complex, interactive system. NASA's Earth Observing System (EOS) consists of a series of spaceborne instruments to monitor crucial components of the Earth system, an advanced data handling system, and teams of scientists who will evaluate on-going climate change and predict future changes. Ultimately, EOS will produce scientifically sound recommendations for environmental policy to national and international bodies to mitigate or prepare for these changes.

SAGE III's role in the EOS program is to provide global, long-term measurements of key components of the Earth's atmosphere. The most important of these are the vertical distribution of aerosols and ozone from the upper troposphere through the stratosphere. In addition, SAGE III also provides unique measurements of temperature in the stratosphere and mesosphere and profiles of trace gases such as water vapor and nitrogen dioxide that play significant roles in atmospheric radiative and chemical processes. See also **Earth Observing System (EOS)**.

SAGE III is a grating spectrometer that measures ultraviolet/visible energy. It relies upon the flight-proven designs used in the Stratospheric Aerosol Measurement (SAM I) and SAGE I and II instruments. The new SAGE III design incorporates Charge Coupled Device (CCD) array detectors and a 16 bit A/D converter. Combined, these devices allow for wavelength calibration, a self-consistent determination of the viewing geometry, lunar occultation measurements, and expanded wavelength coverage. SAGE III sensor assembly is illustrated below and consists of pointing and imaging subsystems and a UV/visible spectrometer. The pointing and imaging systems are employed to acquire light from either the Sun or Moon by vertically scanning across the object. The spectrometer uses an 800 element CCD linear array to provide continuous spectral coverage between 290 and 1030 nm. Additional aerosol information is provided by a discrete photodiode at 1550 nm. This configuration enables SAGE III to make multiple measurements of absorption features of target gaseous species and multi-wavelength measurements of broadband extinction by aerosols. These measurements are vital inputs to the global scientific community for improved understanding of climate, climate change, and human-induced ozone trends.

SAGE III is a joint mission between NASA and the Russian Space Agency (RSA). The SAGE III instrument was developed and managed by NASA Langley Research Center and was built by Ball Aerospace in Boulder, CO. Three copies were produced. One instrument is mounted on the Meteor-3 M spacecraft and a second will be place in orbit on the International Space Station in 2005. See also http://www-sage3.larc.nasa.gov/.

Shuttle Radar Topography Mission (SRTM). (Launched February 11, 2000) The Shuttle Radar Topography Mission (SRTM) obtained elevation data on a near-global scale to generate the most complete high-resolution digital topographic database of earth. SRTM consisted of a specially modified radar system that flew onboard the Space Shuttle Endeavor during an 11-day mission in February of 2000. SRTM collected an unprecedented 8.6 Terabytes of interferometric C-band Synthetic Aperture Radar (SAR) data (equivalent to about 14,317 CDs). This data will be processed to produce a rectified terrain-corrected mosaic of approximately 80% of the Earth's land surface topography (between 60 degrees North and 56 degrees South latitude) at 30-meter (98 foot) resolution. This would be the most accurate and complete topographic map of Earth's surface that has ever been assembled.

The processed SRTM radar data can be tailored to meet the needs of the military, civil, and scientific user communities. But other uses of this data include improved water drainage modeling, more realistic flight simulators, navigation safety, better locations for cell phone towers, and even improved maps for backpackers. Just about any project that requires accurate knowledge of the shape and height of the land can benefit from this data. Some examples are flood control, soil conservation, reforestation, volcano monitoring, earthquake research, and glacier movement monitoring.

To acquire topographic (elevation) data, the SRTM payload was outfitted with two radar antennas, and a technique called *radar interferometry* was used. In radar interferometry, two radar images are taken from slightly different locations. Differences between these images allow for the calculation of surface elevation, or change. One antenna was located in the shuttle's payload bay, the other on the end of a 60-meter (200-foot) mast that extended from the payload pay once the Shuttle was in space. Virtually all of the land surface between +/− 60 degrees latitude was mapped by SRTM. Processing of the C-band data took two years. During this time, JPL generated and released "showpiece" derived products.

SRTM is an international project spearheaded by the National Geospatial-Intelligence Agency (NGA), NASA, NIMA, and the German and Italian space agencies. See also http://www2.jpl.nasa.gov/srtm/.

Total Ozone Mapping Spectrometer (TOMS)-Earth Probe (EP). The Total Ozone Mapping Spectrometer, launched in July 1996 onboard an Earth Probe Satellite (TOMS/EP), continues NASA's long-term daily mapping of the global distribution of the Earth's atmospheric ozone. TOMS/EP will again take high-resolution measurements of the total column amount of ozone from space that began with NASA's Nimbus-7 satellite in 1978 and continued with the TOMS aboard a Russian Meteor-3 satellite until the instrument stopped working in December 1994. This NASA-developed instrument, measures ozone indirectly by mapping ultraviolet light emitted by the Sun to that scattered from the Earth's atmosphere back to the satellite. The TOMS instrument has mapped in detail the global ozone distribution as well as the Antarctic "ozone hole," which forms September through November of each year.

In addition to ozone, TOMS measures sulfur dioxide released in volcanic eruptions. The U.S. Federal Aviation Administration (FAA) is studying ways to use these measurements to detect volcanic ash clouds that are hazardous to commercial aviation.

Ozone, a molecule made up of three oxygen atoms, shields life on Earth from the harmful effects of the ultraviolet radiation of the Sun. The increased amounts of ultraviolet radiation that would reach the Earth's surface because of ozone depletion could increase the incidence of skin cancer and cataracts in humans, harm crops and interfere with marine life.

Researchers face two crucial problems in ozone studies — finding a slow, long-term trend among a variety of short-term trends, and ascertaining how much of the change in global ozone is due to human activities and how much is attributable to natural atmospheric processes. In order to separate these factors, scientists must record data over at least a complete solar cycle, 11 years. TOMS instruments aboard Nimbus-7 and Meteor-3 satellites have proved invaluable in meeting this requirement.

The TOMS instrument is a second-generation backscatter ultraviolet ozone sounder. TOMS can measure "total column ozone" — the total amount of ozone in a "column" of air from the Earth's surface to the top of the atmosphere — under all daytime observing and geophysical conditions. TOMS observations cover the near ultraviolet region of the electromagnetic spectrum, where sunlight is absorbed only partially by ozone.

TOMS/EP measures total ozone by observing both incoming solar energy and backscattered ultraviolet (UV) radiation at six wavelengths. "Backscattered" radiation is solar radiation that has penetrated to the Earth's lower atmosphere and is then scattered by air molecules and clouds back through the stratosphere to the satellite sensors. Along that path, a fraction of the UV is absorbed by ozone. By comparing the amount of backscattered radiation to observations of incoming solar energy at identical wavelengths, scientists can calculate the Earth's albedo, the ratio of light reflected by Earth compared to that it receives. Changes in albedo at the selected wavelengths can be used to derive the amount of ozone above the surface.

TOMS makes 35 measurements every 8 seconds, each covering 30 to 125 miles (50 to 200 kilometers) wide on the ground, strung along a line perpendicular to the motion of the satellite. Almost 200,000 daily measurements cover every single spot on the Earth except areas near one of the poles, where the Sun remains close to or below the horizon during the entire 24-hour period.

The extremely high quality of TOMS ozone data has also helped scientists in detecting a small but steady long-term damage to the ozone layer over several parts of the globe, including most of the heavily populated areas in the northern mid-latitudes. This discovery led to the curtailment of the production of ozone-depleting chemicals through an international treaty signed in Montreal in the 1980s. To ensure that ozone data will be available throughout the next decade, NASA will continue the TOMS program using U.S. and foreign launches.

The TOMS program is managed by NASA's Goddard Space Flight Center, Greenbelt, MD. See also http://jwocky.gsfc.nasa.gov/; and http://toms.gsfc.nasa.gov/eptoms/ep.html.

TOPEX/Poseidon. (Launched August 10, 1992) TOPEX/Poseidon monitored global ocean circulation, improved global climate predictions, and tracked El Niño conditions and ocean eddies. After over 62,000 orbits, the satellite has ceased operations. TOPEX/Poseidon remains in orbit 830 miles above the Earth, posing no threat to the planet.

The mission's most important achievement was to determine the patterns of ocean circulation — how heat stored in the ocean moves from one place to another. Another of the mission's major accomplishments was to develop the most accurate ever global ocean tide models.

Furthermore, TOPEX/Poseidon was the first mission to demonstrate that the Global Positioning System could be used to determine a spacecraft's exact location and track it in orbit. Knowing the satellite's precise position to within 2 centimeters (less than 1 inch) in altitude was a key component in making accurate ocean height measurements possible.

TOPEX/Poseidon used the global perspective available only from space to develop maps of ocean topography showing the barely perceptible hills and valleys of the sea surface. This effort significantly expanded the knowledge developed from shipboard research, which is limited to specific locations. From TOPEX/Poseidon data, scientists calculated speed and direction of ocean currents worldwide to better understand how the oceans transport heat from the Earth's equatorial region toward the poles, thus regulating global climate.

Jason, a follow-on oceanography mission launched in December 2001, is continuing TOPEX/Poseidon's study of ocean circulation and its effects on the Earth's climate. Jason precisely maps the surface height, wind speed and wave height of 95 percent of Earth's ice-free oceans every 10 days. The data provide invaluable input for short-term weather forecasting, long-term climate forecasting and prediction models. In the few years that Jason and TOPEX/Poseidon operated in tandem, they provided twice the coverage of the sea surface and allowed scientists to study smaller features than could be seen by one satellite. See also http://topex-www.jpl.nasa.gov/index.html.

Upper Atmosphere Research Satellite (UARS). After a 14-year deployment on a mission to collect data on Earth's atmosphere and its interactions with the Sun, NASA's Upper Atmosphere Research Satellite (UARS) ceased operations on December 14, 2005. Launched from the Space Shuttle Discovery on September 15, 1991, UARS orbited the Earth more than 78,000 times, using 10 onboard scientific instruments to collect data on a variety of chemicals, including carbon dioxide, ozone, chlorine, methane, nitrogen oxides and chlorofluorocarbons.

As a result, scientists have gained a better understanding of the energy input, chemistry and dynamics of the upper atmosphere and the coupling between the upper and lower atmosphere. As the first satellite dedicated to studying stratospheric science, UARS focused on the processes that lead to ozone depletion, complementing and amplifying the measurements of total ozone made by the Total Ozone Mapping Spectrometer (TOMS) onboard NASA's Nimbus-7 and the Russian Meteor-3 satellites. UARS also measured winds and temperatures in the stratosphere, as well as the energy input from the Sun, research that is now being applied to improve weather forecasting models and help scientists understand the forces behind global climate change.

Before UARS, little was known about the atmospheric region between 80 kilometers (50 miles) and 300 kilometers (186 miles) above the Earth, since radio-equipped balloons would explode at that altitude, and ordinary satellites burn up. UARS orbited at a safe 600-kilometer (373 miles) altitude, aiming its cameras at the atmosphere below. Although the mission was originally intended for only a three-year mission, its deployment was long enough to observe an entire 11-year solar cycle. Some of the mission's most important contributions came from the four instruments onboard that measured concentrations and distribution of gases important to ozone depletion, climate change and other atmospheric phenomena. Data collected from UARS offered conclusive evidence that chlorine in the atmosphere — originating from human-produced chlorofluorocarbons — is at the root of the ozone hole.

In all, the ten UARS instruments have provided the most complete data on upper atmospheric energy inputs, winds, and chemical composition ever gathered. Together, these observations constitute a highly integrated investigation of the nature of the upper atmosphere, and help define the role of the upper atmosphere in climate and climate variability. In its first two weeks of operation, UARS data confirmed the polar ozone-depletion theories by providing three-dimensional maps of ozone and chlorine monoxide near the South Pole during development of the 1991 ozone hole.

Moreover, UARS collected data on the chemistry, dynamics and radiative inputs to the upper atmosphere far beyond its designed lifetime. UARS was designed to last 18 months, but upgrades extended its life for years beyond its expected lifespan. The United Kingdom and Canada both provided instruments for this mission, the first spacecraft launched as part of NASA's systematic, comprehensive study of the Earth system.

NASA has no plans to recover the UARS spacecraft, which will continue to passively orbit Earth until it re-enters the planet's atmosphere and burns up in 2009 or 2010. See also http://umpgal.gsfc.nasa.gov/.

SPACE SCIENCE MISSIONS: SOLAR SYSTEM. Planetary exploration missions are conducted by some of the most sophisticated robots ever built. Through them we extend our senses to the farthest reaches of the solar system and into remote and hostile environments, where the secrets of our origins and destiny lie hidden. The coming years of solar system exploration promise to be the most exciting and productive yet, as we explore entirely new worlds and probe in even greater detail the fascinating environments we have discovered.

Current Missions

Cassini-Huygens. The *Cassini-Huygens* Mission is in the midst of a detailed study of Saturn, its rings, its magnetosphere, its icy satellites, and its moon Titan. Cassini also delivered a probe (called *Huygens*, provided by the European Space Agency) to Titan, and has remained in orbit around Saturn. Cassini-Huygens was launched on October 15, 1997; and arrived at Saturn on June 30, 2004).

Four NASA spacecraft have been sent to explore Saturn. Pioneer 11 was first to fly past Saturn in 1979. Voyager 1 flew past a year later, followed by its twin, Voyager 2, in 1981.

The Cassini spacecraft is the first to explore the Saturn system of rings and moons from orbit. The European Space Agency's *Huygens Probe* dove into Titan's thick atmosphere. The sophisticated instruments on both spacecraft are providing scientists with vital data and the best views ever of this mysterious, vast region of our solar system.

Cassini-Huygens is an international collaboration between three space agencies. Seventeen nations contributed to building the spacecraft. The Cassini orbiter was built and managed by NASA's Jet Propulsion Laboratory. The *Huygens probe* was built by the European Space Agency. The Italian Space agency provided Cassini's high-gain communication antenna. More than 250 scientists worldwide are studying the data streaming back from Saturn on a daily basis. See also **Cassini-Huygens Mission to Saturn and Titan**.

Deep Impact. Deep Impact's probe slammed into the nucleus of comet Tempel 1 right on schedule, releasing an immense cloud of fine powdery material. The team analyzed the data returned by ground- and space-based observatories, as well as the spacecraft's own instruments. After its encounter with comet Tempel 1, the spacecraft successfully executed a trajectory correction maneuver that put it on a path to fly past Earth on Dec. 31, 2007. The burn preserves options for future use of this accomplished comet hunter. (Launched 2005 January 12; Tempel 1 Impact: 2005 July 4). See also **Discovery Program**.

Mars Exploration Rovers. Two powerful new Mars rovers are on the red planet. With far greater mobility than the 1997 Mars Pathfinder rover, these robotic explorers are able to trek up to 100 meters (about 110 yards) across the surface each Martian day. Each rover carries a sophisticated set of instruments that allow it to search for evidence of liquid water that may have been present in the planet's past. The rovers are identical to each other, but will land at different regions of Mars. The first rover, named Spirit, was launched 2003 June 10, and arrived at Mars on 2004 January 4. The second rover, named Opportunity, launched July 7, and arrived at Mars on 2004 January 25. See also **Mars Exploration Rover Mission**.

Mars Express/Analyzer of Space Plasmas and Energetic Atoms (ASPERA). NASA is participating in Mars Express, which is exploring the atmosphere and surface of Mars from polar orbit. Our contribution to the energetic neutral atoms analyzer instrument is called ASPERA-3. ASPERA-3 studies the interaction between the solar wind and the atmosphere of Mars, and attempt to find out what happened to the large amount of water that was once on Mars. Mars Express was successfully launched on June 2, 2003 atop a Soyuz-Fregat launcher from the Baikonur Cosmodrome in Kazakhstan. See also **Mars Exploration Program**.

Mars Global Surveyor. Launched November 7, 1996, the Mars Global Surveyor became the first successful mission to the red planet in two decades. After a year and a half spent trimming its orbit from a looping ellipse to a circular track around the planet, the spacecraft began its prime mapping mission in March 1999. It has continued to observe the planet from a low-altitude, nearly polar orbit ever since. See also **Mars Global Surveyor**; and **Mars Exploration Program**.

Mars Odyssey. The 2001 Mars Odyssey orbiter is mapping the mineralogy and morphology of the Martian surface, and achieving global mapping of the elemental composition of the surface and the abundance of hydrogen in the shallow subsurface. 2001 Mars Odyssey is part of NASA's Mars Exploration Program, a long-term effort of robotic exploration of the red planet. 2001 Mars Odyssey launched on April 7, 2001, and arrived at Mars on October 24, 2001, 0230 Universal Time (October 23, 7:30 pm PDT/ 10:30 EDT). See also **Mars Exploration Program**.

Mars Reconnaissance Orbiter (MRO). The Mars Reconnaissance Orbiter (MRO) will focus on analyzing the surface at new scales in an effort to follow tantalizing hints of water detected in images from the Mars Global Surveyor spacecraft, and to bridge the gap between surface observations and measurements from orbit. For example, MRO will measure thousands of Martian landscapes at 20- to 30-centimeter (8- to 12-inch) resolution, good enough to observe rocks the size of beach balls.

NASA's Mars Reconnaissance Orbiter launched in August, 2005 from Space Launch Complex 41 at Cape Canaveral Air Force Station, and arrived at Mars March 2006. Since beginning its primary science phase in November 2006, the orbiter has returned enough data to fill nearly 1,000 CD-ROMs. This ties the record for Mars data sent back between 1997 and 2006 by NASA's Mars Global Surveyor mission. See also **Mars Global Surveyor**.

The orbiter's primary mission ends about five-and-a-half years after launch, on December 31, 2010.

Mercury Surface, Space Environment, Geochemistry and Ranging (MESSENGER). MESSENGER launched from Cape Canaveral Air Force Station, Fla., on August 3, 2004. It returned to Earth for a gravity boost on August 2, 2005, and then it will fly past Venus twice, in October 2006 and June 2007. The spacecraft uses the tug of Venus' gravity to resize and rotate its trajectory closer to Mercury's orbit.

Three Mercury flybys, each followed about two months later by a course correction maneuver, put MESSENGER in position to enter Mercury orbit in March 2011. During the flybys — set for January 2008, October 2008 and September 2009 — MESSENGER will map nearly the entire planet in color; image most of the areas unseen by Mariner 10, and measure the composition of the surface, atmosphere and magnetosphere. It will be the first new data from Mercury in more than 30 years — and invaluable for planning MESSENGER's yearlong orbital mission. See also **Discovery Program**.

New Horizons. The New Horizons Pluto-Kuiper Belt Mission will help us understand worlds at the edge of our solar system, by making the first reconnaissance of Pluto and Charon. The mission will then visit one or more Kuiper Belt Objects, in the region beyond Neptune. (Launch: 2006 January 19; Pluto arrival: 2015 July).

Rosetta. Rosetta is a European Space Agency mission to rendezvous with comet 67P/Churyumov-Gerasimenko in May 2014. The main spacecraft will orbit the comet, while taking scientific measurements. A Surface Science Package (SSP) will be landed to the comet surface to take in-situ measurements. The U.S. provided science instruments for the orbiter. (Launched March 2, 2004.) See also http://sci.esa.int/science-e/www/area/index.cfm?fareaid=13.

Stardust. Stardust collected interstellar dust, flew by an asteroid, and captured both dust and pictures of Comet P/Wild 2. The spacecraft flew by Earth and dropped off a sample return capsule filled with thousands of particles of primordial dust. The spacecraft itself has been placed in a hibernation state — preserving options for future use. (Launched February 7, 1999; Sample return January 15, 2006.) See also **Stardust Mission**.

Voyager. The twin spacecraft Voyager 1 and Voyager 2 were launched in the summer of 1977. Though originally designed to last for five years and to visit two planets, both spacecraft far exceeded expectations. Between them, the Voyagers explored all the giant outer planets of our solar system, 48 of their moons, and the unique systems of rings and magnetic fields those planets possess. Both spacecraft continue to send back data, providing scientists with valuable observations of the solar system's edge and interstellar space. Voyager 1 is now the furthest human-made object from the Sun, having surpassed Pioneer 10 on February 17, 1998. See also **Voyager Missions to Jupiter and Saturn**.

Future Missions

Dawn. (Launch: June 30, 2007.) The top level question that the mission addresses is the role of size and water in determining the evolution of the planets. Ceres and Vesta are the right two bodies with which to address this question, as they are the most massive of the protoplanets, baby planets whose growth was interrupted by the formation of Jupiter. Ceres is very primitive and wet while Vesta is evolved and dry. The instrumentation to be flown is complete, flight- proven and similar to that used for Mercury, Mars, the Moon, Eros and comets. The science team consists of leading experts in the investigation of the rocky and icy planets using proven measurement and analysis techniques.

Dawn has the potential for making many paradigm-shifting discoveries. Ceres may have active hydrological processes leading to seasonal polar caps of water frost, altering our understanding of the interior of these bodies. Vesta may have rocks more strongly magnetized than on Mars, altering our ideas of how and when dynamos arise with important lessons for Mars, Earth and Mercury. Ceres may have a thin, permanent atmosphere distinguishing it from the other minor planets.

The three principal scientific drivers for the mission are first that it captures the earliest moments in the origin of the solar system enabling us to understand the conditions under which these objects formed. Second, Dawn determines the nature of the building blocks from which the terrestrial planets formed, improving our understanding of this formation. Finally, it contrasts the formation and evolution of two small planets that followed very different evolutionary paths so that we understand what controls that evolution.

This mission is very timely. Its journey in time to understand the conditions at the formation of the solar system provides context for the understanding of the observation of extra solar-planetary systems. It provides data on the role of size and water in planetary evolution and forms a bridge between the exploration of the rocky inner solar system and the icy outer solar system. Finally, it completes the first order exploration of the inner solar system, addresses NASA's goal of understanding the origin and evolution of the solar system and complements ongoing investigations of Mercury, Earth and Mars. See also http://dawn.jpl.nasa.gov/.

Mars Science Beyond 2009. In the second decade of the century, NASA plans additional science orbiters, rovers and landers, and the first mission to return samples of Martian rock and soil to Earth. See also **Mars Exploration Program**.

Mars Science Laboratory 2009. (Launch Date: Fall, 2009; Arrival October, 2010.) Building on the success of the two rover geologists that arrived at Mars in January, 2004, NASA's next rover mission is being planned for travel to Mars before the end of the decade. Twice as long and three times as heavy as the Mars Exploration Rovers Spirit and Opportunity, the Mars Science Laboratory would collect martian soil samples and rock cores and analyze them for organic compounds and environmental conditions that could have supported microbial life now or in the past. The mission is anticipated to have a truly international flavor, with a neutron-based hydrogen detector for locating water provided by the Russian Federal Space Agency, a meteorological package provided by the Spanish Ministry of Education and Science, and a spectrometer provided by the Canadian Space Agency.

Mars Science Laboratory is intended to be the first planetary mission to use precision landing techniques, steering itself toward the martian surface similar to the way the space shuttle controls its entry through the Earth's upper atmosphere. In this way, the spacecraft would fly to a desired location above the surface of Mars before deploying its parachute for the final landing. As currently envisioned, in the final minutes before touchdown, the spacecraft would activate its parachute and retro rockets before lowering the rover package to the surface on a tether (similar to the way a skycrane helicopter moves a large object). This landing method would enable the rover to land in an area 20 to 40 kilometers (12 to 24 miles) long, about the size of a small crater or wide canyon and three to five times smaller than previous landing zones on Mars.

Like the twin rovers now on the surface of Mars, Mars Science Laboratory would have six wheels and cameras mounted on a mast. See also **Mars Exploration Rover Mission**. Unlike the twin rovers, it would carry a laser for vaporizing a thin layer from the surface of a rock and analyzing the elemental composition of the underlying materials. It would then be able to collect and crush rock and soil samples and distribute them to on-board test chambers for chemical analysis. Its design includes a suite of scientific instruments for identifying organic compounds such as proteins, amino acids, and other acids and bases that attach themselves to carbon backbones and are essential to life as we know it. It could also identify features such as atmospheric gases that may be associated with biological activity.

Using these tools, Mars Science Laboratory would examine martian rocks and soils in greater detail than ever before to determine the geologic processes that formed them; study the martian atmosphere; and determine the distribution and circulation of water and carbon dioxide, whether frozen, liquid, or gaseous.

NASA plans to select a landing site on the basis of highly detailed images sent to Earth by the Mars Reconnaissance Orbiter beginning in 2006, in addition to data from earlier missions.

NASA is considering nuclear energy for powering the Mars Science Laboratory. The rover would carry a U.S. Department of Energy radioisotope power supply that would generate electricity from the heat of plutonium's radioactive decay. This type of power supply could give the mission an operating lifespan on Mars' surface of a full Martian year (687 Earth days) or more. NASA is also considering solar power alternatives that could meet the mission's science and mobility objectives. See also http://marsprogram.jpl.nasa.gov/msl/index.html.

Phoenix Mars Mission. (Launched: August 3, 2007) This mission proposes to conduct a stationary, in situ investigation of volatiles (especially water), organic molecules and modern climate. It aims to "follow the water" and measure indicator molecules at high-latitude sites where Mars Odyssey has discovered evidence of large ice concentrations in the Martian soil. See also **Phoenix Mars Mission**.

Past Missions

Clementine. Clementine was launched on 25 January 1994 at 16:34 UTC (12:34 PM EDT) from Vandenberg AFB aboard a Titan IIG rocket. Clementine was a joint project between the Strategic Defense Initiative Organization and NASA, to test sensors and spacecraft components under extended exposure to the space environment and to make scientific observations of the Moon and the near-Earth asteroid 1620 Geographos. The Geographos observations were not made due to a malfunction in the spacecraft. The lunar observations made included imaging at various

wavelengths in the visible as well as in ultraviolet and infrared, laser ranging altimetry, gravimetry, and charged particle measurements. These observations were for the purposes of obtaining multi-spectral imaging the entire lunar surface, assessing the surface mineralogy of the Moon and obtaining altimetry from 60 N to 60 S latitude and gravity data for the near side. There were also plans to image and determine the size, shape, rotational characteristics, surface properties, and cratering statistics of Geographos. Clementine carried 7 distinct experiments on-board: a UV/Visible Camera, a Near Infrared Camera, a Long Wavelength Infrared Camera, a High Resolution Camera, two Star Tracker Cameras, a Laser Altimeter, and a Charged Particle Telescope. The S-band transmitter was used for communications, tracking, and the gravimetry experiment.

Spacecraft and Subsystems. The spacecraft was an octagonal prism 1.88 meters (6.2 feet) high and 1.14 meters (3.7 feet) across with two solar panels protruding on opposite sides parallel to the axis of the prism (Fig. 1). A high-gain fixed dish antenna was at one end of the prism, and the 489 N thruster at the other end. The sensor openings were all located together on one of the eight panels, 90 degrees from the solar panels, and protected in flight by a single sensor cover. The spacecraft propulsion system consisted of a nonpropellant hydrazine system for attitude control and a bipropellant nitrogen tetraoxide and monomethyl hydrazine system for the maneuvers in space. The bipropellant system had a total capability of about 1900 m/s with about 550 m/s required for lunar insertion and 540 m/s for lunar departure. Attitude control was achieved with 12 small attitude control jets, two star tracker cameras, and two inertial measurement units. The spacecraft was three-axis stabilized in lunar orbit via reaction wheels with a precision of 0.05 Deg. in control and 0.03 Deg. in knowledge. Power was provided by gimbaled, single axis, GaAs/Ge solar panels which charged a 15 amp-hour, 47-w hr/Kg Nihau (Ni-H) common pressure vessel battery. Spacecraft data processing was performed using a MIL-STD-1750A computer (1.7 million instructions per second) for savemode, attitude control, and housekeeping operations, a RISC 32-bit processor (18 million ips) for image processing and autonomous operations, and an image compression system provided by the French Space Agency CNES. A data handling unit sequenced the cameras, operated the image compression system, and directed the data flow. Data was stored in a 2 Gbit dynamic solid state data recorder.

Mission Profile. The mission had two phases. After two Earth flybys, lunar insertion was achieved approximately one month after launch. Lunar mapping took place over approximately two months, in two parts. The first part consisted of a five hour elliptical polar orbit with a periapsis of about 400 Km at 30 degrees south latitude and an apoapsis of 8300 Km. Each orbit consisted of an 80 minute lunar mapping phase near periapsis and 139 minutes of downlink at apoapsis. After one month of mapping the orbit was rotated to a periapsis at 30 degrees north latitude, where it remained for one more month. This allowed global imaging and altimetry coverage from 60 degrees south to 60 degrees north, over a total of 300 orbits. After a lunar/Earth transfer and two more Earth flybys, the spacecraft was to head for Geographos, arriving three months later for a flyby, with a nominal approach closer than 100 kilometers (62 miles). Unfortunately, on May 7, 1994, after the first Earth transfer orbit, a malfunction aboard the craft caused one of the attitude control thrusters to fire for 11 minutes, using up its fuel supply and causing Clementine to spin at 80 rpm. Under these conditions, the asteroid flyby could not yield useful results, so the spacecraft was put into a geocentric orbit passing through the Van Allen radiation belts to test the various components on board. The mission ended in June 1994 when the power level onboard dropped to a point where the telemetry from the spacecraft was no longer intelligible. See also http://nssdc.gsfc.nasa.gov/planetary/clementine.html.

Comet Nucleus Tour. CONTOUR's goals were to improve our knowledge of key characteristics of comet nuclei and to assess their diversity, by making close approaches to at least two comets. CONTOUR was launched July 3, 2002; on August 15, when CONTOUR was to have fired its onboard motor to depart from Earth orbit, contact with the spacecraft was lost, and it may have broken into pieces. See also **Discovery Program**.

Deep Space 1. The primary mission of Deep Space 1 was dedicated to testing its payload of advanced, high risk technologies. Three of the technologies had to work within a few minutes of when the spacecraft separated from the rocket that took it into space in order for the mission to get under way. Unlike most interplanetary missions, which have many months of coasting with minimal activity before reaching their destinations, Deep Space 1 immediately began a very intensive period of demanding experiments to characterize the 12 technologies on board. The small team accomplished a tremendous amount during the nine months it took to do most of the testing, surpassing the planned program of experiments.

Following the testing, Deep Space 1 conducted a bonus encounter with an asteroid. Two months later, the primary mission ended, and Deep Space 1 set off to explore comets. Early in the extended mission, a crucial device failed on board. Rather than give up however, the team conducted an amazing rescue from across the solar system, recovering the spacecraft from what should have been a fatal problem.

The extended mission culminated in September 2001 with an amazing and perfect encounter with comet Borrelly, by which time the spacecraft was more than three times its intended lifetime. This provided Earth with its best view ever of a comet.

After the sturdy little ship survived the encounter, the hyperextended mission began. This brought Deep Space 1 back to its roots: all nine of the hardware technologies on board were used (three of the technologies were autonomous software systems, and they were not exercised during the hyperextended mission). This was a bonus opportunity to test these systems after their long operation in space.

Having exceeded both its technology objectives and its science objectives, the spacecraft was retired in December 2001. The transmitter was turned off, but Deep Space 1 remained functional, with the receiver left on.

- Deep Space 1 launched on October 24, 1998 from Cape Canaveral, Florida.
- By July 13, 1999, it had met or exceeded all of its mission success criteria.
- On July 28, 1999, Deep Space 1 flew by asteroid Braille (formerly known as 1992 KD).
- The primary mission ended on September 18, 1999, and the extended mission began.
- The star tracker failed on November 11, 1999, leaving the craft seriously crippled, unable to point its main antenna to Earth or operate its ion propulsion system.

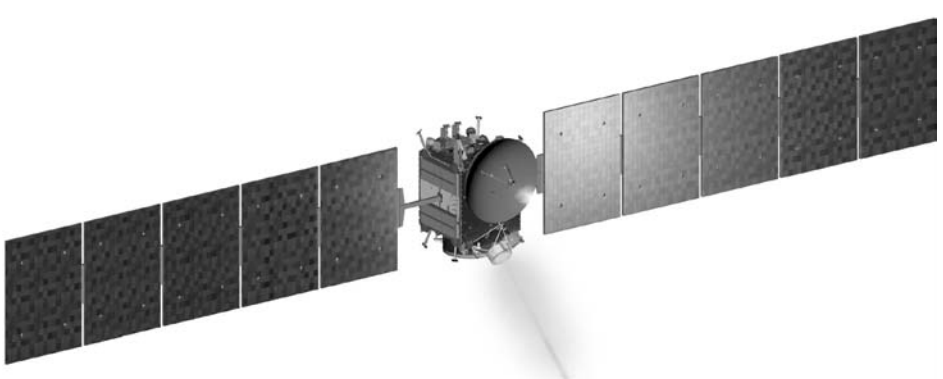

Fig. 1. Clementine spacecraft.

- One of the most complex deep space rescues ever conducted was completed successfully in June 2000, when Deep Space 1 was able to fly without its star tracker, and it resumed thrusting with its ion propulsion to reach a comet.
- On September 22, 2001, Deep Space 1 conducted a flawless encounter with comet Borrelly. After the data were returned, the extended mission concluded and the hyperextended mission began.
- Deep Space 1 was retired on December 18, 2001.

Spacecraft. Although there are 12 advanced technologies on Deep Space 1, the rest of the spacecraft is composed of current, low-cost components that have been tried and tested on other missions. (The Deep Space 1 flight computer, for instance, is based on that used by Mars Pathfinder and other missions.) This approach was used because the focus of the New Millennium Program is on proving that certain advanced technologies work in space, not on building complete spacecraft representative of those to be used in future missions.

The spacecraft structure is an aluminum space frame based on the three Miniature Seeker Technology Integration (MSTI) spacecraft built by Spectrum Astro, Inc. for the Ballistic Missile Defense Organization. (Spectrum was the primary industrial partner on Deep Space 1.) With most of the components mounted on the exterior of the bus, their accessibility simplified replacement during integration and test.

The total mass of the spacecraft as launch was about 486.3 kilograms (1,072 pounds) composed of 373.4 kilograms (823 pounds) dry spacecraft, 31.1 kilograms (68.5 pounds) of hydrazine, and 81.5 kilograms (180 pounds) of xenon. The spacecraft configuration is shown in Figs. 2 and 3.

Deep Space 2. (Launched January 3, 1999). On December 3, 1999 two basketball-sized aeroshells arrived at Mars via the Mars Polar Lander spacecraft. Each aeroshell was designed to shatter on impact with Mars surface, releasing a miniature two-piece science probe that would punch into the soil to a depth of up to 1 meter (3.3 feet). The microprobes' primary science goal: to determine if water ice is present in the Martian subsurface. Unfortunately, no signal was received from the probes following Mars arrival. See also http://nmp.jpl.nasa.gov/ds2/.

Galileo Mission to Jupiter. The Galileo mission produced a string of discoveries about asteroids, a fragmented comet, Jupiter's atmosphere, Jupiter's magnetic environment, and especially about the geologic diversity of Jupiter's four largest moons. The flight team for Galileo ceased operations on 2003 February 28, and Galileo coasted, unattended, before transmitting a few hours of science measurements during its 2003 September 21 plunge into Jupiter's atmosphere. (Launched October 18, 1989; Jupiter arrival December 7, 1995; end of mission September 21, 2003). See also **Galileo Mission to Jupiter**.

Genesis. The Genesis mission was designed to collect samples of the charged particles in the solar wind and return them to Earth laboratories for detailed analysis. Such data are crucial for improving theories about the origin of the Sun and the planets, which formed from the same primordial dust cloud. The samples were returned to Earth in September 2004, but the capsule's two parachutes did not deploy and it hit the ground hard. A NASA team is evaluating the condition of the samples, which were collected in delicate silicon wafers. (Launched August 8, 2001; sample collection ended April 2004; sample return September 8, 2004). See also http://www.genesismission.org/.

International Earth-Sun Explorer-3/International Cometary Explorer. ISEE-3 was originally part of the mother/daughter/heliocentric mission (ISEE 1, 2, and 3). The three spacecraft carried a number of complementary instruments for making measurements of plasmas, energetic particles, waves, and fields. Later, the spacecraft was re-named the International Cometary Explorer (ICE). The primary scientific objective of ICE was to study the interaction between the solar wind and a cometary atmosphere. As planned, the spacecraft traversed the plasma tail of Comet Giacobini-Zinner on 11 September 1985, and made in situ measurements of particles, fields, and waves. Termination of operations was authorized 5 May 1997. See also http://nssdc.gsfc.nasa.gov/database/MasterCatalog?sc=1978-079A.

Leonid Multi-instrument Aircraft Campaign. In November of 1998 and 1999, Earth crossed the fresh ejecta of comet Tempel-Tuttle, resulting in large numbers of meteors. This offered an opportunity to study that comet by using the Earth's atmosphere as a giant detector in a low-cost comet mission. Leonid MAC used two aircraft carrying a variety of instruments to examine the comet particles themselves as well as their impact on the upper atmosphere. See also http://leonid.arc.nasa.gov/.

Lunar Prospector. Lunar Prospector was the third of NASA's Discovery missions. The project mapped the chemical composition of the lunar surface and the Moon's global magnetic and gravity fields at a level of detail greater than that achieved by previous missions. The mission found evidence of water ice in shadowed craters near the lunar poles, a key issue for any future human exploration. LP was launched January 6, 1998 and made a planned crash into the moon on July 31, 1999. See also **Lunar Prospector Mission**.

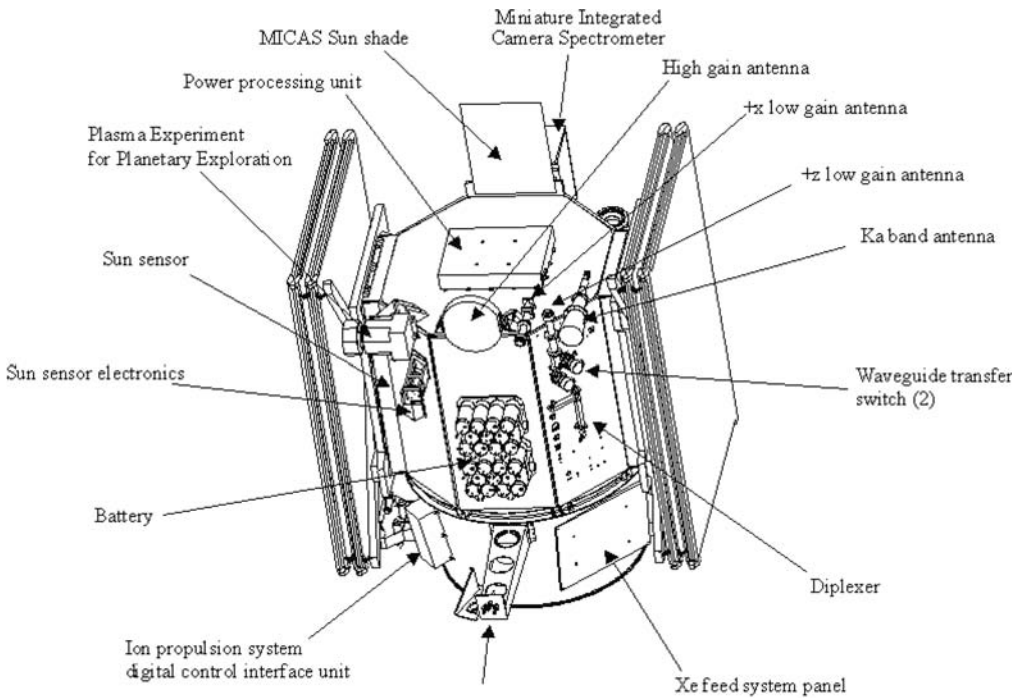

Fig. 2. Stowed Configuration.

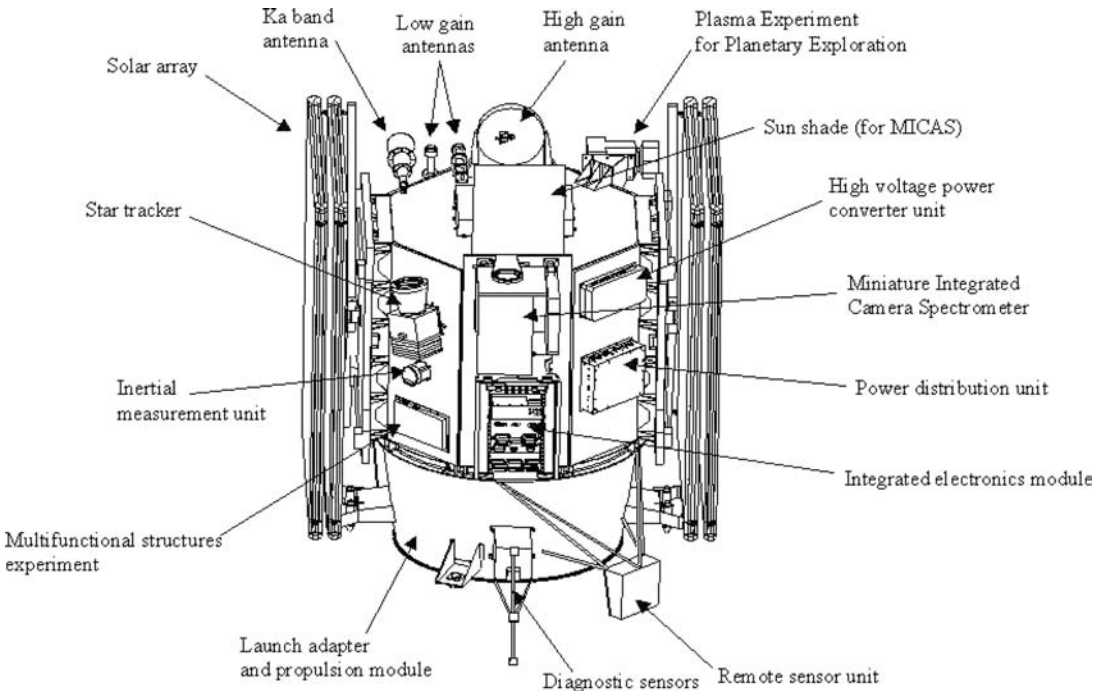

Fig. 3. Stowed configuration.

Magellan. The Magellan spacecraft, named after the sixteenth-century Portuguese explorer whose expedition first circumnavigated the Earth, was launched May 4, 1989, and arrived at Venus on August 10, 1990. Magellan collected radar images of 98 percent of the planet's surface, with resolution 10 times better than that of the earlier Soviet Venera 15 and 16 missions. Altimetry and radiometry data also measured the surface topography and electrical characteristics. The spacecraft made a dramatic conclusion to its highly successful mission when it was commanded to plunge into the planet's dense atmosphere Tuesday, 11 October 1994 to gain data on the planet's atmosphere and on the performance of the spacecraft as it descended. See also **Magellan Mission to Venus**.

Mariner. Between 1962 and 1973, NASA designed and built 10 spacecraft named Mariner to explore the inner solar system — visiting the planets Mercury, Venus, and Mars for the first time, and returning to Venus and Mars for additional close observations. See also **Mars**; **Mercury**; and **Venus**.

Mars Climate Orbiter. The Mars Climate Orbiter and Mars Polar Lander are two spacecraft that were launched separately, but comprise the Mars 98 mission to study the Martian weather, climate, and water and carbon dioxide budget. MCO was launched on December 11, 1998. Upon arrival at Mars, the orbiter was to use a series of aerobraking maneuvers to achieve a stable orbit, and then use atmospheric instruments and cameras to provide detailed information about the surface and climate of Mars. Unfortunately, the spacecraft failed to achieve orbit around Mars, and contact with it was lost on September 23, 1999. See also **Mars**.

Mars Global Surveyor. Mars Global Surveyor was the first successful U.S. mission launched to Mars since the Viking mission in 1976. After a 20-year absence at the planet, Mars Global Surveyor ushered in a new era of Mars exploration with its five science investigations. Mars Global Surveyor arrived at Mars on September 11, 1997 (September 12, UTC), and has contributed a multitude of findings, including signs of past, persistent water such as an ancient delta and currently active water features in the gullies of canyon walls. After nearly a decade of discovery, MGS went silent in November, 2006. See also **Mars**; and **Mars Global Surveyor**.

Mars Pathfinder. The Mars Pathfinder Mission was the second launch in the Discovery Program, a NASA initiative for planetary missions with a maximum three year development cycle and a cost cap of $150 M (FY92) for development. The Mars Pathfinder was managed for NASA by the Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California. See also **Discovery Program**.

The mission was primarily an engineering demonstration of key technologies and concepts for eventual use in future missions to Mars employing scientific landers. Pathfinder also delivered science instruments to the surface of Mars to investigate the structure of the Martian atmosphere, surface meteorology, surface geology, form, and structure, and the elemental composition of Martian rocks and soil. In addition a free-ranging surface rover was deployed to conduct technology experiments and to serve as an instrument deployment mechanism. See also **Pathfinder Mission to Mars**.

Mars Polar Lander. The Mars Climate Orbiter (MCO) and Mars Polar Lander (MPL) are two spacecraft that were launched separately to study the Martian weather, climate, and water and carbon dioxide budget. The goal of MPL was to soft land, under propulsive power, near the edges of the South Polar ice cap on Mars, and to use cameras, a robotic arm and instruments to measure the Martian soil composition. The spacecraft was launched January 3, 1999; no signal was received from the spacecraft upon arrival at Mars on December 3, 1999. See also http://mars.jpl.nasa.gov/msp98/index.html.

Near Earth Asteroid Rendezvous. The Near Earth Asteroid Rendezvous mission was the first launch in the Discovery Program, a NASA initiative for small planetary missions, with a maximum 3-year development cycle and a cost capped at $150 million in FY 1992 dollars. The NEAR mission is managed for NASA by the Johns Hopkins University Applied Physics Laboratory, in Laurel, MD.

As the first spacecraft to orbit (and land on!) an asteroid, the NEAR Shoemaker mission continues to answer fundamental questions about the nature and origin of near-Earth objects. These objects are of interest because they are the primary source of large bodies that collide with Earth, and because clues to the nature of early solar system processes and conditions are preserved on primitive bodies like asteroids, comets, and meteorites. These clues have been altered or destroyed on large, planet-sized bodies by processes of planetary evolution. (Launched February 17, 1996; asteroid landing and final communication February 12, 2001). See also **Discovery Program**.

Pioneer 10 and 11. Launched on March 2, 1972, **Pioneer 10** was the first to be sent to the outer solar system and the first to investigate the planet Jupiter, after which it followed an escape trajectory from the solar system. The spacecraft achieved its closest approach to Jupiter on December 3, 1973, when it reached approximately 2.8 Jovian radii (about 200,000 kilometers (124,273 miles). On Jan. 1, 1997 Pioneer 10 was at about 67 AU from the Sun near the ecliptic plane and heading outward from the Sun at 2.6 AU/year and downstream through the heliomagnetosphere towards

the tail region and interstellar space. This solar system escape direction is unique because the Voyager 1 and 2 spacecraft (and the now terminated Pioneer 11 spacecraft mission) are heading in the opposite direction towards the nose of the heliosphere in the upstream direction relative to the inflowing interstellar gas. The spacecraft is heading generally towards the red star Aldebaran, which forms the eye of Taurus (The Bull). The journey over a distance of 68 light years to Aldebaran will require about two million years to complete. Routine tracking and project data processing operations were terminated on March 31, 1997 for budget reasons. Occasional tracking continued later under support of the Lunar Prospector project at NASA Ames Research Center with retrieval of energetic particle and radio science data. The last successful data acquisitions through NASA's Deep Space Network (DSN) occurred on March 3, 2002, the 30th anniversary of Pioneer 10's launch date, and on April 27, 2002. The spacecraft signal was last detected on Jan. 23, 2003 after an uplink was transmitted to turn off the last operational experiment, the Geiger Tube Telescope (GTT), but lock-on to the sub-carrier signal for data downlink was not achieved. No signal at all was detected during a final attempt on Feb. 6-7, 2003. Pioneer Project staff at NASA Ames then concluded that the spacecraft power level had fallen below that needed to power the onboard transmitter, so no further attempts would be made.

Fifteen experiments were carried to study the interplanetary and planetary magnetic fields; solar wind parameters; cosmic rays; transition region of the heliosphere; neutral hydrogen abundance; distribution, size, mass, flux, and velocity of dust particles; Jovian aurorae; Jovian radio waves; atmosphere of Jupiter and some of its satellites, particularly Io; and to photograph Jupiter and its satellites. Instruments carried for these experiments were magnetometer, plasma analyzer, charged particle detector, ionizing detector, non-imaging telescopes with overlapping fields of view to detect sunlight reflected from passing meteoroids, sealed pressurized cells of argon and nitrogen gas for measuring the penetration of meteoroids, UV photometer, IR radiometer, and an imaging photopolarimeter, which produced photographs and measured polarization. Further scientific information was obtained from the tracking and occultation data.

The spacecraft body was mounted behind a 2.74-meter-diameter (9 foot) parabolic dish antenna that was 46 centimeters (18 inches) deep. The spacecraft structure was a 36-centimeter-deep (14 inch) flat equipment compartment, the top and bottom being regular hexagons. Its sides were 71 centimeters (28 inches) long. One side joined a smaller compartment that carried the scientific experiments. The high-gain antenna feed was situated on three struts, which projected forward about 1.2 meters (4 feet). This feed was topped with a medium-gain antenna. A low-gain omnidirectional antenna extended about 0.76 meter (2.5 feet) behind the equipment compartment and was mounted below the high-gain antenna. Power for the spacecraft was obtained by four SNAP-19 radioisotope thermonuclear generators (RTG), which were held about 3 meters (9.8 feet) from the center of the spacecraft by two three-rod trusses 120 deg apart. A third boom extended 6.6 meters (21.5 feet) from the experiment compartment to hold the magnetometer away from the spacecraft. The four RTG's generated about 155 W at launch and decayed to approximately 140 W by the time the spacecraft reached Jupiter, 21 months after launch. There were three reference sensors: a star sensor for Canopus which failed shortly after Jupiter encounter and two sun sensors. Attitude position could be calculated from the reference directions to the earth and the sun, with the known direction to Canopus as a backup. Three pairs of rocket thrusters provided spin-rate control and changed the velocity of the spacecraft, the spin period near the end of the mission being 14.1 seconds. These thrusters could be pulsed or fired steadily by command. The spacecraft was temperature-controlled between $-23\,^{\circ}\mathrm{C}$ ($-9\,^{\circ}\mathrm{F}$) and $+\,38\,^{\circ}\mathrm{C}$ ($100\,^{\circ}\mathrm{F}$). A plaque was mounted on the spacecraft body with drawings depicting a man, a woman, and the location of the sun and the earth in our galaxy.

Communications were maintained via (1) the omnidirectional and medium-gain antennas which operated together while connected to one receiver and (2) the high-gain antenna which was connected to another receiver. These receivers could be interchanged by command to provide some redundancy. Two radio transmitters, coupled to two traveling-wave tube amplifiers, produced 8 W at 2292 MHz each. Uplink was accomplished at 2110 MHz, while data transmission downlink was at 2292 MHz. The data were received by NASA's Deep Space Network (DSN) at bit rates up to 2048 bps enroute to Jupiter and at 16 bps near end of the mission. See also **Deep Space Network (DSN)**.

Space experiments mostly continued to operate for planetary or interplanetary measurements until failure or until insufficient spacecraft power from the RTG's was available for operation of all instruments, such that some were turned off permanently and others were cycled on and off in accordance with a power sharing plan implemented in September 1989. The Asteroid/Meteoroid Detector failed in December 1973, followed by the Helium Vector Magnetometer (HVM) in November 1975 and the Infrared Radiometer in January 1974. The Meteoroid Detector was turned off in October 1980 due to inactive sensors at low temperatures. The spacecraft sun sensors became inoperative in May 1986, and the Imaging Photopolarimeter (IPP) instrument was used to obtain roll phase and spin period information until being turned off in October 1993 to conserve power. The Trapped Radiation Detector (TRD) and Plasma Analyzer (PA) were respectively turned off in November 1993 and September 1995 for the same reason. As of January 1996 the final power cycling plan included part-time operations of the Charged Particle Instrument (CPI), the Cosmic Ray Telescope (CRT), the Geiger Tube Telescope (GTT), and the Ultraviolet Photometer (UV). As of August 2000, only the GTT instrument was still returning data. See also http://web.archive.org/web/20051101010355/spaceprojects.arc.nasa.gov /SpaceProjects/pioneer/PNhome.html.

Various other spacecraft subsystems also either failed or were turned off for power or other reasons, and an account of these may be of interest for engineering design of long duration deep space missions. The primary antenna feed offset bellows failed sometime in 1976 but a redundant unit was available for use thereafter. The Program Storage and Execution (PSE) subsystem was turned off in September 1989 for power conservation, after which spacecraft maneuvers were performed by ground command sequences. A receiver problem in mid-1992 prevented uplink to the high gain antenna, after which uplink commands could only be sent with 70-meter DSN antennas which also supported the 16 bps downlink. The Backup Line Heater experienced a sticking thermostat operation in March 1993 for 30 days but the problem did not reoccur. Undervoltage Protection Logic was turned off in December 1993 to prevent loss of critical spacecraft systems in the event of a transient undervoltage condition. Duration and Steering Logic (DSL) was turned off in February 1995 to conserve power, after which it was turned on again only for spacecraft maneuvers. RTG power levels are low enough that the spacecraft occasionally relies in part on battery power (accumulated during inactive periods) to run experiments and other systems.

The total mission cost for Pioneer 10 through the 1997 end of official science operations was about 350 million in FY 2001 U.S. dollars. This included about 200 million dollars for pre-launch design and development, and another 150 million for launch, telemetry tracking, mission operations and data analysis. These estimates were provided by the former Pioneer Project at NASA Ames Research Center. See also **Jupiter**; and **Saturn**.

Pioneer 11 was the second mission to investigate Jupiter and the outer solar system and the first to explore the planet Saturn and its main rings. Pioneer 11, like Pioneer 10, used Jupiter's gravitational field to alter its trajectory radically. It passed close to Saturn and then it followed an escape trajectory from the solar system.

The spacecraft was 2.9 meters (9.5 feet) long and contained a 2.74-meter (9 foot) diameter high-gain antenna of aluminum honeycomb sandwich material whose feed was topped with a medium-gain antenna. A low-gain, omnidirectional antenna was mounted below the high-gain dish. The spacecraft contained two nuclear electric-power generators, which generated 144 W at Jupiter, but decreased to 100 W at Saturn. There were three reference sensors: a star (Canopus) sensor, and two sun sensors. Attitude position could be calculated from the reference direction to the earth and the sun, with the known direction to Canopus as backup. Pioneer 11's star sensor gain and threshold settings were modified based on experience gained from the settings used on Pioneer 10. Three pairs of rocket thrusters provided spin-axis control (maintained at 4.8 rpm) and change of the spacecraft velocity. The thrusters could be either fired steadily or pulsed, by command.

Communications were maintained via the omnidirectional and medium-gain antennas, which operated together, connected to one receiver, while the high-gain antenna was connected to the other receiver. The receivers could be interchanged by command. Two radio transmitters, coupled to two traveling-wave tube amplifiers, produced 8 W power each in

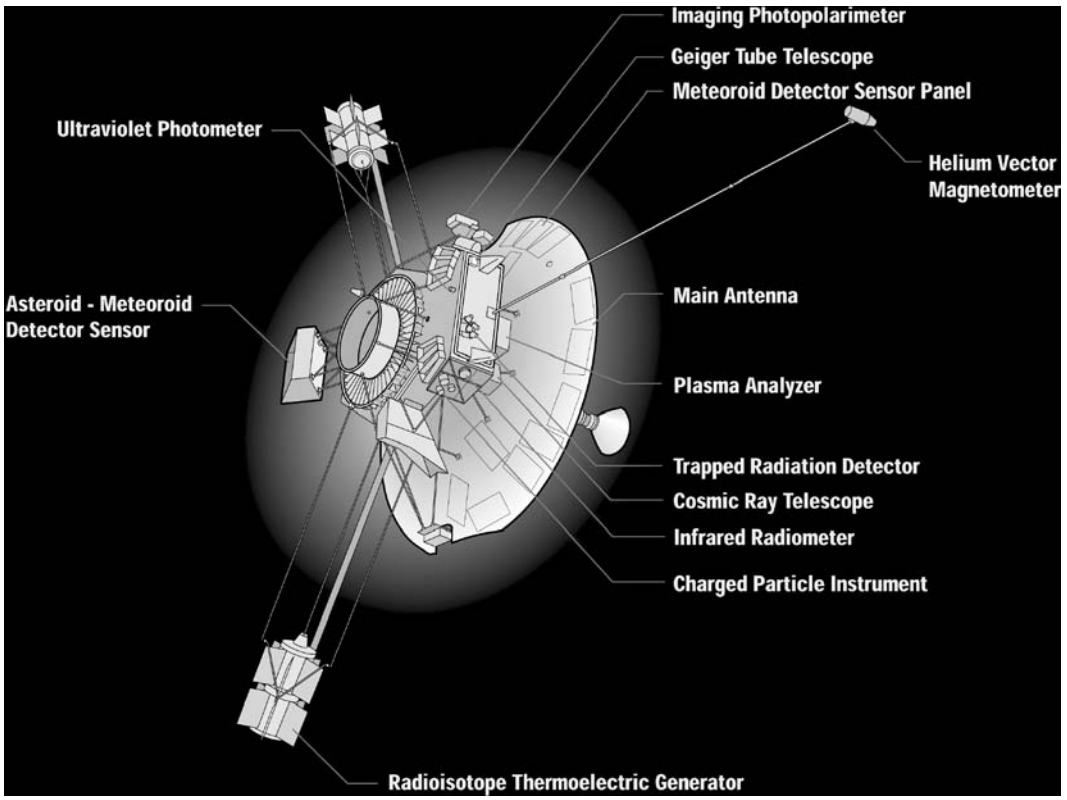

Fig. 4. Pioneer Systems.(Image courtesy of JPL/NASA)

S-band. Communication uplink (earth to spacecraft) operated at 2110 MHz, and downlink (spacecraft to earth) at 2292 MHz. At Jupiter's distance, round-trip communication time took 92 min. Data were received at the Deep Space Network (DSN). The spacecraft was temperature-controlled to between -23 and $+38\,^{\circ}$C (-10 to $+100\,^{\circ}$F). An additional experiment, a low-sensitivity fluxgate magnetometer, was added to the Pioneer 11 payload.

Instruments studied the interplanetary and planetary magnetic fields; solar wind properties; cosmic rays; transition region of the heliosphere; neutral hydrogen abundance; distribution, size, mass, flux, and velocity of dust particles; Jovian aurorae; Jovian radio waves; the atmospheres of planets and satellites; and the surfaces of Jupiter, Saturn, and some of their satellites. Instruments carried for these experiments were magnetometer, plasma analyzer (for solar wind), charged-particle detector, ionizing detector, non-imaging telescopes with overlapping fields of view to detect sunlight reflected from passing meteoroids, sealed pressurized cells of argon and nitrogen gas for measuring penetration of meteoroids, UV photometer, IR radiometer, and an imaging photopolarimeter, which produced photographs and measured the polarization (Fig. 4). Further scientific information was obtained from celestial mechanics and occultation phenomena. See also http://nssdc.gsfc.nasa.gov/database/MasterCatalog?sc=1973-019A&ex=.

This spacecraft, like Pioneer 10, contains a plaque that has a drawing depicting man, woman, and the location of the sun and earth in the galaxy (Fig. 5).

During its closest approach, December 4, 1974, Pioneer 11 passed to within 34,000 kilometers (21,126 miles) of Jupiter's cloud tops. It passed by Saturn on September 1, 1979, at a distance of 21,000 kilometers (13,048 miles) from Saturn's cloud tops. The spacecraft has operated on a backup transmitter since launch. Instrument power sharing began in February 1985 due to declining RTG power output. Science operations and daily telemetry ceased on September 30, 1995 when the RTG power level was insufficient to operate any experiments. As of the end of 1995 the spacecraft was located at 44.7 AU from the Sun at a nearly asymptotic latitude of 17.4 degrees above the solar equatorial plane and was heading outward at 2.5 AU/year.

Pioneer Venus Project. The Pioneer mission consisted of two components, launched separately: an Orbiter (Launched: May 20, 1998) and a Multiprobe (Launched: August 8, 1978).

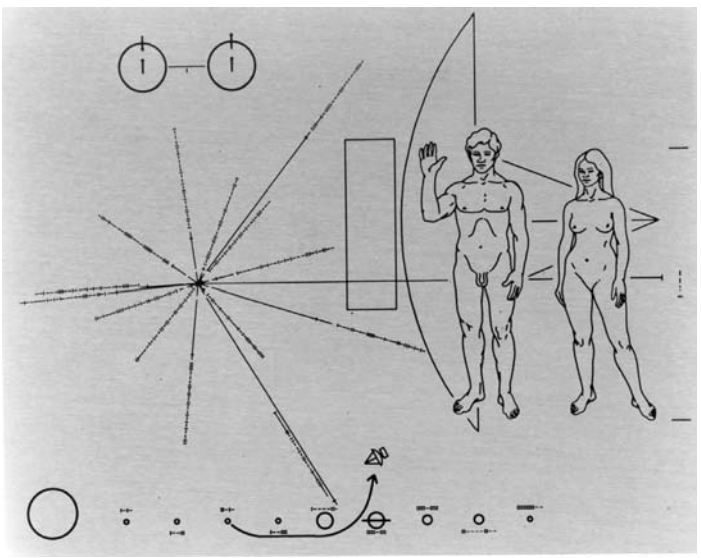

Fig. 5. The plaque on board the Pioneer spacecraft.

The Pioneer Venus Orbiter was inserted into an elliptical orbit around Venus on December 4, 1978 to July 1980. The Orbiter was a flat cylinder 2.5 meters (8 feet) in diameter and 1.2 meters (4 feet) high (Fig. 6). All instruments and spacecraft subsystems were mounted on the forward end of the cylinder, except the magnetometer, which was at the end of a 4.7 meter (15 foot) boom. A solar array extended around the circumference of the cylinder. A 1.09 meter (3.6 foot) despun dish antenna provided S and X band communication with Earth.

The Pioneer Venus Orbiter carried 17 experiments (with a total mass of 45 kilograms (99 pounds):

- a cloud photopolarimeter to measure the vertical distribution of the clouds

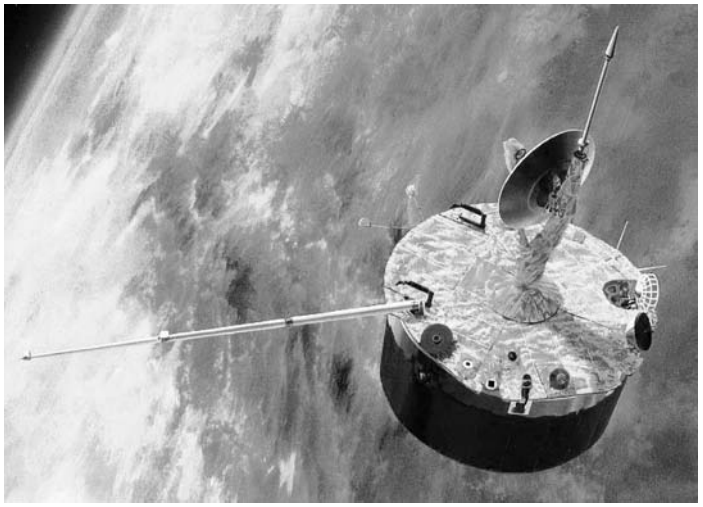

Fig. 6. The Pioneer Venus Orbiter.

- a surface radar mapper to determine topography and surface characteristics
- an infrared radiometer to measure IR emissions from the Venus atmosphere
- an airglow ultraviolet spectrometer to measure scattered and emitted UV light
- a neutral mass spectrometer to determine the composition of the upper atmosphere
- a solar wind plasma analyzer to measure properties of the solar wind
- a magnetometer to characterize the magnetic field at Venus
- an electric field detector to study the solar wind and its interactions
- an electron temperature probe to study the thermal properties of the ionosphere
- an ion mass spectrometer to characterize the ionospheric ion population
- a charged particle retarding potential analyzer to study ionospheric particles
- two radio science experiments to determine the gravity field of Venus
- a radio occultation experiment to characterize the atmosphere
- an atmospheric drag experiment to study the upper atmosphere
- a radio science atmospheric and solar wind turbulence experiment
- a gamma ray burst detector to record gamma ray burst events

See also http://nssdc.gsfc.nasa.gov/database/MasterCatalog?sc=1978-051A&ex=*

From Venus orbit insertion to July 1980, periapsis was held between 142 (88 miles) and 253 kilometers (157 miles) (at 17 degrees north latitude) to facilitate radar and ionospheric measurements. The spacecraft was in a 24 hour orbit with an apoapsis of 66,900 km. Thereafter, the periapsis was allowed to rise (to 2,290 kilometers (1,423 miles) at maximum) and then fall, to conserve fuel. In 1991 the Radar Mapper was reactivated to investigate previously inaccessible southern portions of the planet. In May 1992 Pioneer Venus began the final phase of its mission, in which the periapsis was held between 150 and 250 kilometers (93 and 155 miles) until the fuel ran out and atmospheric entry destroyed the spacecraft the following August.

The orbiter cost $125 million to build and operate for the first 10 years. See also **Venus**.

The Pioneer Venus Multiprobe. The Pioneer Venus Multiprobe consisted of a bus which carried one large and three small atmospheric probes. The large probe was released on November 16, 1978 and the three small probes on November 20. All four probes entered the Venus atmosphere on December 9, followed by the bus.

The Pioneer Venus large probe was equipped with 7 science experiments, contained within a sealed spherical pressure vessel. This pressure vessel was encased in a nose cone and aft protective cover. After deceleration from initial atmospheric entry at about 11.5 km/s near the equator on the Venus night side, a parachute was deployed at 47 kilometer (29 mile) altitude. The large probe was about 1.5 meter (5 foot) in diameter and the pressure vessel itself was 73.2 centimeters (29 inches) in diameter. The science experiments were:

- a neutral mass spectrometer to measure the atmospheric composition
- a gas chromatograph to measure the atmospheric composition
- a solar flux radiometer to measure solar flux penetration in the atmosphere
- an infrared radiometer to measure distribution of infrared radiation
- a cloud particle size spectrometer to measure particle size and shape
- a nephelometer to search for cloud particles
- temperature, pressure, and acceleration sensors

See also http://nssdc.gsfc.nasa.gov/planetary/pvdata.html.

The three small probes were identical to each other, 0.8 meter (2.6 foot) in diameter. These probes also consisted of spherical pressure vessels surrounded by an aeroshell, but unlike the large probe, they had no parachutes and the aeroshells did not separate from the probe. Each small probe carried a nephelometer and temperature, pressure, and acceleration sensors, as well as a net flux radiometer experiment to map the distribution of sources and sinks of radiative energy in the atmosphere. The radio signals from all four probes were also used to characterize the winds, turbulence, and propagation in the atmosphere. The small probes were each targeted at different parts of the planet and were named accordingly. The North probe entered the atmosphere at about 60 degrees north latitude on the day side. The night probe entered on the night side. The day probe entered well into the day side, and was the only one of the four probes which continued to send radio signals back after impact, for over an hour. More detailed information on the probes; See http://nssdc.gsfc.nasa.gov/planetary/pvprobes.html.

The Pioneer Venus bus also carried two experiments, a neutral mass spectrometer and an ion mass spectrometer to study the composition of the atmosphere. With no heat shield or parachute, the bus survived and made measurements only to about 110 kilometer (68 mile) altitude before burning up. The bus was a 2.5 meter (8 foot) diameter cylinder weighing 290 kilograms (639 pounds), and afforded us our only direct view of the upper Venus atmosphere, as the probes did not begin making direct measurements until they had decelerated lower in the atmosphere.

Ranger. The Ranger series of spacecraft were designed to take high-quality pictures of the Moon and transmit them back to Earth in real time. The images were to be used for scientific study, as well as selecting landing sites for the Apollo Moon missions.

All the Ranger spacecraft were designed to head straight into the Moon and send close-range images back to Earth right up until they crashed into the surface. The cameras onboard each spacecraft were designed to provide different exposure times, fields of view, lenses, and scan rates, and they were arranged in two separate self-contained chains, each with its own power supply, timer, and transmitter.

After a frustrating series of malfunctions (these were the early days of space exploration), Rangers 7, 8 and 9 were successful. The images they sent back were 1000 times better than what could be made by Earth-based telescopes. See also **Lunar Exploration**.

Surveyor. Following the Ranger missions, NASA's Surveyor program was designed to find a way to safely land on the Moon. The Surveyor program consisted of seven unmanned lunar missions that were launched between May 1966 and January 1968. Five of these spacecraft, *Surveyor 1, 3, 5, 6,* and *7* successfully soft-landed on the lunar surface. In addition to demonstrating the feasibility of lunar surface landings, the *Surveyor* missions obtained lunar and cislunar photographs and both scientific and technological information needed for the Apollo manned landing program. Four spacecraft, *Surveyor 1, 3, 5,* and *6,* returned data from selected mare sites from Apollo program support, and *Surveyor 7* provided data from a contrasting rugged highland region.

Each spacecraft weighed 1,000 kilograms (2,205 pounds) at launch, was 3.3 meters (10.8 feet) high, and had a 4.5-meter (14.5 foot) diameter. The tripod structure of aluminum tubing provided mounting surfaces for scientific and engineering equipment (Fig. 7). Onboard equipment consisted of a 3-meter-square (9.8 foot-square) solar panel that provided approximately 85-watt output, a main battery and 24-volt non-rechargeable battery that together yielded a 4090-watt total output, a planar array antenna, two omnidirectional antennas, and a radar altimeter. The soft

landing was achieved by the spacecraft free falling to the lunar surface after the engines were turned off at a 3.5-meter (11.5 foot) altitude. Operations began shortly after landing.

Fig. 7. Surveyor Spacecraft.

Four *Surveyor* spacecraft landed in the lunar maria near the equator. These sites were selected primarily because they were being considered for *Apollo* manned lunar landings. *Surveyor 7,* the last in the series, landed in the highland region close to Tycho Crater, a site chosen primarily for its scientific interest. The suitability of each site for making a safe landing was also evaluated as part of the site selection process.

Initially intended to be a series of robotic scientific missions, the project's focus was switched to engineering in support of the Apollo program to land men on the Moon. The Surveyors tested landing techniques designed to bring the American astronauts safely to the Moon. The Surveyors also took close-up images of the lunar surface and made other observations that helped pinpoint locations that would be safe for Apollo landings.

Although Russia's Luna 2 is credited as the first spacecraft to touch down on another celestial body (it impacted the Moon in 1959), Surveyor 1 was the first spacecraft to make a survivable "soft" landing beyond Earth. A year later, Surveyor 6 became the first spacecraft to lift off from the Moon. See also **Lunar Exploration**; and **Moon Exploration Missions (By The USSR)**.

Scientific Investigations. In addition to the objectives of developing and validating the technology for landing softly on the Moon and providing data on the compatibility of the *Apollo* spacecraft design with conditions on the lunar surface, the Surveyor program had the objective of adding to our scientific knowledge of the Moon. Toward that end, the following investigations were performed by the *Surveyor* spacecraft (note that not all investigations were carried out on every mission).

Television Observations. Each *Surveyor* spacecraft carried a television camera, and more than 86,000 70-millimeter pictures were obtained at very high resolution (to 1 millimeter). This photography provided information on the nature of the surface terrain in the immediate vicinity of the spacecraft as well as the number, distribution, and sizes of the craters and boulders in the area. In addition to lunar terrain studies, the photography supported investigations of soil mechanics, magnetic properties, and composition of the surface material.

Lunar Surface Mechanical Properties. Mechanical property estimates are the result of interpretations of landing telemetry data and television pictures as noted above. Measurements from strain gauges mounted on the spacecraft landing gear were analyzed. The surface sampler, flown on *Surveyor 3* and *Surveyor 7,* also obtained data on mechanical properties. To study soil erosion effects and to determine soil properties, the vernier engines and attitude jets were operated after the landings and the results observed with the television camera.

Lunar Surface Soil Mechanics. The soil mechanics investigation was performed by the surface sampler carried on *Surveyor 3* and *7.* The sampler proved to be an extremely versatile and useful piece of equipment. Using this device, operators performed a number of bearing and impact tests and trenching operations. All these operations were monitored using the television camera, and photography of the results provided information for this investigation.

Lunar Surface Temperature and Thermal Characteristics. None of the *Surveyor* spacecraft carried any instruments, as such, to measure lunar surface temperatures or thermal characteristics. However, there were temperature sensors on the outer surfaces of two electronic compartments, on the solar panel, and on the planar array, which were highly dependent on the local thermal radiation environment.

Lunar Surface Electromagnetic Properties. Surveyor 5, 6, and *7* had a magnet attached to one of the spacecraft footpads to determine magnetic properties and composition of the soil. *Surveyor 7* had additional magnets on a second footpad and the surface sampler. Photographs showing the amount of dust adhering to magnets indicated the amount of magnetic particles in the soil and allowed estimates of the lunar soil compositions when compared with premission experiment photographs of magnets in terrestrial soils of various compositions.

Alpha-Scattering Chemical Analysis. Composition of surface materials was also determined from data obtained by the alpha-scattering instrument. This instrument was carried by *Surveyor* 5, 6, and 7 to allow chemical analysis of the lunar surface material. The performance of the alpha-scattering equipment and operational system during the three missions was excellent. In all, six lunar samples were examined. The *Surveyor* 5, 6, and 7 missions provided the first chemical analysis of lunar surface material.

Program Summary. In summary, five *Surveyor* spacecraft landed successfully on the lunar surface. Four of these examined widely separated mare sites in the Moon's equatorial belt. The fifth investigated a region within the southern highlands. Four spacecraft survived the extreme cold of the lunar night and operated for more than one day/night cycle. In total, the five spacecraft operated for a combined elapsed time of about 17 months, transmitted 87,000 pictures, performed 6 separate chemical analyses of surface and near-surface samples, dug into and otherwise manipulated and tested lunar material, measured its mechanical properties, and obtained a wide variety of other data that greatly increased our knowledge of the Moon.

Viking. The Viking Mars mission was performed by two spacecraft, *Viking 1* and *Viking 2*, launched within a couple of weeks of each other. Each spacecraft consisted of an orbiter and a lander, which traveled attached together for nearly a year to reach Mars orbit. The orbiters then began taking pictures of the Martian surface, from which a landing site was selected. The landers then separated from the orbiters and soft landed. The orbiters continued imaging and, between *Viking 1* and *Viking 2*, imaged the entire planet at what was then high resolution. The orbiters also conducted atmospheric water vapor measurements and infrared thermal mapping. The *Viking 1* orbiter flew within 90 kilometers (56 miles) of Phobos to take images of this larger, inner moon of Mars. The Viking landers took full 360-degree pictures, collected and analyzed samples of the Martian soil, and monitored the temperature, wind direction, and wind speed. The Viking missions revealed further details of volcanoes, lava plains, huge canyons, and the effects of wind and water. Analysis of the soils at the landing sites showed them to be rich in iron, but devoid of any signs of life. See also **Mars**; and **Viking Mission to Mars**.

Jet Propulsion Laboratory (JPL), Pasadena, CA

National Aeronautics And Space Administration (Nasa), Washington, DC

SPACE SCIENCE MISSIONS: SUN. We live in the extended atmosphere of an active star. While sunlight enables and sustains life, the Sun's variability produces streams of high energy particles and radiation that can harm life or alter its evolution.

Under the protective shield of a magnetic field and atmosphere, the Earth is an island in the Universe where life has developed and flourished. The origins and fate of life on Earth are intimately connected to the way the Earth responds to the Sun's variations.

Understanding the Sun, Heliosphere, and Planetary Environments as a single connected system is the goal of the Science Mission Directorate's Heliophysics Research Program. In addition to solar processes, our domain of study includes the interaction of solar plasma and radiation with Earth, the other planets, and the Galaxy. By analyzing the connections between the Sun, solar wind, planetary space environments, and our place in the Galaxy, we are uncovering the fundamental physical processes that occur throughout the Universe. Understanding the connections between the Sun and its planets will allow us to predict the impacts of solar variability on humans, technological systems, and even the presence of life itself.

We have already discovered ways to peer into the internal workings of the Sun and understand how the Earth's magnetosphere responds to solar activity. Our challenge now is to explore the full system of complex interactions that characterize the relationship of the Sun with the solar system. Understanding these connections is especially critical as we contemplate our destiny in the third millennium. Heliophysics is needed to facilitate the accelerated expansion of human experience beyond the confines of our Earthly home. Recent advances in technology allow us, for the first time, to realistically contemplate voyages beyond the solar system.

There are three primary objectives that define the multi-decadal studies needed: To understand the changing flow of energy and matter throughout the Sun, Heliosphere, and Planetary Environments; to explore the fundamental physical processes of space plasma systems; to define the origins and societal impacts of variability in the Earth-Sun System.

A combination of interrelated elements is used to achieve these objectives. They include complementary missions of various sizes; timely development of enabling and enhancing technologies; and acquisition of knowledge through research, analysis, theory, and modeling.

Current Missions

Advanced Composition Explorer (ACE). ACE observes of particles of solar, interplanetary, interstellar, and galactic origins, spanning the energy range from that of KeV solar wind ions to galactic cosmic ray nuclei up to 600 MeV/nucleon. It is a major mission in the Explorer program. (Launched August 25, 1997).

See also **Advanced Composition Explorer (ACE)**.

Cluster. Cluster is a European Space Agency program with major NASA involvement. The four Cluster spacecraft carry out three-dimensional measurements in the Earth's magnetosphere, covering both large- and small-scale phenomena in the sunward and tail regions. The first 2 spacecraft were launched on 2000 July 16; the 2nd pair were launched on August 9, 2000. See also **Cluster Mission**.

Fast Auroral Snapshot Explorer (FAST). FAST studies the detailed plasma physics of the Earth's auroral regions. Ground support campaigns coordinate satellite measurements with ground observations of the Aurora Borealis, commonly referred to as the Northern Lights. The science instruments on board FAST are helping scientists to learn about the interaction of the solar wind with Earth's magnetosphere. FAST was launched August 21, 1996 from a Pegasus rocket into a highly elliptical orbit. See also **Fast Auroral Snapshot Explorer (FAST)**.

Geotail. The Geotail mission is a collaborative project undertaken by the Japanese Institute of Space and Astronautical Science (ISAS) and NASA. Its primary objective is to study the tail of the Earth's magnetotail over a wide range of distance, extending from the near-Earth region (8 Earth radii (Re) from the Earth) to the distant tail (about 200 Re). The GEOTAIL spacecraft was designed and built by ISAS and was launched on July 24, 1992.

See also **Geotail Mission**.

Hinode. Hinode (formerly known as Solar-B) is a Japanese ISAS mission proposed as a follow-on to the highly successful Japan/US/UK Yohkoh (Solar-A) collaboration. The mission consists of a coordinated set of optical, EUV and X-ray instruments that will study the interaction between the Sun's magnetic field and its high temperature, ionized atmosphere. The result will be an improved understanding of the mechanisms which give rise to solar magnetic variability and how this variability modulates the total solar output and creates the driving force behind space weather. Hinode was launched at 6:36 a.m. on September 23, 2006 (Japan Standard Time).

The satellite weighs approximately 700 kilograms (1,543 pounds) (dry) with some 170 kilograms (375 pounds) of thruster gas for maintaining a polar, sun-synchronous orbit for more than two years. Two solar panels will provide 1000 watts of power.

The Solar Optical Telescope (SOT), http://solar-b.nao.ac.jp/sot_e/, is composed of two main parts: an optical telescope assembly, which holds the mirrors and other optics of the instrument and a *focal plane package*, http://sot.lmsal.com/, which uses polarizing optics to measure magnetic fields in the solar photosphere. The Solar Optical Telescope will obtain measurements of the magnetic field with a spatial resolution of 0.2 arcseconds and will become the first telescope in space to measure the Sun's three-dimensional magnetic field vector.

The Extreme Ultraviolet Imaging Spectrometer was built by a consortium led by the UK's Mullard Space Science Laboratory (MSSL), the Extreme Ultraviolet Imaging Spectrometer (EIS) has a total length of 3 meters. EIS will obtain high-cadence, monochromatic images of the transition region and corona of the Sun. See also http://msslxr.mssl.ucl.ac.uk:8080/SolarB/Instruments.jsp.

The Solar X-Ray Telescope, http://solar-b.nao.ac.jp/xrt_e/, was built by the High Energy Astrophysics Division of the Smithsonian Astrophysical Observatory. Similar to the X-ray telescope of Yohkoh, the new SXT will have significant improvements in spatial resolution and temperature response. The focal length of the telescope will be 2.7 meters and when combined with imaging electronics, will yield a resolution of 1.0 arcsec.

New Millennium Program Earth Observing-1 (NMP EO-1). The NMP EO-1 mission is an advanced land-imaging mission that will demonstrate new instruments and spacecraft systems. EO-1 will validate technologies contributing to the significant reduction in cost of follow-on Landsat missions. The future of Earth science measurements requires that spacecraft have even greater capabilities packaged in more compact and lower cost spacecraft. To this end, EO-1 tests, for the first time, five new technologies that will enable new or more cost-effective approaches to conducting science missions in the 21st Century.

See also **Earth Observing System (EOS)**.

Reuven Ramaty High Energy Solar Spectroscope Imager (RHESSI). RHESSI studies solar flares in X-rays and gamma-rays. It explores the basic physics of particle acceleration and explosive energy release in these energetic events in the Sun's atmosphere. This is accomplished by imaging spectroscopy of X-rays and gamma-rays with unprecedented spectral, spatial and temporal resolution. RHESSI was launched on February 5, 2002 aboard a Pegasus XL launch vehicle from the Kennedy Space Center.

Solar and Heliospheric Observatory (SOHO). SOHO, a joint venture of the European Space Agency and NASA, is a solar observatory studying the structure, chemical composition, and dynamics of the solar interior; the structure (density, temperature and velocity fields) and dynamics of the outer solar atmosphere; and the solar wind and its relation to the solar atmosphere.

SOHO was launched on December 2, 1995. The SOHO spacecraft was built in Europe by an industry team led by prime contractor Matra Marconi Space (now EADS Astrium) under overall management by ESA. The twelve instruments on board SOHO were provided by European and American scientists. Nine of the international instrument consortia are

led by European Principal Investigators (PI's), three by PI's from the US. Large engineering teams and more than 200 co-investigators from many institutions supported the PI's in the development of the instruments and in the preparation of their operations and data analysis. NASA was responsible for the launch and is now responsible for mission operations. Large radio dishes around the world which form NASA's Deep Space Network are used for data downlink and commanding. Mission control is based at Goddard Space Flight Center in Maryland.

SOHO moves around the Sun in step with the Earth, by slowly orbiting around the First Lagrangian Point (L1), where the combined gravity of the Earth and Sun keep SOHO in an orbit locked to the Earth-Sun line. The L1 point is approximately 1.5 million kilometers away from Earth (about four times the distance of the Moon), in the direction of the Sun. There, SOHO enjoys an uninterrupted view of our daylight star. All previous solar observatories have orbited the Earth, from where their observations were periodically interrupted as our planet 'eclipsed' the Sun.

The mission has revealed the true nature of the Sun's violent atmosphere as it flings clouds into space and as huge magnetic loops tie themselves in knots to generate solar flare explosions. Scientists have discovered that the solar atmosphere is riddled with Earth-sized explosions and occasional tornadoes and the mission has also revealed how the interior of the Sun rotates. SOHO has even discovered over 1000 comets as they pass close to the Sun — a world record. Sophisticated observations have allowed scientists to monitor the far-side of the Sun and instruments have enabled weather maps of the Sun's atmosphere — probing temperatures, densities, solar wind speeds and even what the Sun is made of, from a distance of 150 million km.

The 12 instruments on board SOHO probe the Sun's every detail. One, the Coronal Diagnostic Spectrometer (CDS), is led from the UK, another was partly built in the UK, and UK scientists are involved in the operations and research of all instruments. SOHO's instruments are monitoring the complex, violent solar atmosphere, the charged gases that the Sun expels into space and examining the solar interior.

Below is a list of links and a brief introduction to in depth information about the on-board instruments, the teams that built and operate them and their scientific goals.

CDS (Coronal Diagnostic Spectrometer). CDS: http://solar.bnsc.rl.ac.uk/scientificops/tech.shtml, from Rutherford Appleton Laboratory, United Kingdom, http://www.cclrc.ac.uk/. CDS addresses two of the three main goals of SOHO, namely, 1) Why does the corona exist, how is it heated, and 2) How are the solar wind-streams accelerated? Critical to the pursuit of these goals is the determination of plasma characteristics (densities, temperatures, velocities, abundances etc.) on spatial, temporal and spectral scales and ranges appropriate to those of the solar atmosphere.

CELIAS (Charge, Element, and Isotope Analysis System). CELIAS: http://www.space.unibe.ch/soho/ from the Universitat Bern, in Switzerland. The CELIAS instrument is designed to study the composition of the solar wind (SW) and of solar and interplanetary energetic particles. The CELIAS instrument consists of three different sensors with associated electronics, which are optimized each for a particular aspect of ion composition. These aspects are the elemental, isotopic, and ionic charge composition of SW or energetic ions emanating from the Sun. In addition, the Solar EUV Monitor (SEM) has been included into CELIAS for monitoring the absolute EUV flux from the Sun.

COSTEP (Comprehensive Suprathermal and Energetic Particle Analyzer). COSTEP: http://www.ieap.uni-kiel.de/et/ag-heber/costep/, from the University of Kiel, Germany. COSTEP consists of two instruments, which are called EPHIN (**E**lectron **P**roton **H**elium **In**strument) and LION (**L**ow Energy **Ion** and Electron Instrument). Both instruments are measuring energetic particles emitted by the Sun.

EIT (Extreme Ultraviolet Imaging Telescope). EIT: http://umbra.nascom.nasa.gov/eit/, from the NASA/Goddard Space Flight Center, USA. The *SOHO* EIT is able to image the solar transition region and inner corona in four, selected bandpasses in the extreme ultraviolet (EUV): Fe IX/X, 171 Å; Fe XII, 195 Å; Fe XV, 284 Å; and He II, 304 Å.

Using either full-disk or subfield images, the EIT can image active regions, filaments and prominences, coronal holes, coronal "bright points," polar plumes, and a variety of other solar features. The instrument was designed to be used in conjunction with other *SOHO* instruments, particularly the LASCO visible-light coronagraphs and the SUMER and CDS imaging spectrographs, as well as with ground-based instruments.

ERNE (Energetic and Relativistic Nuclei and Electron Experiment). ERNE http://www.srl.utu.fi/projects/erne/index_english.html, from the University of Turku, Finland. The energy eruptions in the solar atmosphere can lead to the acceleration of local gas particles to extremely high energies and their injection into the interplanetary space. These fast moving streams of particles are recorded by ERNE. At times, when there is no energetic particle production at the Sun, ERNE is observing the continuous flux of energetic particles from Milky Way (galactic cosmic rays), and from the boundary of the heliosphere accelerated by the termination shock (anomalous cosmic rays).

GOLF (Global Oscillations at Low Frequencies). GOLF: http://golfwww.medoc-ias.u-psud.fr/, from the Institut d'Astrophysique Spatiale, France. The GOLF experiment aims to study the internal structure of the sun by measuring the spectrum of global oscillations in the frequency range 10^{-7} to 10^{-2} Hz. Both p and g mode oscillations will be investigated, with the emphasis on the low order long period waves which penetrate the solar core.

LASCO (Large Angle and Spectrometric Coronagraph). LASCO: http://lasco-www.nrl.navy.mil/, from the Naval Research Laboratory, USA. LASCO is a set of three "coronagraph" telescopes. A coronagraph is a special type of telescope that uses a solid disk ("occulter" or "occulting disk") to actually cover up the Sun itself, completely blocking direct sunlight, and allowing us to see the atmosphere around the outside of the Sun (known as the "corona"). LASCO: http://star.mpae.gwdg.de/indexe.shtml, from the Max Planck Institute for Solar System Research, Germany

MDI/SOI (Michelson Doppler Imager/Solar Oscillations Investigation). MDI/SOI: http://soi.stanford.edu/, from the Stanford University, Palo Alto, California, USA. The Michelson Doppler Imager is capable of making a wide range of observations within the constraints imposed by the instrument design, by telemetry availability, and by the limits associated with the running observing programs. The observing programs of MDI are organized around the telemetry opportunities, which fall into 5 classes. A narrow channel of 5 kbps is available at all times, sometimes in near-real time and sometimes via recorded dump. A wide channel of 160 kbps is available for 8 hours per day most of the year, and continuously for two months a year. Virtually all of the 160 kbps data are recorded on the ground and delivered later, but about 15 minutes of high-rate telemetry data per day are made available immediately. (There is an additional very narrow channel for housekeeping data.)

SUMER (Solar Ultraviolet Measurements of Emitted Radiation). SUMER: http://www.mps.mpg.de/en/projekte/soho/sumer/, from the Max Planck Institute for Solar System Research, Germany. SUMER is a powerful UV instrument capable of making reliable measurements of bulk motions in the chromosphere, TR and low corona with an accuracy better than 2 $\mathrm{km\,s^{-1}}$, with a spatial resolution of 1 arcsec (one arcsec at L1 corresponds to 715 km on the Sun) across the slit and 2 arcsec along the slit.

SWAN (Solar Wind Anisotropies). SWAN: http://www.fmi.fi/research_space/space_7.html, from the Finnish Meteorological Institute (FMI), Finland. SWAN: http://www.aero.jussieu.fr/experience/SWAN/, from the Service d'Aeronomie, France. SWAN is dedicated to the determination of the large scale solar wind distribution in the heliosphere by remote sensing in the Lyman-α (Ly-α) UV light of interplanetary (IP) H atoms. Thus, the word "anisotropies" in SWAN's name refers mainly to the variation with latitude of the solar wind. Therefore SWAN can be qualified of "solar wind mapper", though from an instrumental point of view, it could better be described as a full-sky Ly-α imager.

UVCS (Ultraviolet Coronagraph Spectrometer). UVCS: http://cfa-www.harvard.edu/uvcs/, from the Harvard-Smithsonian Center for Astrophysics, USA. The UVCS is composed of three reflecting telescopes with external and internal occultation and a spectrometer assembly consisting of two toric grating spectrometers and a visible light polarimeter. The purpose of the UVCS instrument is to provide a body of data that can be used to address a broad range of scientific questions regarding the nature of the solar corona and the generation of the solar wind. The primary scientific goals are the following: to locate and characterize the coronal source

regions of the solar wind, to identify and understand the dominant physical processes that accelerate the solar wind, to understand how the coronal plasma is heated in solar wind acceleration regions, and to increase the knowledge of coronal phenomena that control the physical properties of the solar wind as determined by in situ measurements. To progress toward these goals, the UVCS will perform ultraviolet spectroscopy and visible polarimetry to be combined with plasma diagnostic analysis techniques to provide detailed empirical descriptions of the extended solar corona from the coronal base to a heliocentric height of 12 solar radii.

VIRGO (Variability of Solar Irradiance and Gravity Oscillations). VIRGO: http://www.ias.u-psud.fr/virgo/, from the Institut d'Astrophysique Spatiale, France. The VIRGO experiment will provide the following observational and derived data:

- continuous high-precision, high-stability and high-accuracy measurements of the solar total and spectral irradiance and spectral radiance variation;
- continuous measurements of the solar polar and equatorial diameters;
- frequencies, amplitudes and phases of oscillation modes in the frequency range of 1 uHz to 8 mHz;

The total irradiance is measured with active cavity radiometers (PM06-V and the Dual Irradiance Absolute Radiometer, DIARAD), the spectral irradiance by three-channel Sunphotometers (SPM) and the radiance with 12 resolution elements on the solar disk using the Luminosity Oscillations Imager (LOI).

These data will be utilized to achieve the main scientific objectives of VIRGO summarized in the following list:

- detect and classify low-degree g modes of solar oscillations;
- determine the sound speed, density stratification and rotation in the solar interior, specifically determine the physical and dynamical properties of the solar core;
- study the solar atmosphere through comparison of amplitudes and phases of the p modes with these from GOLF (Global Oscillations at Low Frequencies) and SOI/MDI (Solar Oscillation Investigation/Michelson Doppler Imager);
- search for the long periodicities or quasiperiodicities that have been found in other solar parameters;
- utilize the solar 'noise' signal to develop models for the global signature of stellar surface parameters;
- determine properties of the solar asphericity and its variation in time;
- study the relation between p-mode frequency changes and irradiance variations;
- study the influence of solar active regions and other large-scale structures on total and spectral irradiance;
- study the solar energy budget;
- provide accurate total and spectral irradiance data for input in terrestrial climate modelling.

Solar Radiation and Climate Experiment (SORCE). SORCE is a NASA-sponsored satellite mission that will provide state-of-the-art measurements of incoming x-ray, ultraviolet, visible, near-infrared, and total solar radiation. The measurements provided by SORCE specifically address long-term climate change, natural variability and enhanced climate prediction, and atmospheric ozone and UV-B radiation. These measurements are critical to studies of the Sun, its effect on our Earth system, and its influence on humankind. See also **Earth Observing System (EOS)**.

Solar Terrestrial Relations Observatory (STEREO). NASA's STEREO spacecraft — en route as the first mission to capture the sun in 3-D — successfully launched on October 25, 2006, aboard a Delta II launch vehicle from Cape Canaveral Air Force Station, FL.

STEREO is the third mission in NASA's Solar Terrestrial Probes program (STP). This two-year mission will provide a unique and revolutionary view of the Sun-Earth System. The two nearly identical observatories — one ahead of Earth in its orbit, the other trailing behind — will trace the flow of energy and matter from the Sun to Earth as well as reveal the 3D structure of coronal mass ejections and help us understand why they happen. STEREO will also provide alerts for Earth-directed solar ejections, from its unique side-viewing perspective adding it to the fleet of Space Weather detection satellites.

Coronal mass ejections (CMEs) are powerful eruptions in which as much as ten billion tons of the Sun's atmosphere can be blown into interplanetary space. The goal of STEREO is to understand the origin coronal mass ejections and their consequences for Earth. The mission will consist of two spacecraft, one leading and the other lagging Earth in its orbit. The spacecraft will each carry instrumentation for solar imaging and for in-situ sampling of the solar wind.

Each STEREO observatory is carrying two instruments and two instrument suites, providing more than a dozen instruments per observatory. See Fig. 1. APL designed and built the spacecraft platform housing the instruments. When combined with data from observatories on the ground or in space, STEREO's data will allow scientists to track the buildup and liftoff of magnetic energy from the sun and the trajectory of Earth-bound coronal mass ejections in 3-D.

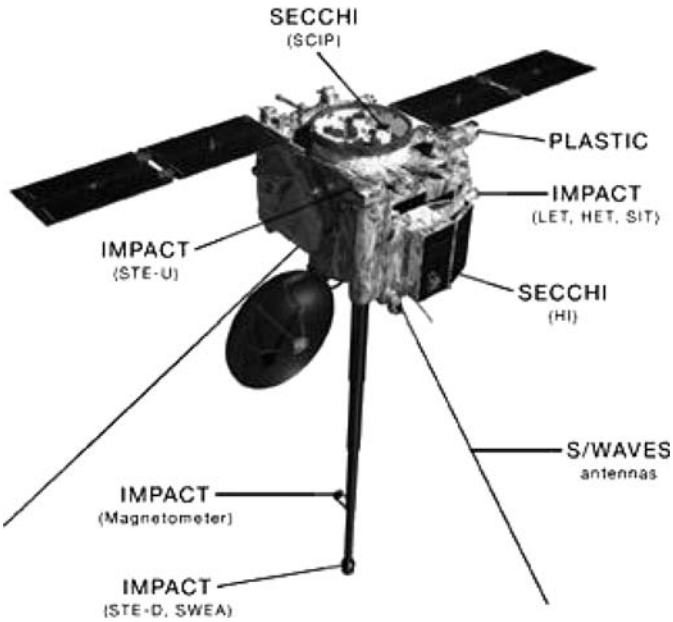

Fig. 1. Mounted onto the STEREO Spacecraft are four instrument packages: SECCHI, SWAVES, IMPACT, and PLASTIC Image Credit: APL

STEREO's instruments were built by numerous organizations worldwide with a principal investigator, or PI, leading each instrument team. The instruments and PIs are as follows: Sun-Earth Connection Coronal and Heliospheric Investigation (SECCHI) — Russell Howard, Naval Research Laboratory; In situ Measurements of PArticles and CME Transients (IMPACT) — Janet Luhmann, University of California, Berkeley; PLAsma and SupraThermal Ion Composition (PLASTIC) — Antoinette Galvin, University of New Hampshire; and STEREO/WAVES (S/WAVES) — Jean-Louis Bougeret, Paris Observatory, Meudon.

STEREO instrument packages mounted on each of the two spacecraft include:

- ***Sun Earth Connection Coronal and Heliospheric Investigation (SECCHI)*** will have four instruments: an extreme ultraviolet imager, two white-light coronagraphs and a heliospheric imager. These instruments will study the 3-D evolution of CME's from birth at the Sun's surface through the corona and interplanetary medium to its eventual impact at Earth.
- ***STEREO/WAVES (SWAVES)*** is an interplanetary radio burst tracker that will trace the generation and evolution of traveling radio disturbances from the Sun to the orbit of Earth.
- ***In-situ Measurements of Particles and CME Transients (IMPACT)*** will sample the 3-D distribution and provide plasma characteristics of solar energetic particles and the local vector magnetic field.
- ***PLAsma and SupraThermal Ion Composition (PLASTIC)*** will provide plasma characteristics of protons, alpha particles and heavy ions. This experiment will provide key diagnostic measurements of the form of

mass and charge state composition of heavy ions and characterize the CME plasma from ambient coronal plasma.

Sounding Rockets. Sounding rockets take their name from the nautical term "to sound", which means to take measurements. Sounding rockets are used to study the Earth's upper atmosphere, ionosphere, and aurora. Also, since sounding rockets can get above the atmosphere, they are used to study astronomical targets in the ultraviolet and x-ray portions of the electromagnetic spectrum. NASA launches an average of 20 sounding rockets each year. See also **Sounding Rockets**.

Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED) Mission. TIMED explores the Earth's Mesosphere and Lower Thermosphere (60–180 kilometers up), the least explored and understood region of our atmosphere. It is known that the global structure of this region can be perturbed during stratospheric warming's and solar-terrestrial events, but the overall structure and dynamics responses of these effects are not understood. Advances in remote sensing technology employed by TIMED will enable us to explore this region on a global basis from space.

The TIMED spacecraft was launched on December 7, 2001, from Vandenberg Air Force Base, California, aboard a Delta II launch vehicle. See also **Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED) Mission**.

Transition Region and Coronal Explorer (TRACE). TRACE observes the effects of the emergence of magnetic flux from deep inside the Sun to the outer corona with high spatial and temporal resolution. TRACE was launched on a Pegasus launch vehicle from Vandenberg Air Force Base in April 1998. See also **Explorers Program**.

Ulysses. The Ulysses Mission is the first spacecraft to explore interplanetary space at high solar latitudes, orbiting the Sun nearly perpendicular to the plane in which the planets orbit. The spacecraft and spacecraft operations team are provided by the European Space Agency (ESA); the launch of the spacecraft, radio tracking, and data management operations are provided by NASA. Scientific experiments are provided by investigation teams both in Europe and the USA. The Shuttle Discovery launched the Ulysses spacecraft on October 6, 1990. See also **Ulysses Mission**.

Voyager. The VIM is an extension of the Voyager primary mission that was completed in 1989 with the close flyby of Neptune by the Voyager 2 spacecraft. This extended mission is continuing to characterize the outer solar system environment and search for the heliopause boundary, the outer limits of the Sun's magnetic field and outward flow of the solar wind. Voyager 1 launched September 5, 1977; and Voyager 2 launched August 20, 1977. See also **Voyager Missions to Jupiter and Saturn**.

Time History of Events and Macroscale Interactions during Substorms (THEMIS). THEMIS is a study of the onset of magnetic storms within the tail of the Earth's magnetosphere. THEMIS will fly five microsatellite probes through different regions of the magnetosphere and observe the onset and evolution of storms. THEMIS will determine the causes of the global reconfigurations of the Earth's magnetosphere that are evidenced in auroral activity.

The THEMIS probes will line up over North America once every four days. Over the mission's two-year lifetime, the probes should be able to observe some 30 substorms. THEMIS was launched on February 15, 2007 aboard a Delta 2 launch vehicle, from Kennedy Space Center, FL.

Understanding and predicting space weather is important to describe the environment in which spacecraft and astronauts operate and ensure their safety. Just as hail and tornadoes accompany the most severe thunderstorms, substorms accompany the most intense space storms — those that disrupt communications, cause power line transmission failures, and produce the most penetrating radiation. THEMIS will study substorms to gain insight into the most severe space storms.

Substorms occur when the magnetosphere suddenly releases vast amounts of stored solar wind energy. Substorms start from a small region in space but within minutes cover an immense region of the magnetosphere. Different possible triggers have different locations, so the key to solving this mystery is placing spacecraft in various locations in Earth's magnetic field to figure to help find the elusive substorm point of origin.

THEMIS is the fifth medium-class mission under NASA's Explorer Program, which was conceived to provide frequent flight opportunities for world-class scientific investigations from space within the Heliophysics and Astrophysics science areas. The Explorers Program Office at Goddard Space Flight Center, Greenbelt, Md., manages this NASA-funded mission. The University of California, Berkeley's Space Sciences Laboratory and Swales Aerospace, Beltsville, Md., built the THEMIS probes. See also **Explorers Program**.

Future Missions

Aeronomy of Ice in the Mesosphere (AIM). AIM is a mission to determine the causes of the highest altitude clouds in the earth's atmosphere. The number of clouds in the middle atmosphere (mesosphere) over the Earth's poles has been increasing over the past couple of decades, and it is hypothesized that this results from increasing concentrations of greenhouse gases at high altitudes. AIM will determine the connection between the clouds and their environment and lead to the study of long-term changes in the upper atmosphere and global climate change. See also **Aeronomy of Ice in the Mesosphere (AIM) Mission**.

Coupled Ion-Neutral Dynamics Investigation (CINDI). CINDI is a mission to understand the dynamics of the Earth's ionosphere. CINDI will provide two instruments for the Communication/Navigation Outage Forecast System (C/NOFS) satellite, a project of the United States Air Force. See also http://www.fas.org/spp/military/program/nssrm/initiatives/cnofs.htm#de.

The CINDI instruments provide measurements of the neutral wind velocity vector and the ion drift velocity vector. Both the **Neutral Wind Meter (NWM)** and the **Ion Velocity Meter (IVM)** are mounted on a spin stabilized satellite to view approximately along the velocity vector.

The Neutral Wind Meter consists of two sensors. The Ram Wind Sensor (RWS) measures the kinetic energy of the neutral gas along the sensor look direction and the Cross-Track Sensor (CTS) measures the arrival angle of the gas in two mutually perpendicular planes containing the sensor look direction. See also http://129.110.7.63/heelis/cindi.html.

The Ion Velocity Meter also consists of two sensors. The Retarding Potential Analyzer (RPA) measures the kinetic energy of the ambient ions along the sensor look direction and the Ion Drift Meter (IDM) measures the arrival angle of the ions in two mutually perpendicular planes containing the sensor look direction. See also http://129.110.7.63/heelis/cindi.html.

Interstellar Boundary Explorer (IBEX). BEX will be the first mission designed to detect the edge of the Solar System. As the solar wind from the sun flows out beyond Pluto, it collides with the material between the stars, forming a shock front. IBEX will contain two neutral atom imagers designed to detect particles from the termination shock at the boundary between the Solar System and interstellar space. IBEX will also study galactic cosmic rays, energetic particles from beyond the Solar System that pose a health and safety hazard for humans exploring beyond Earth orbit. IBEX is scheduled for launched June 15, 2008 from the Reagan Test Site on Kwajalein Island, an Army base in the Marshall Islands.

Magnetospheric MultiScale (MMS) Mission. The Magnetospheric Multiscale (MMS) mission is a Solar-Terrestrial Probe mission comprising four identically instrumented spacecraft that will use Earth's magnetosphere as a laboratory to study the microphysics of three fundamental plasma processes: **magnetic reconnection**, **energetic particle acceleration**, and **turbulence**. These processes occur in all astrophysical plasma systems but can be studied in situ only in our solar system and most efficiently only in Earth's magnetosphere, where they control the dynamics of the geospace environment and play an important role in the processes known as "space weather."

MMS will determine the small-scale basic plasma processes which transport, accelerate and energize plasmas in thin boundary and current layers — and which control the structure and dynamics of the Earth's magnetosphere. MMS will for the first time measure the 3D structure and dynamics of the key magnetospheric boundary regions, from the subsolar magnetopause to the distant tail.

SMART, for "Solving Magnetospheric Acceleration, Reconnection, and Turbulence," is the name of the MMS science investigation. SMART will be carried out by a team headed by Prinicipal Investigator James L. Burch of Southwest Research Institute, http://www.swri.org/ and consisting of researchers from a number of U.S. and foreign institutions. A particular focus of the SMART investigation will be on magnetic reconnection,

a process that explosively converts magnetic energy into heat and the kinetic energy of charged particles.

The MMS Project is currently planning for a launch in the last quarter of 2013.

Space Technology 6 (ST6). Two ST6 technologies will be demonstrated, on two different spacecraft.

Autonomous Sciencecraft Constellation. This software will give future spacecraft unprecedented decision-making capabilities, allowing it to process data onboard, make intelligent decisions to downlink data that it deems scientifically important, and choose science observations that appear interesting. The software is being incrementally tested on the Earth Observing-1 spacecraft.

Inertial Stellar Compass. A miniature star camera and microscopic gyro will enable a spacecraft to determine its orientation whether it is spinning or stable. It will also enable a spacecraft to sense its position and recover its orientation after a power loss. ISC will be demonstrated on a commercial spacecraft.

See also **Autonomous Sciencecraft Constellation**; **Inertial Stellar Compass**; **New Millennium Program (NMP)**; and **Space Technology 6 (ST6)**.

Space Technology 7 (ST7). In March 2002 NASA selected two organizations to lead the work on the New Millennium ST7 Disturbance Reduction System, a set of sensor and thrust-producing technologies to control a space vehicle's flight path so the payload responds only to gravitational forces. Space Technology 7's (ST7) Disturbance Reduction System (DRS) will fly onboard the European Space Agency's (ESA) LISA Pathfinder, formerly called SMART-2, in late 2009 or 2010. See also **New Millennium Program (NMP)**; and **Space Technology 7 (ST7)**.

Space Technology 8 (ST8). Four specific space technology capability need areas deemed important by NASA for its future science missions:

- Deployment of Ultra Lightweight Booms
- Deployment of Lightweight Solar Array
- Thermal Management Subsystem for Small Spacecraft
- Commercial-Off-The-Shelf (COTS)-Based High Performance Computing for Space

The ST8 Mission, slated for launch in 2008. See also **New Millennium Program (NMP)**; and **Space Technology 8 (ST8)**.

Solar Dynamics Observatory (SDO). SDO, the first satellite mission in NASA's Living With a Star Program, is a solar observatory whose primary goals are to understand the solar variations that influence life on Earth and our technological systems. The mission's objectives are to understand the production of the Sun's magnetic field and its conversion into solar activity, as well as predicting solar activity. The instruments will measure the velocity and magnetic field at the surface, the temperature and structure of the corona, and the spectral irradiance that creates the Earth's ionosphere. The orbit will be geosynchronous over White Sands, New Mexico, with a continuous high-speed data link from the observatory to the ground station. The SDO mission is slated for launch August 1, 2008. See also **Living with a Star Program**.

Space Technology 9 (ST9). Five specific space technology capability need areas deemed important by NASA for its future science missions:

- Solar Sail Flight System Technology
- Precision Formation Flying System Technology
- System Technology for Large Space Telescopes
- Descent and Terminal Guidance System Technology for Pinpoint Landing and Hazard Avoidance
- Aerocapture System Technology for Planetary Missions.

See also **New Millennium Program (NMP)**.

Two Wide-Angle Imaging Neutral-Atom Spectrometers (TWINS). TWINS will provide stereo imaging of the Earth's magnetosphere, the region surrounding the planet controlled by its magnetic field and containing the Van Allen radiation belts and other energetic charged particles. TWINS will enable three-dimensional global visualization of this region, which will lead to greatly enhanced understanding of the connections between different regions of the magnetosphere and their relation to the solar wind. See also **Explorers Program**.

Past Missions

Dynamics Explorer-1 (DE-1). The DE mission's general objective was to investigate the strong interactive processes coupling the hot, tenuous, convecting plasmas of the magnetosphere and the cooler, denser plasmas and gases corotating in the earth's ionosphere, upper atmosphere, and plasmasphere. Two satellites, DE-1 and DE-2, were launched together on August 3, 1981 at 09:56:00 UTC and were placed in polar coplanar orbits, permitting simultaneous measurements at high and low altitudes in the same field-line region. The DE 1 spacecraft (high-altitude mission) uses an elliptical orbit selected to allow (1) measurements extending from the hot magnetospheric plasma through the plasmasphere to the cool ionosphere; (2) global auroral imaging, wave measurements in the heart of the magnetosphere, and crossing of auroral field lines at several earth radii; and (3) measurements for significant periods along a magnetic field flux tube. The spacecraft approximated a short polygon 137 centimeters (54 inches) in diameter and 115 centimeters (45 inches) high. The antennas in the X-Y plane measured 20 meters (65.5 feet) tip-to-tip, and on the Z-axis are 9 meters (29.5 feet) tip-to-tip. Two six-meter (20 foot) booms are provided for remote measurements. Power is supplied by a solar cell array, mounted on the side and end panels. The spacecraft is spin stabilized, with the spin axis normal to the orbital plane, and the spin rate at ten plus or minus 0.1 rpm. A pulse code modulation (PCM) telemetry data system is used that operates in real time or in a tape-recorder mode. Data have been acquired on a science-problem-oriented basis, with closely coordinated operations of the various instruments, both satellites, and supportive experiments. Data acquired from the instruments are temporarily stored on tape recorders before transmission at an 8:1 playback-to-record ratio. Additional operational flexibility allows a playback-to-record ratio of 4:1. The primary data rate is 16,384 bits per second. Since commands are stored in a command memory unit, spacecraft operations are not real time, except for the transmission of the wideband analog data from the Plasma Wave Instrument (81-070A-02). DE-2 reentered the atmosphere on February 19, 1983; DE-1 operations were terminated on February 28, 1991.

EQUATOR-S. EQUATOR-S is a low-cost mission designed to study the Earth's equatorial magnetosphere out to distances of 67,000 kilometers (41,632 miles) and it forms an element of the closely-coordinated fleet of satellites that comprise the International Solar-Terrestrial Physics program (IASTP) program. It is based on a simple spacecraft design and carries a science payload consisting of advanced instruments that were developed for other IASTP missions. Unique features of EQUATOR-S are its nearly equatorial orbit and its high spin rate. It was launched as an auxiliary payload on an Ariane-4 on December 2nd, 1997, and stopped transmitting data on May 1, 1998. The mission was intended for a two-year lifetime. See also **International Solar-Terrestrial Physics Program (IASTP)**.

The idea of an equatorial satellite dates back to NASA's GGS (Global Geospace Science) program originally conceived in 1980. When the equatorial element of the program was abandoned in 1986 and several subsequent attempts to rescue the mission had failed, the Max-Planck-Institut für extraterrestrische Physik (MPE), http://www.mpe-garching.mpg.de/index.html, decided in 1991 to fill this gap in the GGS (and in the international IASTP) program because of its interest in the global magnetospheric science, and because it provided an opportunity for a test of an advanced instrument, EDI, to measure electric fields with dual electron beams. The realization of EQUATOR-S was possible through a grant from the German Space Agency DARA (meanwhile part of DLR), http://www.dlr.de/en/desktopdefault.aspx/, that was approved in late 1994, but also through MPE-internal funds and personnel.

The mission provided high-resolution plasma, magnetic, and electric field measurements in the equatorial magnetosphere and across the low-latitude dayside magnetopause and boundary layer. These regions play key roles for our understanding of the global perspective of solar-terrestrial relations as well as the detailed plasmaphysical processes. EQUATOR-S thus complements the Inter-Agency Solar-Terrestrial Physics (IASTP) program. Another important objective was the validation of an advanced instrument for the measurement of electric fields that is based on electron-beam sensing.

See also http://www.mpe-garching.mpg.de/EQS/eq-s-spacecraft.html, for spacecraft design and http://www.mpe-garching.mpg.de/EQS/eq-s-instruments.html, for scientific instruments.

Imager for Magnetopause-to-Aurora Global Exploration (IMAGE). The IMAGE spacecraft was launched from Vandenberg Air Force Base, CA. on March 25, 2000 and operations ended January 2006.

IMAGE was the first satellite mission dedicated to study the global response of the magnetosphere to changes in the solar wind. Major changes occur to the configuration of the magnetosphere as a result of changes in and on the sun, which in turn change the solar wind. IMAGE used neutral atom, ultraviolet, and radio imaging techniques to detect and gather data on these changes. See also **Explorers Program**.

Interplanetary Monitoring Platform-8 (IMP-8). IMP-8 (IMP-J) was launched by NASA on October 26, 1973 and terminated October 26, 2001. IMP-8 was a drum-shaped spacecraft, 135.6 centimeters (53 inches) across and 157.4 centimeters (62 inches) high, instrumented for interplanetary, magnetotail, and magnetospheric boundary studies of cosmic rays, energetic solar particles, plasma, and electric and magnetic fields. Its initial orbit was more elliptical than intended, with apogee and perigee distances of about 45 and 25 earth radii. Its eccentricity decreased after launch. Its orbital inclination varied between 0 deg and about 55 deg with a periodicity of several years. The spacecraft spin axis was normal to the ecliptic plane, and the spin rate was 23 rpm. The data telemetry rate was 1600 bps. The spacecraft was in the solar wind for 7 to 8 days of every 12.5 day orbit. Telemetry coverage was 90% in the early years, but only 60–70% through most of the 1980's and early 1990's. Coverage returned to the 90% range in the mid to late 1990's. The objectives of the extended IMP-8 operations were to provide solar wind parameters as input for magnetospheric studies and as a 1-AU baseline for deep space studies, and to continue solar cycle variation studies with a single set of well-calibrated and understood instruments.

Satelite de Aplicaciones Cientificas-B (SAC-B). SAC-B was an international cooperative project between NASA and Argentina's National Commission of Space Activities (CONAE) and launched November 4, 1996. The satellite was designed to advance the study of solar physics and astrophysics through the examination of solar flares, gamma ray bursts, diffuse X-ray cosmic background, and energetic neutral atoms. The satellite was also designed to test and characterize the performance of new equipment and technologies which may be used in future operational or scientific missions. The satellite payload included three astronomical instruments — the Hard X-ray Spectrometer (HXRS), the Goddard X-ray Experiment (GXRE), and the Cosmic Unresolved X-ray Background Instrument (CUBIC). Also flying was an Italian instrument called ISENA which plans to measure energetic neutral atoms. The spacecraft body was 62 × 62 centimeters (24 × 24 inches) wide by 80 centimeters (31.5 inches) high rectangular parallelepiped wotj 4 extended solar panels 62 centimeters (24 inches) wide by 76 centimeters (30 inches) long.

The SAC-B satellite was launched with the NASA satellite HETE 1. The SAC-B solar arrays did not automatically deploy due to a battery failure in the Pegasus XL rocket third stage. The solar arrays were deployed via ground commands, however because of spacecraft tumbling and shadowing of the Pegasus XL third stage, they were unable to generate enough power to keep the satellite's batteries charged. On November 4, 1996, power on board the spacecraft was lost.

Solar, Anomalous, and Magnetospheric Particle Explorer (SAMPEX). SAMPEX is a momentum-biased, sun-pointed spacecraft that maintains the experiment-view axis in a zenith direction as much as possible, especially while traversing the polar regions of the Earth. It points its solar array at the Sun by aiming the momentum vector toward the Sun and rotating the spacecraft one revolution per orbit about the Sun/spacecraft axis.

SAMPEX is investigating the composition of local interstellar matter and solar material and the transport of magnetospheric charged particles into the Earth's atmosphere. SAMPEX was launched on July 3, 1992 aboard a Scout G launch vehicle from Vandenberg Air Force Base, CA. The orbit of SAMPEX has an altitude of 550 by 675 kilometers (342 by 419 miles) and an 82 deg inclination. See also **Explorers Program**.

Space Technology 5 (ST5). ST5, or the Nanosat Constellation Trailblazer mission, is the fourth deep space mission in our New Millennium Program (NMP). ST5 will test methods for operating a constellation of spacecraft as a single system, using three miniature spacecraft. Each spacecraft is about the size of a birthday cake. The mission will also test eight innovative new technologies. ST5 was launched on March 22, 2006, and completed June 20, 2006. See also **New Millennium Program (NMP)**; and **Space Technology 5 (ST5)**.

Student Nitric Oxide Explorer (SNOE). SNOE ("snowy") was a small satellite investigating the effects of energy from the sun and from the magnetosphere on the density of nitric oxide in the Earth's upper atmosphere. The SNOE spacecraft and its instrument complement were designed and built, and are being operated, entirely at the University of Colorado at Boulder, Laboratory for Atmospheric and Space Physics (CU/LASP). SNOE was launched on February 26, 1998, and reentered Earth's atmosphere December 13, 2003, after 5 years and 290 days completing a very successful mission. See also http://lasp.colorado.edu/snoe/spacecraft/project_library.html; and http://lasp.colorado.edu/snoedata/.

Spartan Spacecraft. The Spartan spacecraft were a series of experiments carried by the Space Shuttle. They addressed a variety of scientific questions, and capitalized on the Space Shuttle's ability to accommodate long duration experiments that are large or heavy, or that require retrieval or other on-orbit operations.

The Spartan program was based on the idea of a simple, low-cost platform deployed from a space shuttle in orbit for a 2–3 day flight, then recovered and returned to Earth. The platform freed experiments of any shuttle pointing constraints.

Spartan 201 Missions. The Spartan 201 spacecraft, which flew five times, carried two telescopes to study the Sun's extremely hot corona and its expansion into the solar wind. The telescopes were:

- The Ultraviolet Coronal Spectrometer used ultraviolet emissions from neutral hydrogen and ions in the corona to determine the velocities of the coronal plasma within the solar wind source region, and the temperature and density distributions of protons.
- The White Light Coronagraph measured visible light to determine the density distribution of coronal electrons within the same regions. Because the Earth's atmosphere interferes with emissions at these wavelengths, the measurements had to be made from space, rather than from the ground.

The coordinated results have provided new insight into the unknown source of energy that heats the solar corona and accelerates the solar wind particles. No previous missions focused specifically on these fundamental questions.

Spartan 201-01: **Solar Physics**
Flown April 1993 on STS-56
Spartan 201-02: **Coordinated Observations — Ulysses**
Flown September 1994 on STS-64
Spartan 201-03: **Coordinated Observations — Ulysses**
Flown September 1995 on STS-69
Spartan 201-04: **Calibration Flight — SOHO**
Flown November 1997 on STS-87
Spartan 201-05: **Calibration Flight — SOHO**
Flown October 1998 on STS-95

The Spartan 201 spacecraft now resides at the National Air and Space Museum.

Spartan 203 Mission: UV Observation of Comet Halley. Spartan Halley was a quick response to provide ultra-violet observations of Comet Halley. The experiment and spacecraft were prepared for flight in just 14 months. Spartan Halley was lost in the Challenger accident.

Spartan 204 Mission: UV Astronomy (Stellar). Flown on the Space Shuttle Discovery STS-63 mission February 3, 1995, and returned on February 11, 1995. Spartan 204 carried a science instrument called the Far Ultraviolet Imaging Spectrograph, or FUVIS, provided by the Naval Research Laboratory (NRL) and sponsored by the Department of Defense Space Test Program. FUVIS obtained far ultraviolet spectroscopy of diffuse sources, both natural and man-made. The data acquired from natural sources such as diffuse nebulae and the galactic background provided information on interstellar gas and dust.

Data acquired from man-made sources such as the shuttle surface glow and plume emissions from the Reaction Control System (RCS) thrusters provided information on the effect of man-made objects traveling through the space environment. A better understanding of these effects may provide a means for detecting and tracking ballistic and orbiting vehicles. See also http://www.nasa.gov/mission_pages/shuttle/shuttlemissions/archives/sts-63.html.

Project Starshine. This project consisted of three small, optically reflective spherical "STARSHINE" student satellites designed by the U.S. Naval Research Laboratory and built by an informal, volunteer coalition of organizations and individuals in the USA and Canada. This coalition is called "Project Starshine" and is headquartered in Monument, Colorado. It receives no formal funding and operates by means of contributions of materials and labor from its member individuals and institutions. NASA has deployed the coalition's satellites into highly inclined low earth orbits from two Space Shuttles and an Athena expendable launch vehicle at no cost to the Starshine project, as a service to the international educational community. Each of the satellites is covered by approximately 1000 small, front-surface aluminum mirrors that are machined by technology students in Utah and polished by tens of thousands of students in schools and other participating organizations around the world. These mirrors have been coated with a scratch-resistant, anti-oxidizing layer of Silicon Dioxide by optical engineers and technicians at the Hill Air Force Base in Utah and the NASA Marshall Space Flight Center in Alabama. See also http://www.azinet.com/starshine/ Project Starshine.

Tomographic Experiment using Radiative Recombinative Ionospheric EUV and Radio Sources (TERRIERS). TERRIERS was a very small "University-class" Explorer intended to study a number of ionospheric and thermospheric phenomena, and test the utility of long term solar EUV (extreme ultraviolet) irradiance measurements. Launched 1999 May 17, the spacecraft apparently failed to properly orient its solar panels towards the sun, and ran out of battery power shortly after launch. See also Boston University TERRIERS: http://www.bu.edu/satellite/.

Tethered Satellite System (TSS). The Tethered Satellite System (TSS) consists of a satellite, a conducting tether, and a tether deployment/retrieval system to be flown on the Space Shuttle. The objectives of the TSS-1 mission were to: (1) verify engineering performance of the Tethered Satellite System (TSS); (2) determine and understand the electro-magnetic interaction between the tether/satellite/orbiter system and the ambient space plasma; (3) investigate and understand the dynamical forces acting upon a tethered satellite; and, (4) develop the capability for future tether applications on the Shuttle and Space Station.

The TSS released a satellite while remaining attached to a reel in the orbiter payload bay. This mission was intended to demonstrate control of the satellite during deployment, aerodynamic stability at flight altitude, and the ability of the system to collect meaningful scientific data and to return the data to the Orbiter, and then to the Payload Operations Control Center (POCC). The satellite was to be deployed 20 kilometers (12.5 miles) above the Orbiter. The deploying equipment consisted of a Spacelab pallet, a reel for tether deployment, an extendible/retractable boom for initial deployment and final retrieval of the satellite, an electrical power and distribution subsystem, a communications and data management subsystem, and a tether control capability. A separate support structure carried science instrumentation.

The spherical satellite was 1.6 meters (5.25 feet) in diameter, with the upper hemisphere containing some of the scientific payload, and the lower hemisphere containing the support equipment. The satellite contained cold gas (nitrogen) thrusters used for deployment, retrieval, and attitude control. The 2.54 mm diameter conducting tether cowas constructed using Kevlar and Nomex with 10 strands of 34 AWG copper wire and a Teflon sheath.

NASA was responsible for the TSS deployer and systems integration, and Italy for building the satellite. Five investigations from Italy and five from the USA were selected for the first mission.

Because of a technical problem (a protruding bolt) the tether could only be released to about 256 meters (840 feet). A reflight of the tether system (TSS-1 R) was scheduled for February 1996. On February 25, 1996, with 19.7 km (12 miles) of 20.7 planned (12.9 miles) of tether released, the tether cable suddenly snapped near the top of the deployment boom. The TSS satellite shot away into a higher orbit. TSS instruments could be re-actived and produced science data for three days until battery power ran out. An independent review panel was formed to review the TSS-1 R failure.

Yohkoh Solar Observatory. Yohkoh, an observatory for studying X-rays and gamma-rays from the Sun, is a project of the Institute for Space and Astronautical Sciences, Japan. The spacecraft was built in Japan, but the observing instruments had contributions from the U.S. and from Great Britain.

There are four instruments on the satellite that detect energetic emissions from the Sun: the Bragg Crystal Spectrometer (BCS); the Wide Band Spectrometer (WBS); the Soft X-Ray Telescope (SXT); the Hard X-Ray Telescope (HXT).

A team from the United States collaborated on SXT, and teams from the United States and Great Britain collaborated on BCS.

The BCS consists of four bent crystal spectrometers. Each is designed to observe a limited range of soft x-ray wavelengths containing spectral lines that are particularly sensitive to the hot plasma produced during a flare. The observations of these spectral lines provide information about the temperature and density of the hot plasma, and about motions of the plasma along the line of sight. Images are not obtained, but this is offset by enhanced sensitivity to the line emission, high spectral resolution, and time resolution on the order of one second.

The WBS consists of three detectors: a soft x-ray, a hard x-ray, and a gamma-ray spectrometer. They were designed to provide spectra across the full range of wavelengths from soft x-rays to gamma rays with a time resolution on the order of one second or better. Like the BCS, images are not obtained.

The SXT images x-rays in the 0.25−4.0 keV range. It uses thin metallic filters to acquire images in restricted portions of this energy range. SXT can resolve features down to 2.5 arc seconds in size. Information about the temperature and density of the plasma emitting the observed x-rays is obtained by comparing images acquired with the different filters. Flare images can be obtained every 2 seconds. Smaller images with a single filter can be obtained as frequently as once every 0.5 seconds.

The HXT observes hard x-rays in four energy bands through sixty-four pairs of grids. These grid pairs provide information about 32 spatial scales of the x-ray emission. This information is combined on the ground to construct an image of the source in each of the four energy bands. Structures with angular sizes down to about 5 arc seconds can be resolved. These images can be obtained as frequently as once every 0.5 seconds.

The *Yohkoh* Spacecraft is in a slightly elliptical low-earth orbit, with an altitude ranging from approximately 570 kilometers (354 miles) to 730 kilometers (454 miles). The orbital period is 90 minutes. Sixty-five to seventy-five minutes of this time is spent in sunlight. During five to six of it's orbits per day, *Yohkoh* passes through the radiation belts of the South Atlantic Anomaly where the instruments using high voltages must be turned off (the BCS, HXT, and most WBS channels). Otherwise the radiation could destroy the instruments or the satellite.

Observations from the instruments are stored in the Spacecraft Bubble Data Recorder (BDR). The capacity of the BDR is 10 Mbytes. In order to optimize the recorder, it can operate at several bit-rates; high, medium, and low. Switching between the bit-rates is controlled two different ways, by the on-board deferred commands and automatically. This switching is necessary since the high-bit rate only holds 42 minutes worth of data. Some overwriting of the data is permitted.

The satellite can operate in a large number of spacecraft modes and several different subsystem modes. The two modes of principal interest are the Quiet Mode and Flare Mode. Switching between these two particular modes is controlled by a flare flag generated by the WBS instruments. Allocation of which instruments can collect what data and how much of it depends on which mode *Yohkoh* is operating in. Generally, more HXT data is taken during the Flare Mode as opposed to the Quiet Mode.

During each orbit, about five or six times a day, *Yohkoh* passes over the Kagoshima Space Center. Commanding of the satellite can be performed at this time. (The rest of the time the satellite is controlled by on-board deferred command storage.) In addition, Kennedy Space Center also receives the current data from the Data Recorder. At other locations in

the orbit, the data gets sent to ground stations in the NASA Deep Space Network.

Yohkoh was launched August 30, 1991; the spacecraft lost attitude control in December 2001, and recovery attempts have been unsuccessful.

SPACE SCIENCE MISSIONS: UNIVERSE. Eighty years ago, we didn't know that our galaxy was not the entire universe, that the fuzzy "nebulae" floating in the cosmos were really neighboring "island universes" like our own galaxy. People have gazed at the stars, given them names, and observed their changes for thousands of years. NASA joined the ancient pursuit of knowledge of our universe comparatively recently; nevertheless, in our 40 plus years of space science we contributed to several major advances in astronomy, including:

- Detecting the atmosphere of a planet outside our solar system
- Completing the first detailed full-sky map of the oldest light in the universe
- Finding that dark energy is accelerating the expansion of the universe

Even so, we still have perplexing and important puzzles to solve, such as:

- How did the Universe begin?
- Does time have a beginning and an end?
- Where did we come from?
- Are we alone?

To answer these questions, NASA missions (current, future, and past) linked by powerful new technologies and complementary approaches have begun to answer these science questions. In the first few decades of this new century astronomers will greatly advance the study of classical cosmology: the description of the universe on the largest scales and how the universe works. We will also begin to write the final chapter of the story of galaxies, witnessing the actual birth of these vast collections of stars.

We will investigate the cycles of matter and energy that govern the universe, and come to understand how the universe relentlessly expands: even while gravity pulls pockets of its dark matter and other constituents together, the energy of collapse and resulting nucleosynthesis later fling them apart once again.

In years to come, we will determine the properties of dark energy — the mysterious force whose presence is inferred by astronomers but has not been seen directly. Probes will detect the imprints left by quantum effects and gravitational waves at the beginning of the Big Bang; later, we could detect these phenomena directly. We will count how many black holes populate our local universe, and one day actually take a picture of the area near the edge of a black hole.

We will peer one-by-one at hundreds of our nearest neighbor stars and inventory their planets, searching for solar systems resembling our own with a balmy, wet planet like Earth. More ambitious telescopes could study such a world in greater detail, gathering enough light to find the signatures of life in the atmospheres of planets. We cannot yet know whether the worlds we seek are common or exceedingly rare, so our journey may eventually involve great flotillas of large telescopes that can extend our search to thousands or tens of thousands of stars.

Current Missions

Chandra X-Ray Observatory. Since its launch on July 23, 1999, the Chandra X-ray Observatory has been NASA's flagship mission for X-ray astronomy, taking its place in the fleet of "Great Observatories." See also **Great Observatory Program**. Chandra explores the hot turbulent regions in space with images 25 times sharper than previous x-ray pictures. Chandra is performing detailed studies of black holes, supernovas, and dark matter, to increase our understanding of the origin, evolution, and destiny of the universe. See also **Chandra X-Ray Observatory**.

Far Ultraviolet Spectroscopic Explorer (FUSE). *FUSE* is a NASA-supported astrophysics mission that was launched on June 24, 1999, to explore the Universe using the technique of high-resolution spectroscopy in the far-ultraviolet spectral region. The Johns Hopkins University has the lead role in developing and now operating the mission, in collaboration with The University of Colorado at Boulder, The University of California at Berkeley, international partners the Canadian Space Agency (CSA) and the French Space Agency (CNES), and corporate partners. FUSE studies the wavelength range of 90 to 120 nanometers from high orbit. This range provides an opportunity to answer important questions about many types of astrophysical objects, such as the nuclear regions of active galaxies and quasars, massive stars, supernovae, planetary nebulae, and the outer atmospheres of cool stars and planets. See also **Explorers Program**.

Galaxy Evolution Explorer (GALEX). GALEX is an orbiting space telescope exploring the origin and evolution of galaxies and the origins of stars and heavy elements, and is also conducting an all-sky ultraviolet survey. Such observations will tell scientists how galaxies, the basic structures of our Universe, evolve and change. Additionally, GALEX will probe the causes of star formation during a period when most of the stars and elements we see today had their origins. GALEX was launched on April 28, 2003 from Cape Canaveral Air Force Station, FL., by a Pegasus XL rocket and will orbit 690 kilometers (428 miles) above Earth for 29 months. See also **Explorers Program**.

Gravity Probe B (GP-B). Gravity Probe B is the relativity gyroscope experiment being developed by NASA and Stanford University to test two extraordinary, unverified predictions of Albert Einstein's general theory of relativity. It will measure how space and time are warped by the presence of the Earth, and, more profoundly, how the Earth's rotation drags space-time around with it. The GP-B spacecraft launched from Vandenberg Air Force Base, CA, atop a Boeing Delta II rocker on April 20, 2004.

The experiment will check, very precisely, tiny changes in the direction of spin of four gyroscopes contained in an Earth satellite orbiting at 400-mile altitude directly over the poles. So free are the gyroscopes from disturbance that they will provide an almost perfect space-time reference system. They will measure how space and time are warped by the presence of the Earth, and, more profoundly, how the Earth's rotation drags space-time around with it. These effects, though small for the Earth, have far-reaching implications for the nature of matter and the structure of the Universe.

Gravity Probe B is among the most thoroughly researched programs ever undertaken by NASA.

The major components of the science instrument (four gyroscopes, the optical telescope, and mounting block) are all made of fused quartz. Quartz is very stable over wide temperature ranges — expanding and contracting very little and uniformly. The science instrument's optical telescope has an aperture of 14.0 centimeters (5.5 inches). Throughout the experiment, it is pointed at the center of GP-B's guide star IM Pegasi (HR 8703), which provides the experiment's frame-of-reference in space.

Technicians at the Marshall Space Flight Center originally built the highly advanced polishing equipment needed to manufacture the gyroscope

rotors. Engineers at Stanford developed the thin-film technology for placing a superconductive metal coating of Niobium on the gyroscope rotors.

The gyroscope rotors are perhaps the most spherical objects ever made. If the gyroscope rotors were enlarged to the size of the Earth, the tallest mountain or the deepest ocean ravine would be only 2.4 meters (8 feet) in height. These gyroscopes are sufficient to achieve the specified 0.5 milliarcsecond (1.4×10^{-7} degrees) per year accuracy in their drift rate measurements.

The GP-B instrument assembly is contained within the 2.7 meter (9 foot) long, cigar shaped cryogenic probe. See Fig. 1. Surrounding the probe is a shield of superconducting lead foil.

This "lead bag" shields the instrument from interference from the Earth's magnetic field. In turn, the probe and lead bag are contained within a large thermos-like Dewar, containing 2,441 liters (645 gallons) of superfluid helium. The cryogenic temperature of 1.8 Kelvin is necessary to cause the niobium metal coating on the gyroscope rotors to become superconducting. The direction of the rotor's spin axis is determined through the magnetic moment ("London moment") generated by a spinning super conductor.

The superfluid helium inside the Dewar serves both as a refrigerant for maintaining the probe's cryogenic environment and, when vented from the Dewar in the form of helium gas, as a propellant for controlling the spacecraft's position and roll rate.

A minuscule amount of heat is conducted into the Dewar via some 400+ cables and tubes that connect the various systems inside the probe with control and instrumentation systems mounted on the spacecraft frame and also by light radiating down through the telescope bore. This heat caused some of the liquid helium to boil off. A "porous plug," invented at Stanford, allows helium gas to escape from the Dewar, drawing heat out with it, while leaving behind the liquid helium and maintaining the necessary cryogenic temperature and pressure inside the Dewar.

The escaping helium gas is cycled past cooling shields in the Dewar's outer layer, and then vented into space through eight pairs of micro-thrusters on the spacecraft frame. Based on data from the telescope and one of the four gyroscopes that serves as a proof mass (center of mass for the spacecraft), the helium gas escaping from the Dewar is carefully metered through these micro-thrusters so that the spacecraft flies around the proof mass gyroscope, maintaining a "drag free" orbit.

During the 50-week science phase of the GP-B mission and the 7-week instrument calibration phase, which lasted from August 2004-September 2005, over a terabyte of experimental data was collected. Analysis of this data has been steadily progressing through a 3-phase plan, each subsequent phase building on those preceding it.

In Phase I, which lasted from the end of September 2005 through February 2006, the analysis focused on a short-term, day-by-day or even orbit-by-orbit, examination of the data. The overall goals of this phase were to optimize the data analysis routines, calibrate out instrumentation effects, and produce initial "gyro spin axis orientation of the day" estimates for each gyro individually. At this stage, the focus was on individual gyro performance; there was no attempt to combine or compare the results of all four gyros, nor was there even an attempt to estimate the gyro drift rates.

Phase II, which lasted from March-August, 2006, focused on understanding and compensating for certain long-term systematic effects in the data that spanned weeks or months. During this phase, the team was accurately able to model the time-varying polhode paths of the four gyros, as reported in our November 2006 GP-B Mission News story, http://einstein.stanford.edu/highlights/hl_polhodestory.html, yielding increased precision for gyro precession rates over short intervals. This modeling of the gyro polhode behavior plus the development of a geometric interpretation of the data has enabled the team to make significant improvements in the precision of the analysis. See also http://einstein.stanford.edu/index.html.

High Energy Transient Explorer-2 (HETE-2). The High Energy Transient Explorer is a small scientific satellite designed to detect and localize gamma-ray bursts. The coordinates of GRBs detected by HETE are distributed to interested ground-based observers within seconds of burst detection, thereby allowing detailed observations of the initial phases of GRBs.

The concept of a satellite capable of multiwavelength observations of GRBs was discussed at the Santa Cruz meeting on GRBs in 1981. In 1986, the first realistic implementation of the HETE concept by an MIT-led International Team was proposed. This concept, which was adopted, emphasized accurate locations and multiwavelength coverage as the primary scientific goals for a sharply-focused small satellite mission which would ultimately solve the gamma-ray burst mystery.

In 1989, NASA approved funding for a low-cost "University Class" explorer satellite to search for GRBs. In 1992, the HETE-1 program was funded, and the design and construction of HETE-1 began.

The original spacecraft contractor for HETE-1 was AeroAstro, Inc., of Ashburn, VA., http://www.aeroastro.com/. AeroAstro was responsible for the spacecraft bus, including power, communications, attitude control, and computers.

The instrument complement for HETE-1 consisted of

- Four wide-field gamma-ray detectors, supplied by the CESR of Toulouse, France
- A wide-field coded-aperture X-ray imager, supplied by a collaboration of Los Alamos National Laboratory and the Institute of Chemistry and Physics (RIKEN) of Tokyo, Japan.
- Four wide-field near-UV CCD cameras, supplied by the Center for Space Research at the Massachusetts Institute of Technology.

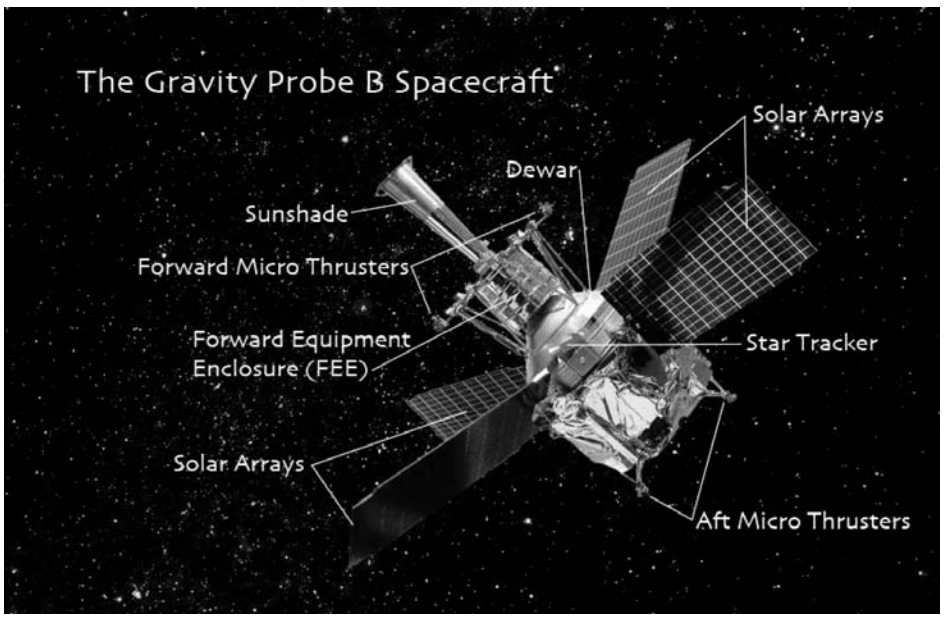

Fig. 1. GP-B spacecraft.

The HETE-1 satellite was launched on November 4, 1996; along with the Argentine satellite SAC-B, on a Pegasus rocket from Wallops Island, VA. The Pegasus rocket achieved a good orbit, but the third stage failed to release the two satellites. As a result, SAC-B and HETE-1 were unable to function as designed and both died due to lack of solar power within a day of launch. Due to the tragic fate of HETE-1 and the continuing timeliness of GRB science, NASA agreed to a reflight of the HETE-1 satellite, using flight spare hardware from the first satellite. In July, 1997, funding for a second HETE satellite was granted, with a target launch date of late 1999 or early 2000.

Construction of the HETE-2 satellite began in mid-1997. The HETE-2 satellite bus was built entirely at MIT. In January, 2000, the HETE-2 satellite was fully complete and being prepared for launch from Kwajalein Atoll in the Republic of the Marshall Islands. On January 14, 2000, NASA decided to postpone the launch. Several factors contributed to the decision to delay the launch. Although the *required* primary HETE-2 telemetry ground station at Kwajalein was completely launch ready, NASA was concerned that neither of the two HETE-2 *backup* stations (Cayenne, French Guiana; Singapore) were completely operational. Delays in the ITAR (State Department) export approval process meant that the Cayenne station would come on line just a week prior to the scheduled launch, while the Singapore station would possibly not be available until after January 28. The recent heightened concern for additional ground station availability was a consequence of NASA's desire that there be ample telemetry contact with HETE-2 in the critical early phases of the mission, so that any unforeseen satellite activation difficulties of the type encountered by a number of recent NASA-launched missions could be avoided or minimized. HETE-2 was successfully launched on October 9, 2000.

The HETE program is an international collaboration led by the Center for Space Research at the Massachusetts Institute of Technology. Our collaborating institutions include the Institute for Chemistry and Physics (RIKEN), the Los Alamos National Laboratory (LANL), the Center d'Etude Spatiale des Rayonnements (CESR), the University of Chicago, the University of California, Berkeley, the University of California, Santa Cruz, the Center Nationale d'Etudes Spatiales (CNES), the Ecole Nationale Superieure de l'Aeronautique et de l'Espace (Sup'Aero), the Consiglio Nazionale delle Ricerche (CNR), the Instituto Nacional de Pesquisas Espaciais (INPE), and the Tata Institute of Fundamental Research (TIFR).

The HETE-2 spacecraft is a small satellite, measuring roughly a meter high (3.28 feet) by half a meter (1.64 feet) in diameter. HETE-2 retains most of the original HETE-1 design, with significant modifications made primarily to the power system. It was developed and constructed by essentially the same MIT team that completed HETE-1, relying in part on key spacecraft design and development consultants.

The spacecraft consists of a spacecraft bus, in which the satellite control hardware and the spacecraft computers reside, and the science payload, which point out one end of the spacecraft. The four solar panels (which are stowed, parallel to the spacecraft, for launch) are connected at the bottom of the spacecraft bus, and the science instruments point out the top. See Fig. 2. On orbit, the science instruments will always be pointing away from the sun, and the deployed solar panels will be directed toward the sun.

HETE-2 is equipped with instruments sensitive to gamma- and X-radiation. These instruments share a common field of view of 1.5 steradians, span a detectable energy range of about 3 decades, and are capable of immediate inter-instrument communication.

- The gamma-ray instrument, FREGATE, is sensitive to photons in the 6-400 keV energy range. It will provide accurate burst triggers and moderate resolution spectra. FREGATE was built by the CESR in Toulouse, France. The design of the French Gamma Telescope (FREGATE) is based on that of the successful gamma-ray burst experiment LILAS on board the Russian Phobos mission. Its prime objectives are the detection and spectroscopy of gamma-ray bursts and the monitoring of variable X-ray sources.
- The wide-field X-ray Monitor (WXM) is sensitive in the 2-25 keV energy range, with good energy resolution and localization accuracy to $\sim$10 arc-minutes or better. The WXM consists of two identical units of one-dimensional position sensitive X-ray detectors. They are oriented orthogonally to each other to measure the X and Y directions independently.
  The WXM detectors were built by RIKEN and Los Alamos National Laboratory.
- The soft X-ray camera (SXC) is sensitive in the 0.5-10 keV energy range, with very good energy resolution and localization accuracy to 30 arc-seconds or better. The soft X-ray cameras are a set of CCD-based one-dimensional coded-aperture X-ray imagers, similar in function to the WXM. There are two SXCs on HETE-2: one localizes X-rays parallel to the spacecraft X-axis, the other parallel to the Y-axis. Because of the small CCD pixel size, the angular size of a SXC pixel is only 33 arc-seconds. The SXC was built by the Center for Space Research at MIT

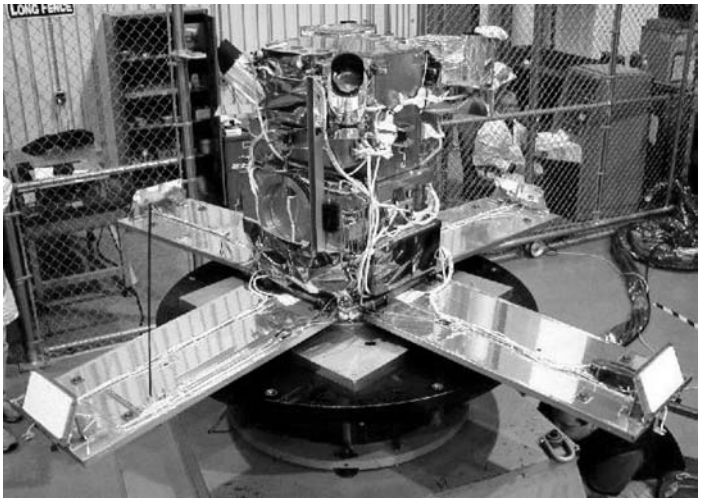

Fig. 2. HETE-2 spacecraft in it deployed state. *(MIT)*

Each HETE-2 instrument operates independently of the others; however, if a burst is detected by one of the instruments, the others are notified and begin collecting data at higher temporal and energy resolution. All instruments utilize on board sensors to determine safe and appropriate operational conditions.

Hubble Space Telescope (HST). The Hubble Space Telescope (HST) is a space-based telescope deployed on April 25, 1990 by the space shuttle Discovery (STS-31). From its position 380 miles above the Earth's surface, the HST has expanded our understanding of star birth, star death, and galaxy evolution, and has helped move black holes from theory to fact. In its first 15 years, the telescope recorded over 700,000 images.

The telescope's instruments are the astronomer's eyes to the universe. Its instruments include the Wide Field Planetary Camera 2 (WFPC2), Near Infrared Camera and Multi-Object Spectrometer (NICMOS), Advanced Camera for Surveys (ACS), and Fine Guidance Sensors (FGS).

When first launched, the HST's primary mirror was out of shape on the edges by 1/50 of a human hair. This very small defect made it difficult to focus faint objects being viewed by the Hubble. Because the HST is in low Earth orbit, it could be serviced by a shuttle. The defect was corrected in one such servicing mission (SM1) in December 1993. Hubble was designed to be repaired and upgraded by astronauts, and these servicing missions have occurred several times since Hubble's launch in 1990. Servicing mission 2 (SM2) was accomplished in March 1997 and SM3 in December 1999. SM4 scheduled for 2008 has an ambitious program of activities. Over a series of five spacewalks, astronauts will replace worn-out telescope components, installing new batteries, new gyroscopes, a refurbished Fine Guidance Sensor, replacement thermal blankets, and more. It will significantly enhance Hubble's prowess with the installation of two new science instruments: the Wide Field Camera 3 and the Cosmic Origins Spectrograph. These upgrades will keep Hubble functioning at the pinnacle of astronomy well into the next decade. See also **Hubble Space Telescope (HST)**.

Quick Facts about Hubble include:

- **size**: Hubble is nearly the size of al large school bus — but it can fit inside a space shuttle cargo bay. Length 43.5 ft. (13.2 m); weight 24,500 lb (11,110 kg); and maximum diameter 14 ft. (4.2 m).
- **Cost at Launch**: $1.5 billion.
- **Spaceflight Statistics**: The Hubble Space Telescope whirls around Earth at a speed of 5 miles per second. If cars moved that fast, a coast-to-coast trip across the continental United States would take only 10 minutes. Orbit: At an altitude of 307 nautical miles (569 km, or 353 miles), inclined 28.5 degrees to the equator (low-Earth orbit;) Time to Complete One Orbit: 97 minutes; Speed: 17,500 mph (28,000 kph).
- **Hubble Cannot Observe**: The Sun or Mercury, which is too close to the Sun.
- **Sensitivity to Light**: Ultraviolet through infrared (115–2500 nanometers).
- **First Image**: May 20, 1990: Star Cluster NGC 3532. The most frequently observed celestial object is Earth. Earth is observed regularly for calibration — to make sure that all the charge-coupled detectors (CCDs) are working properly. The images from these "test" observations show no detail.
- **Data Stats**: Hubble transmits about 120 gigabytes of science data every week. That's equal to about 3,600 feet (1,097 meters) of books on a shelf. The rapidly growing collection of pictures and data is stored on magneto-optical disks.
- **Power Needs**: Energy source the Sun; Mechanism two 25-foot (7.6 meter) solar panels; Power usage 2,800 watts. In an average orbit, Hubble uses about the same amount of energy as 28 100-watt light bulbs.
- **Pointing Accuracy**: In order to take images of distant, faint objects, Hubble must be extremely steady and accurate. The telescope is able to lock onto a target without deviating more than 7/1000th of an arcsecond, or about the width of a human hair seen at a distance of 1 mile. Pointing the Hubble Space Telescope and locking onto distant celestial targets is like holding a laser light steady on a dime that is 200 miles away.
- **Hubble's Mirrors: Primary Mirror**; Diameter: 94.5 in (2.4 m), Weight 1,825 lb (828 kg); **Secondary Mirror**; Diameter: 12 in (0.3 m), Weight 27.4 lb (12.3 kg). Hubble's two mirrors were ground so that they do not deviate from a perfect curve by more than 1/800,000ths of an inch. If Hubble's primary mirror were scaled up to the diameter of the Earth, the biggest bump would be only six inches tall.
- **Power Storage: Batteries**: 6 nickel-hydrogen (NIH); **Storage capacity**: equal to 20 car batteries.

International Gamma-Ray Astrophysics Laboratory (INTEGRAL). INTEGRAL is an abbreviation for **INTE**rnational **G**amma-**R**ay **A**strophysics **L**aboratory. The task of INTEGRAL, ESA's International Gamma-Ray Astrophysics Laboratory, in cooperation with Russia and the United States, is to gather some of the most energetic radiation that comes from space. It is the most sensitive gamma-ray observatory ever launched and it may help to solve some of the biggest mysteries in astronomy.

INTEGRAL was successfully launched by a Proton rocket, on 17 October 2002, Russia's largest operational launch vehicle from the Baikonur Cosmodrome in the Republic of Kazakhstan, about 2,100 kilometers (1,302 miles) south-east of Moscow, Russia.

INTEGRAL is providing new insight into the most violent and exotic objects of the Universe, such as black holes, neutron stars, active galactic nuclei and supernovae. INTEGRAL is also helping us to understand processes such as the formation of new chemical elements and mysterious gamma-ray bursts, the most energetic phenomena in the Universe. This will be possible thanks to INTEGRAL's combination of fine spectroscopy and imaging of gamma-ray emissions in the energy range of 15 keV to 10 MeV. INTEGRAL also has an optical camera and X-ray detector, energy range 3 to 35 keV, for simultaneous observations across the EM spectrum.

The following topics are steadily being addressed by INTEGRAL:

- Compact Objects (White Dwarfs, Neutron Stars, Black Hole Candidates, High Energy Transients and Gamma-Ray Bursts)
- Extragalactic Astronomy (Galaxies, Clusters, AGN, Seyferts, Blazars, Cosmic Diffuse Background)
- Stellar Nucleosynthesis (Hydrostatic Nucleosynthesis (AGB, WR Stars), Explosive Nucleosynthesis (Supernovae, Novae))
- Galactic Structure (Cloud Complex Regions, Mapping of continuum and line emission, ISM, CR distribution)
- The Galactic Center Particle Processes and Acceleration (Transrelativistic Pair Plasmas, Beams, Jets)
- Identification of High Energy Sources (Unidentified Gamma-Ray Objects as a Class)
- PLUS: Unexpected Discoveries A unique aspect of the INTEGRAL mission is the weekly scans of the galactic plane. These are building-up into a detailed survey. Each weekly scan consists of a "slew, stop, stare" profile along a saw-tooth track, inclined at 21° to the galactic equator.

Every three days INTEGRAL orbits the Earth once. The spacecraft spends most of its time at the furthest parts of its orbit, at an altitude higher than 40,000 kilometers (24,855 miles), well outside the Earth's radiation belts, to avoid background radiation effects. From here ESA's gamma-ray observatory sends back to Earth new information about the most exciting phenomena in the universe. It reports on violent explosions, the formation of elements, black holes and other exotic objects in our Milky Way, the cosmic neighborhood and much further, in distant galaxies at the edge of the observable universe.

The spacecraft standing 5 meters (16 feet) high and more than 4 tonnes (8,819 pounds) in weight, the INTEGRAL spacecraft is impressive. See Fig. 3. The satellite has two main parts: (1)The service module is the lower part of the satellite and contains all spacecraft subsystems,(2)The payload module is mounted on the service module and carries the scientific instruments.

Fig. 3. An artist's impression of the INTEGRAL spacecraft. At the front is the SPI instrument with its circular coded mask and behind the square mask of the IBIS instrument. JEM-X, the X-ray monitor, is located between these two instruments with the OMC (Optical Monitoring Camera) to the side. (*Image courtesy of ESA*)

To limit the costs of the mission the service module is a rebuild of the one developed for XMM-Newton, ESA's X-ray Multi-Mirror satellite. It is a closed structure made of composite material, a combination of aluminium and carbon fiber. It houses the satellite systems, including solar power generation, power conditioning and control, data handling, telecommunications and thermal, attitude and orbit control.

The four scientific instruments of INTEGRAL's payload module weigh 2 tonnes (4,409 pounds), making this payload the heaviest ever placed in orbit by ESA. This is due to the need to shield the detectors from background radiation in order to make them sensitive. There are two main instruments detecting gamma-rays. The imager gives the sharpest gamma-ray images yet seen from astronomical targets. Meanwhile the spectrometer precisely measures gamma-ray energies. Two other instruments, an X-ray monitor and an optical camera, help to identify the gamma-ray sources.

There is a special support structure 4 meters (13 feet) above the platform with the instrument detectors carrying the coded masks. These metal masks produce the images of the gamma-ray sources. Since gamma-rays cannot be focused by conventional lenses or mirrors, INTEGRAL has to use an entirely different technique to make its images, known as the coded mask technique. A coded-mask telescope is a pinhole camera with not just one but many pinholes.

Rossi X-Ray Timing Explorer (RXTE). The Rossi X-ray Timing Explorer (RXTE) is a satellite that observes the fast-moving, high-energy worlds of black holes, neutron stars, X-ray pulsars and bursts of X-rays that light up the sky and then disappear forever. See Fig. 4.

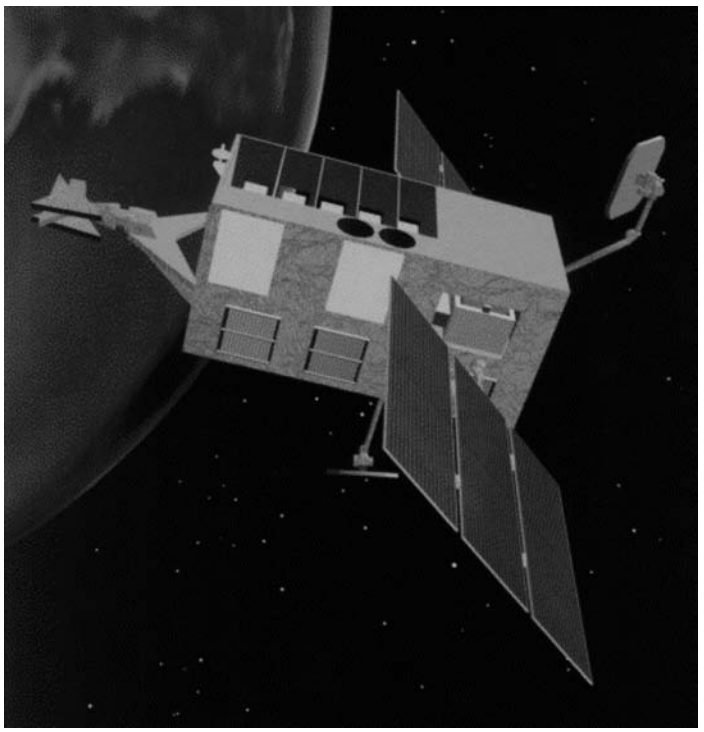

Fig. 4. Artist's impression of RXTE observing a source. (*NASA*)

How fast and how energetic are they? Well, some pulsars spin faster than a thousand times a second. And a neutron star produces a gravitational pull so powerful that a marshmallow striking the star's surface would hit with the force of a thousand hydrogen bombs. Astronomers study changes that happen from microseconds to months in cosmic objects to learn about how gravity works near black holes, how pulsars in binary systems are affected by mass transferring from one star to the other, and how the giant engines in distant galaxies are powered. RXTE was launched into low-Earth orbit on December 30, 1995, and is still going strong, making unique contributions to our understanding of these extreme objects.

For RXTE, the trick to observing these kinds of objects is all in the timing — an ability to observe changes in X-ray brightness that occur in a mere thousandths of a second, or over several years. Learn more about how this one-of-a-kind satellite has reshaped our understanding of what goes on in the most violent and bizarre regions of the Universe. See also **Rossi X-Ray Timing Explorer (RXTE)**.

Scientific Balloons. Large unmanned helium balloons provide NASA with an inexpensive means to place payloads into a space environment, crucial for the development of new technologies and payloads for NASA's space flight missions. Also, important scientific observations in fields such as hard x-ray/gamma-ray and infra-red astronomy, cosmic rays and atmospheric studies are being made from balloons. See also **Balloon**; and **Scientific Balloons**.

Spitzer Space Telescope. Spitzer (formerly known as SIRTF) conducts infrared astronomy from space. From an unusual heliocentric orbit designed to keep its sensitive instruments away from Earth's radiated heat, Spitzer has detected several distant objects — including several supermassive black holes — that are nearly invisible in even the deepest images from telescopes operating at other wavelengths.

The Spitzer Space Telescope was launched into space by a Delta rocket from Cape Canaveral, Florida on 25 August 2003. During its 2.5-year mission, Spitzer will obtain images and spectra by detecting the infrared energy, or heat, radiated by objects in space between wavelengths of 3 and 180 microns (1 micron is one-millionth of a meter). Most of this infrared radiation is blocked by the Earth's atmosphere and cannot be observed from the ground. See also **Great Observatory Program**; and **Spitzer Space Telescope**.

Suzaku (formerly Astro-E2). *Suzaku* is Japan's fifth X-ray astronomy mission, and was developed at the Institute of Space and Astronautical Science of Japan Aerospace Exploration Agency (ISAS/JAXA) in collaboration with U.S. (NASA/GSFC, MIT) and Japanese institutions, and launched on July 10, 2005. *Suzaku* is the recovery mission for *ASTRO-E*, which did not achieve orbit during launch in February 2000. See Fig. 5.

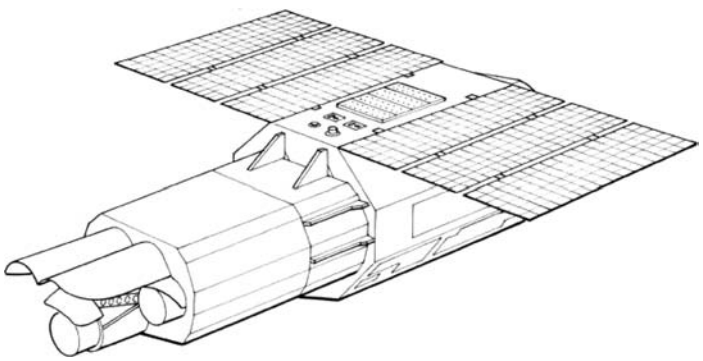

Fig. 5. Although this drawing was made for ASTRO-E, it also accurately represents *Suzaku*. (*Image courtesy of ISAS/JAXA*)

Suzaku instruments will achieve:(1)High X-ray spectral resolution throughout the 0.2-10 keV energy band where the bulk of K-shell lines of astrophysically abundant elements (O-Ni) exist. (2)Imaging spectroscopy of extended sources using non-dispersive spectrometers. (3)Large collecting area for high sensitivity. (4)Very large simultaneous bandwidth to enable disentangling complex, multi-component spectra.

Thus *Suzaku* is complementary to Chandra and XMM-Newton observatories.

Suzaku has three major instruments. These are:

- ***The X-Ray Spectrometer (XRS)*** http://astroe.gsfc.nasa.gov/docs/suzaku/about/xrs_inst.html which is the acknowledged "primary" instrument. This is the same instrument that was to have been part of AXAF. It is a non-dispersive (thus, high-efficiency) imaging (30-element) spectrometer (about 6.5 eV FWHM). It is cryogenically cooled by an adiabatic diamagnetic refrigerator within a helium dewar, which, as well as the XRS sensor, is provided by GSFC. The helium dewar is located within a Japanese-provided solid neon dewar, which in turn is cooled by a mechanical cooler. The current estimate of the cryo lifetime is about 2.5 years, but it is hoped to get to three. The life time depends upon design requirements associated with considerations such as launch loads. The detector array sits behind a conical foil mirror (X-ray Telescope, or XRT) http://astroe.gsfc.nasa.gov/docs/suzaku/about/xrt_inst.html, assembly provided by the GSFC, with spatial resolution of about 1.8' half power diameter (HPD). The effective area of this system at 6 keV is about 150 cm^2.
- There are 4 units of ***X-ray Imaging Spectrometer (XIS)*** http://astroe.gsfc.nasa.gov/docs/suzaku/about/xis_inst.html. Each XIS, an X-ray CCD camera, is at the focus of an XRT. All 4 XIS units are co-aligned, with the XRS field-of-view at its center. The telescopes are provided by GSFC, while the CCD chips are the responsibility of MIT, and the digital electronics are supplied by a consortium of Japanese institutions.
- ***The Hard X-ray Detector (HXD)*** http://astroe.gsfc.nasa.gov/docs/suzaku/about/hxd_inst.html, is a non-imaging instrument provided by a

Japanese consortium led by the University of Tokyo and ISAS/JAXA. It is a hard X-ray (of order 10-600 keV) collimated system of "well" detectors. The HXD is characterized by the low background of $\sim 10^{-5}$ cts/s/cm^2/ keV; its sensitivity is higher than any past missions in the energy range from a few tens keV to several hundreds keV. The anti-counters, whose main purpose is to reject particle background, are also expected to detect transient high energy phenomena such as the gamma-ray bursts.

The U.S. *Suzaku* Guest Observer Facility (GOF) is located at NASA's Goddard Space Flight Center in Greenbelt, Maryland. The GOF is part of the Office of General Investigator Programs (OGIP) in the Astrophysics Science Division (ASD).

The primary responsibility of the U.S. *Suzaku* GOF is to enable U.S. astronomers to make the best use of the *Suzaku* mission. To fulfill this responsibility, the *Suzaku* GOF staff performs such activities as supporting the U.S. side of the *Suzaku* proposal selection process, distributing usable data to U.S. Guest Observers, helping Guest Observers to analyze their data, and creating the mission archive.

In addition to the tasks listed above, the U.S. *Suzaku* GOF activities include the development of software, the compilation and production of documentation for that software, and the provision of expert help. All of the U.S. *Suzaku* GOF's activities involve close collaboration with the Japanese *Suzaku* team.

Swift Gamma Ray Burst Explorer. Swift is a three-telescope space observatory for studying the position, brightness, and physical properties of gamma ray bursts. See Fig. 6. Although gamma ray bursts are the largest known explosions in the Universe, outshining the rest of the Universe when they explode unpredictably in distant galaxies, their underlying nature and the cause of the explosion are true mysteries of astrophysics. Swift is part of NASA's medium explorer (MIDEX) program and was launched into a low-Earth orbit on a Delta 7320 rocket on November 20, 2004. See also **Explorers Program**.

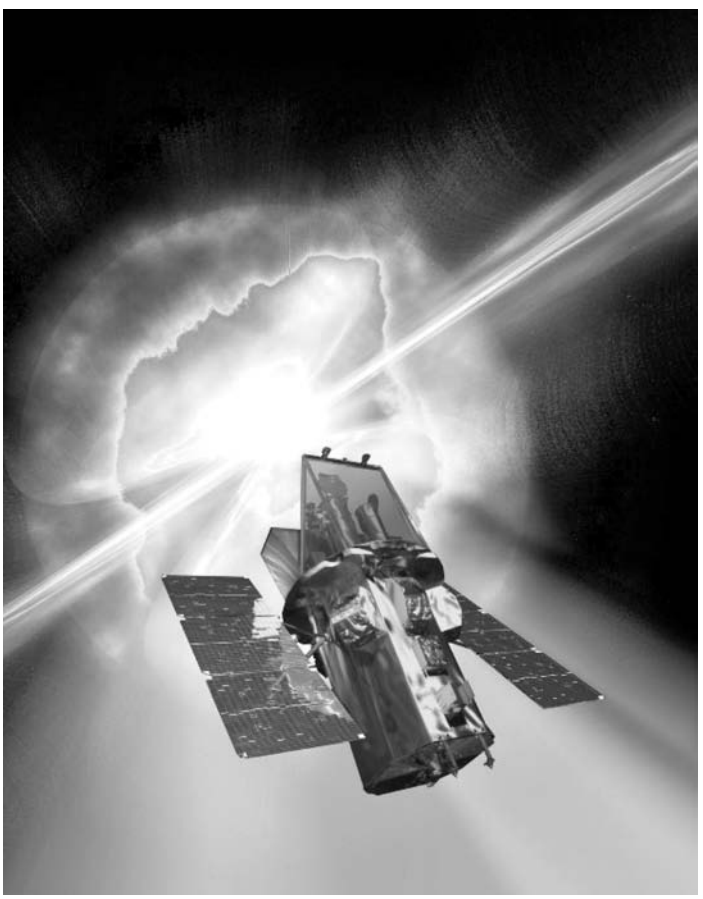

Fig. 6. An artist rendering of the Swift spacecraft with a gamma-ray burst going off in the background. (*Image courtesy of Spectrum Astro*)

Wilkinson Microwave Anisotropy Probe (WMAP). WMAP produced the earliest "baby picture" of the universe, showing temperature variation of microwave light 379,000 years after the Big Bang, over 13 billion years ago. WMAP was launched on June 30, 2001 from the Cape Canaveral Air Force Base aboard a Delta II rocket. See also **Beyond Einstein Program**; and **Explorers Program**.

XMM-Newton (The High-Throughput X-Ray Spectroscopy Mission). After launch from Kourou, French Guiana atop an Ariane 5 launch vehicle on 10 December 1999, the European Space Agency's X-ray Multi-Mirror satellite is the most powerful X-ray telescope ever placed in orbit. See Fig. 7. Scientists are sure the mission will help solve many cosmic mysteries, ranging from enigmatic black holes to the formation of galaxies.

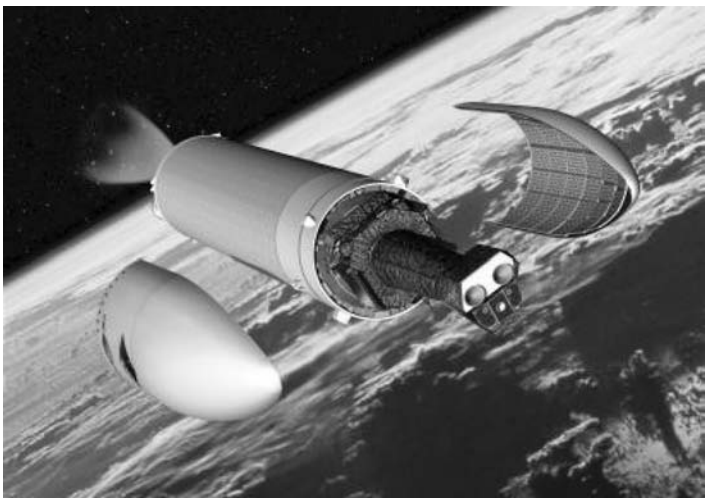

Fig. 7. Artist's impression of launcher fairing separation. (*ESA*)

On launch XMM-Newton became the most sensitive X-ray observatory ever launched. Its high quality focusing mirrors and battery of instruments enable it to achieve the following:

- Investigate spectra of cosmic X-ray sources with a limiting flux of 10^{-15} erg cm^{-2} s^{-1}
- Performing sensitive medium-resolution spectroscopy with resolving powers between 100 and 700 over the wavelength band 5–35 Å (350–2500 eV)
- Broad band imaging spectroscopy from 100 eV to 15 keV (0.8–120 Å)
- Simultaneous sensitive coverage of the wavelength band 1600 to 6000 Å through a dedicated co-aligned optical monitor

Many celestial objects generate X-rays in extremely violent processes. But Earth's atmosphere blocks out these X-rays, messengers of what occurred in the distant past when stars were born or died, and clues to our future. Only by placing X-ray detectors in space can such sources be detected, pinpointed and studied in detail. XMM-Newton, the largest science satellite ever built in Europe, has an unprecedented sensitivity.

XMM-Newton carries three very advanced X-ray telescopes. They each contain 58 high-precision concentric mirrors, delicately nested to offer the largest collecting area possible to catch the elusive X-rays. These Mirror Modules allow XMM-Newton to detect millions of sources, far more than any previous X-ray mission. See also **XMM-Newton (The High-Throughput X-Ray Spectroscopy Mission)**.

Large Binocular Telescope (LBTI). The Large Binocular Telescope (LBT) will study the formation of solar systems and will be capable of directly detecting giant planets outside our solar system.

LBT Two 8.4-meter (27.5 -foot) class telescopes on Mount Graham, Arizona, will be connected in an infrared interferometer. The resulting instrument will have a maximum baseline of 22.8 meters (74 feet). When completed, it will be the world's most advanced optical telescope.

Because of its unique geometry and relatively direct optical path, the LBTI will offer science capabilities that are different from other

interferometers. It will provide high-resolution images of many faint objects over a wide field-of-view, including galaxies in the Hubble Deep Field with 10 times the Hubble resolution.

Nulling techniques will enable the LBTI to study emissions from faint dust clouds around other stars. These dust clouds reflect light and give off heat, and so interfere with the search for planets. By helping to characterize these emissions, the LBTI will provide critically needed data for the design of the Terrestrial Planet Finder (TTP), a future mission that will study planets orbiting nearby stars. See also **Terrestrial Planet Finder (TTP)**.

The Large Binocular Telescope (LBT) is a collaboration between the Italian astronomical community (represented by the Instituto Nazionale di Astrofisica (INAF)), The University of Arizona, Arizona State University, Northern Arizona University, the LBT Beteiligungsgesellschaft in Germany (Max-Planck-Institutfür Astronomie in Heidelberg, Landesternwarte in Heidelberg, Astrophysikalisches Institut in Potsdam, Max-Planck-Institut für Extraterrestrische Physik in Munich, and Max-Planck-Institut für Radioastronomie in Bonn), The Ohio State University, Research Corporation in Tucso, and the University of Notre Dame. See also **Origins Program**.

Future Missions

Constellation-X. Constellation-X has been designed to perform X-ray spectroscopy with unprecedented sensitivity and spectral resolution, to determine the flow of gas in accretion disks around black holes in active galactic nuclei and in binary X-ray sources, to measure the population of newly created elements in supernova remnants, and to detect the influence of dark matter on the hot intergalactic medium in clusters of galaxies. See also **Beyond Einstein Program**.

Gamma-ray Large Area Space Telescope (GLAST). An heir to its successful predecessor — the Compton Gamma Ray Observatory — GLAST will have the ability to detect gamma rays in a range of energies from thousands to hundreds of billions of times more energetic than the light visible to the human eye. Radiation of such magnitude can only be generated under the most extreme conditions, thus GLAST will focus on studying the most energetic objects and phenomena in the universe. See also **Compton Gamma-Ray Observatory (CGRO)**.

The Universe is home to numerous exotic and beautiful phenomena, some of which can generate almost inconceivable amounts of energy. Supermassive black holes, merging neutron stars, streams of hot gas moving close to the speed of light ... these are but a few of the marvels that generate gamma-ray radiation, the most energetic form of radiation, billions of times more energetic than the type of light visible to our eyes. What is happening to produce this much energy? What happens to the surrounding environment near these phenomena? How will studying these energetic objects add to our understanding of the very nature of the Universe and how it behaves?

The Gamma-ray Large Area Space Telescope (GLAST) will open this high-energy world to exploration and help us to answer these questions. With GLAST, astronomers will at long last have a superior tool to study how black holes, notorious for pulling matter in, can accelerate jets of gas outward at fantastic speeds. Physicists will be able to study subatomic particles at energies far greater than those seen in ground-based particle accelerators. And cosmologists will gain valuable information about the birth and early evolution of the Universe.

The key scientific objectives of the GLAST mission are:

1. To understand the mechanisms of particle acceleration in AGNs, pulsars, and SNRs. This understanding is a key to solving the mysteries of the formation of jets, the extraction of rotational energy from spinning neutron stars, and the dynamics of shocks in SNRs.
2. Resolve the gamma-ray sky: unidentified sources and diffuse emission.Interstellar emission from the Milky Way and a large number of unidentified sources are prominent features of the gamma-ray sky.
3. Determine the high-energy behavior of gamma-ray bursts and transients. Variability has long been a powerful method to decipher the workings of objects in the Universe on all scales. Variability is a central feature of the gamma-ray sky.
4. Probe dark matter and early Universe. Observations of gamma-ray AGN serve to probe supermassive black holes through jet formation and evolution studies, and provide constraints on the star-formation rate at early epochs through photon-photon absorption over extragalactic distances. There are also the possibilities of observing monoenergetic gamma-ray "lines" above 30 GeV from supersymmetric dark matter interaction; detecting decays of relics from the very early Universe, such as cosmic strings or evaporating primordial black holes; or even using gamma-ray bursts to detect quantum gravity effects.

For this unique endeavor, one that brings together the astrophysics and particle physics communities, NASA is teaming up with the U.S. Department of Energy and institutions in France, Germany, Japan, Italy and Sweden. General Dynamics has been chosen to build the spacecraft. The launch is scheduled for October 7, 2007.

The GLAST Large Area Telescope will consist of four main components.

Precision Tracker. The LAT baseline design for the GLAST tracker consists of a four-by-four array of tower modules. Each tower module consists of interleaved planes of silicon-strip detectors and lead converter sheets. Silicon-strip detectors are able to more precisely track the electron or positron produced from the initial gamma-ray than previous types of detectors. SSDs will have the ability to determine the location of an object in the sky to within 0.5 to 5 arc minutes. The pair conversion signature is also used to help reject the much larger background of charged cosmic rays. The high intrinsic efficiency and reliability of this technology enables straight forward event reconstruction and excellent resolution with small tails. These ease-of-use properties will maximize the mission science return for guest observers.

In each module, there are 19 pairs of of silicon — in each pair, one plane has the strips oriented in the "x-direction", while the other has the strips oriented in the perpendicular "y-direction". When a particle interacts in the silicon, its position on the plane can therefore be determined in two dimensions. The third dimension of the track is determined by analyzing signals from adjacent planes, as the particle travels down through the telescope towards the calorimeter.

Calorimeter. The calorimeter design for GLAST produces flashes of light that are used to determine how much energy is in each gamma-ray. A calorimeter ("calorie-meter") is a device that measures the energy (heat: *calor*) of a particle when it is totally absorbed. CsI(Tl) bars, arranged in a segmented manner, give both longitudinal and transverse information about the energy deposition pattern. Once a gamma ray penetrates through the anticoincidence shield, the silicon-strip tracker and lead converter planes, it then passes into the cesium-iodide, and the resultant light flash is photoelectrically converted to a voltage. This voltage is then digitized, recorded and relayed to earth by the spacecraft's onboard computer and telemetry antenna. Cesium-iodide blocks are arranged in two perpendicular directions, to provide additional positional information about the shower.

Data Acquisition System. The Data acquisition system (DAQ) is the brain behind GLAST, as it makes the initial distinction between false signals and real gamma ray signals, and decides which of the signals should be relayed to the ground. This system collects the data from the subsystems, implements the multi-level event trigger, and provides an on-board science analysis platform to search for transients. The DAQ consists of specialized electronics and 32-bit radiation-hard processors that record and analyze the information generated by the silicon-strip detectors and the calorimeter. The DAQ will be shielded from the rigors of space-flight, such as extreme high and low temperatures as well as high energy cosmic rays, which can cause the electronics to malfunction.

Anticoincidence Detector. The Anticoincidence Detector is the first line of defense against the enormous charged particle background from cosmic ray primary and Earth albedo secondary electrons and nuclei. It consists of segmented plastic scintillator tiles, read out by wave-shifting fibers and photo-multiplier tubes. The segmentation is designed to avoid the self-veto problem of EGRET at high energies while still providing high cosmic-ray rejection.

Herschel Space Observatory. The Herschel Space Observatory will be the largest ever infrared space observatory when it is launched in 2008. Equipped with a 3.5 meter (11.5 foot) diameter reflecting telescope and instruments cooled to close to absolute zero, Herschel will observe at wavelengths that have never previously been explored. After a four-month

journey from Earth, Herschel will spend a nominal mission lifetime of three years in orbit around the second Lagrange point of the Sun-Earth system (L2).

The Herschel spacecraft is approximately 9 meters (29.5 feet) high and 4×4 meters (13×13 feet) in overall cross section, with a launch mass of around 3.3 tonnes (7,275 pounds). See Fig. 8. The spacecraft comprises a service module, which houses systems for power conditioning, attitude control, data handling and communications, together with the warm parts of the scientific instruments, and a payload module. The payload module consists of the telescope, the optical bench, with the parts of the instruments that need to be cooled, i.e. the sensitive detector units and cooling systems. The payload module is fitted with a sunshield, which protects the telescope and cryostat from solar visible and infrared radiation and also prevents Earth straylight from entering the telescope. The sunshield also carries solar cells for the electric power generation.

Fig. 8. A computer generated image of the Herschel spacecraft. (*Image courtesy of ESA*)

The Herschel telescope is a Cassegrain design with a primary mirror diameter of 3.5 meters (11.5 feet), the largest ever built for use in space. The Herschel science payload comprises three instruments that perform a combination of spectrometry, imaging spectrometry and imaging photometry covering a wavelength range from 60 to 670 μm.

Herschel's primary objectives are to:

- Study the formation of galaxies in the early universe and their subsequent evolution
- Investigate the creation of stars and their interaction with the interstellar medium
- Observe the chemical composition of the atmospheres and surfaces of comets, planets and satellites
- Examine the molecular chemistry of the universe

With its ability to observe across the far infrared and sub-millimeter wavelengths, Herschel will furnish observation data that has previously been unobtainable.

The instruments are provided by collaborative efforts between scientific institutes in ESA member states, Canada and the USA. Principal investigators in different countries lead the nationally funded collaborations. The three scientific instruments are: (1) **HIFI** (**H**eterodyne **I**nstrument for the **F**ar **I**nfrared), a very high resolution heterodyne spectrometer. (2) **PACS** (**P**hotodetector **A**rray **C**amera and **S**pectrometer) — an imaging photometer and medium resolution grating spectrometer. (3) **SPIRE** (**S**pectral and **P**hotometric **I**maging **R**eceiver) — an imaging photometer and an imaging Fourier transform spectrometer.

The instruments have been designed to take maximum advantage of the characteristics of the Herschel mission. In order to make measurements at infrared and sub-millimeter wavelengths, parts of the instruments have to be cooled to near absolute zero. The optical bench, the common mounting structure of all three instruments, is contained within the cryostat and over 2000 liters of liquid helium will be used during the mission for primary cooling. Individual instrument detectors are equipped with additional, specialized cooling systems to achieve the very lowest temperatures.

James Webb Space Telescope (JWST). The James Webb Space Telescope (JWST) is a large, infrared-optimized space telescope, scheduled for launch in 2013. JWST will find the first galaxies that formed in the early Universe, connecting the Big Bang to our own Milky Way Galaxy. JWST will peer through dusty clouds to see stars forming planetary systems, connecting the Milky Way to our own Solar System. JWST's instruments will be designed to work primarily in the infrared range of the electromagnetic spectrum, with some capability in the visible range. JWST will have a large mirror, 6.5 meters (21.3 feet) in diameter and a sunshield the size of a tennis court. Both the mirror and sunshade won't fit onto the rocket fully open, so both will fold up and open only once JWST is in outer space. JWST will reside in an orbit about 1.5 million km (1 million miles) from the Earth.

The JWST was formerly known as the "Next Generation Space Telescope" (NGST). The JWST was renamed after a former NASA Administrator. See also **James Webb Space Telescope**.

Kepler. The *Kepler Mission* is a special purpose space mission specifically designed to detect Earth-size planets around stars in the solar neighborhood of the Galaxy. By monitoring 100,000 stars over a four-year mission, *Kepler* could detect on the order of 500 Earth-size planets and on the order of 1000 Jupiter-size planets. Kepler is scheduled to launch November 1, 2008. See also **Kepler Mission**.

Laser Interferometer Space Antenna (LISA). LISA is a gravity wave telescope which will open up one of the last non-electromagnetic channels for studying the Universe. Its goal is to detect gravitational radiation with periods of minutes to hours such as that produced by two coalescing massive black holes in a distant galaxy. LISA will also provide an unprecedented test of strong field general relativity. See also **Laser Interferometer Space Antenna (LISA)**. LISA has a planned launch date early 2015. See also **Beyond Einstein Program**; and **Laser Interferometer Space Antenna (LISA)**.

Planck. The Planck mission will collect and characterize radiation from the Cosmic Microwave Background (CMB) using sensitive radio receivers operating at extremely low temperatures. These receivers will determine the black body equivalent temperature of the background radiation and will be capable of distinguishing temperature variations of about one microkelvin. These measurements will be used to produce the best ever maps of anisotropies in the CMB radiation field.

Planck will be carried into space from the Guiana Space Center, Kourou, French Guiana, in July 2008 by an Ariane-5 launcher. Planck has a nominal operational lifetime of twenty-one months. Planck will be launched together with ESA's Herschel spacecraft. The two vehicles will separate shortly after launch and proceed independently to different orbits about the second Lagrange point of the Earth-Sun system (L2). See Fig. 9.

After a journey lasting between four and six months, Planck will make a major maneuver to enter its operational orbit, a small Lissajous orbit around L2, 1.5 million kilometers (1 million miles) away from the Earth.

The Planck spacecraft is 4.2 meters (13.8 feet) high and has a maximum diameter of 4.2 meters (13.8 feet), with a launch mass of around 1.8 tonnes

Fig. 9. Planck (lower, covered by the speltra) and Herschel (upper) in dual launch configuration under the Ariane 5 fairing. (*Image courtesy of ESA*.)

(3,968 pounds). The spacecraft comprises a service module, and payload module. See Fig. 10.

The payload module comprises: (1) The Telescope, equipped with primary and secondary mirrors that collect microwave radiation and direct it onto the instrument focal plane units and a baffling system to restrict the entry of stray radiation into the telescope optics. (2) The cryogenic focal plane units of the two instruments. (3) The instrument cooling chains (excluding the compressors and control electronics)

The service module contains the systems needed to operate the spacecraft:

- Power: generation, storage, conditioning and distribution of electric power
- Attitude and Orbit Control: measurement of the spacecraft's attitude using star trackers and sun sensors, and changing the spacecraft's attitude or orbit by means of hydrazine thrusters
- Control and Data Management: receipt, storage and execution of ground commands, autonomous operation of the spacecraft in the absence of a ground station link, storage and management of observation and housekeeping data
- RF Communications: linking the spacecraft with the ground station to send back data and receive commands

The service module also houses those parts of the instruments that do not require cooling, and the compressors and control electronics for the instrument cooling chains.

The Planck science payload consists of two instruments that are designed to study the Cosmic Microwave Background (CMB) radiation field by making high sensitivity measurements in the frequency range 27 GHz to 1 THz, and a telescope that collects the microwave radiation and focuses it onto the instrument detector arrays.

Planck's primary science objectives are to: (1) Map Cosmic Microwave Background anisotropies. (2) Test inflationary models of the early universe. (3) Measure the amplitude of structures in the Cosmic Microwave Background. (4) Perform measurements of the Sunyaev-Zeldovich effect.

Planck has the ability to: Detect much smaller temperature variations in the CMB than previous missions; perform CMB measurements with a higher angular resolution than ever before; and measure over a wider band of frequencies to enhance the separation of the CMB from interfering foreground signals.

The CMB anisotropy map produced using Plank's observations will be markedly superior to those currently available and will be used to set constraints on the values of the main parameters that govern the large scale structure of the Universe.

The instruments and telescope are provided by collaborative efforts between scientific institutes in ESA member states and the USA. Principal investigators in different countries lead the nationally funded collaborations.

The telescope design is an off-axis tilted Gregorian system, offering the advantages of no blocking of the optical path combined with compactness. The eccentricity and tilt angle of the secondary mirror and the off-axis angle obey the Dragone-Mizuguchi condition, which allows the system to operate without significant degradation over a large focal plane array, while simultaneously minimizing the polarization effects introduced by the telescope.

The baffling system is composed of two elements. The shield element is a large, self-supporting and roughly conical structure covered with multi-layer insulation (MLI), which surrounds the telescope and focal plane instruments. Together with the optical bench, it defines the optical enclosure. It has two important functions, reducing the level of straylight (which at the chosen orbit is in large part due to the spacecraft itself) and promoting the radiative cooling of the optical enclosure towards deep space. The baffle element consists of one half of a conically shaped surface that links the focal plane instruments to the bottom edge of the sub-reflector. The function of the baffle is to shield the detectors from thermal radiation originating within the optical enclosure.

Space Interferometry Mission (SIM). SIM would be the world's first long-baseline optical interferometer in space, and a technological precursor to the Terrestrial Planet Finder (TPF). With its unprecedented astronomical accuracy and high spatial resolution, SIM will allow indirect detection of planets through observation of thousands of stars, and will investigate the structure of planetary disks. SIM is scheduled for launch in 2014, with an operational life of five to 9 years. See also **Origins Program**.

Stratospheric Observatory for Infrared Astronomy (SOFIA). NASA and the German space agency, DLR, are working together to create SOFIA — a Boeing 747-SP aircraft modified to accommodate a 2.5 meter reflecting telescope. SOFIA will be the largest airborne telescope in the world, and will make observations that are impossible for even the largest and highest of ground-based telescopes. The observatory is being developed and operated for NASA by a team led by the Universities Space Research Association (USRA). SOFIA is scheduled for its first flight test in 2007, and the first scientific observational flights are planned for 2008. See also **Origins Program**.

Widefield Infrared Survey Explorer (WISE). An estimated $300-million mission, the Wide-field Infrared Survey Explorer, or "Wise," has been in the planning stages for the past eight years. It is scheduled to launch into an Earth orbit in late 2009. It will spend seven months collecting data.

Such extensive sky coverage means the mission will find and catalogue all sorts of celestial eccentrics. These may include brown dwarfs, or failed stars, that are closer to Earth than Proxima Centauri, the nearest star other than our sun. Brown dwarfs are balls of gas that begin life like stars but lack the mass to ignite their internal fires and light up like normal stars. They do, however, produce warm infrared glows that Wise will be able to see.

WISE is a NASA-funded scientific research project that will provide a vast storehouse of knowledge about the solar system, the Milky Way, and the Universe. Among the objects WISE will study are asteroids, the coolest and dimmest stars, and the most luminous galaxies.

WISE is an unmanned satellite carrying an infrared-sensitive telescope that will image the entire sky. Since objects around room temperature emit infrared radiation, the WISE telescope and detectors are kept very

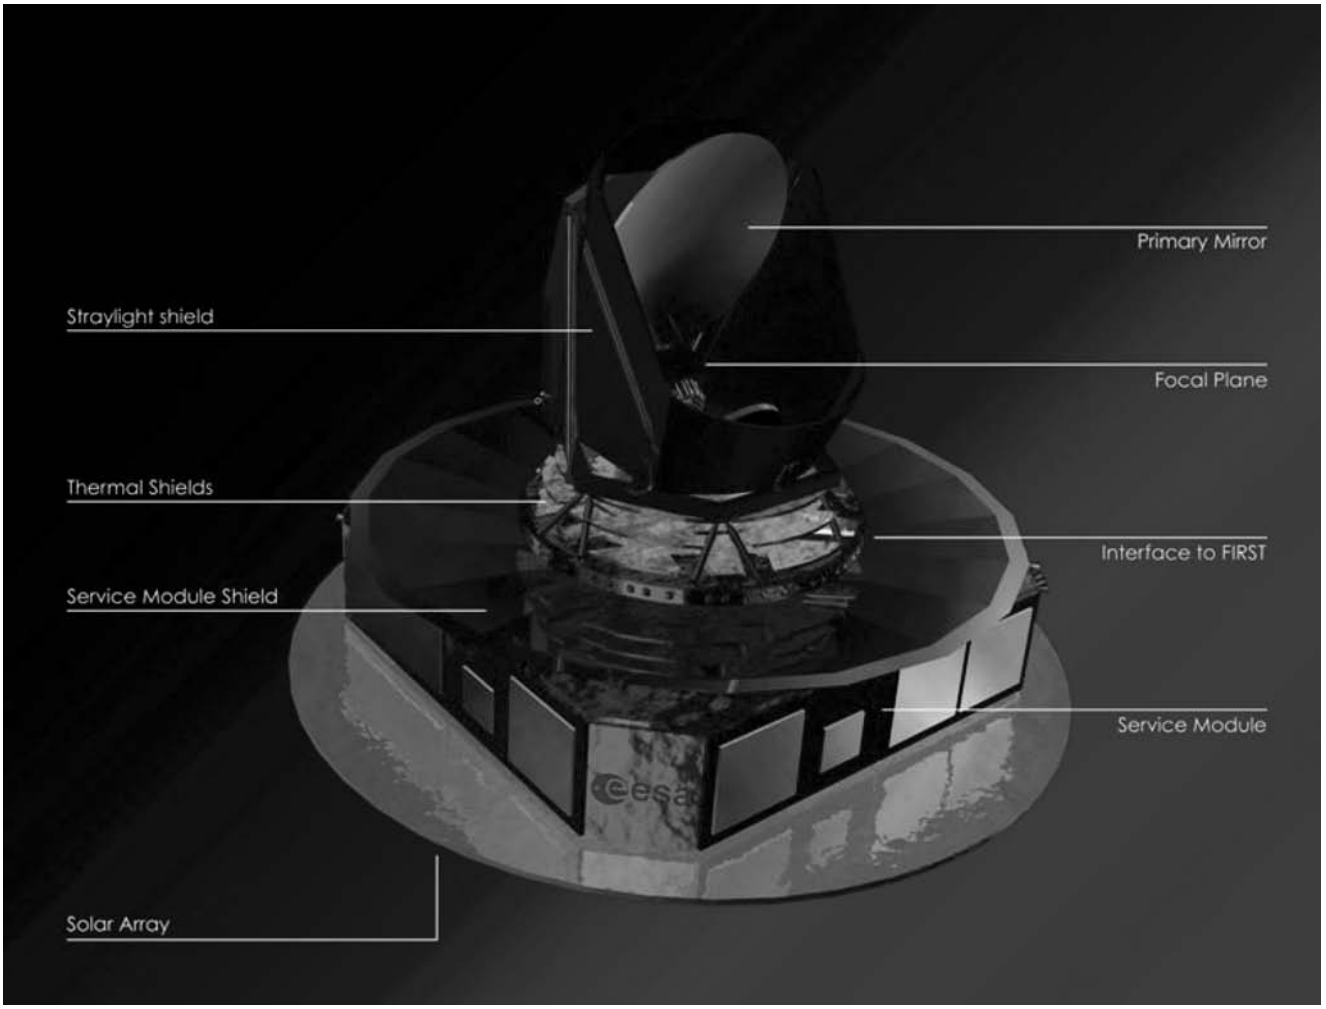

Fig. 10. The Planck spacecraft. (*Image courtesy of ESA*.)

cold (below −430 °F /15° K, which is only 15° Centigrade above absolute zero) by a cryostat — like an ice chest but filled with solid hydrogen instead of ice.

Solar panels will provide WISE with the electricity it needs to operate, and will always point toward the Sun. Orbiting several hundred miles above the dividing line between night and day on Earth, the telescope will look out at right angles to the Sun and will always point away from Earth. As WISE orbits from the North pole to the equator to the South pole and then back up to the North pole, the telescope will sweep out a circle in the sky. As the Earth moves around the Sun, this circle will move around the sky, and after six months WISE will have observed the whole sky.

As WISE sweeps along the circle a small mirror scans in the opposite direction, capturing an image of the sky onto an infrared sensitive digital camera which will take a picture every 11 seconds. Each picture will cover an area of the sky 3 times larger than the full Moon. After 6 months WISE will have taken nearly 1,500,000 pictures covering the entire sky. Each picture will have one megapixel at each of four different wavelengths that range from 5 to 35 times longer than the longest waves the human eye can see. Data taken by WISE will be downloaded by radio transmission 4 times per day to computers on the ground which will combine the many images taken by WISE into an atlas covering the entire celestial sphere and a list of all the detected objects.

JPL manages the Wide-field Infrared Survey Explorer mission for NASA's Science Mission Directorate and Explorer Program. The Explorer Program is managed by NASA's Goddard Space Flight Center, Greenbelt, Md. See also **Explorers Program**. The infrared cryogenic instrument for Wise will be designed and built by the Space Dynamics Laboratory, Logan, Utah, and the spacecraft will be built by Ball Aerospace and Technologies Corporation in Boulder, Colo. Mission operations will be conducted at JPL, and images will be processed and distributed at the Infrared Processing and Analysis Center at the California Institute of Technology in Pasadena. The Center for Science Education at the University of California, Berkeley, Space Sciences Laboratory, will manage the Wise education program. JPL is a division of the California Institute of Technology in Pasadena.

For more information on NASA's Wise mission, visit http://wise.ssl.berkeley.edu/.

Past Missions

Advanced Satellite for Cosmology and Astrophysics (ASCA). ASCA (Advanced Satellite for Cosmology and Astrophysics; was launched by ISAS (Institute of Space and Astronautical Sciences), Japan, on February 20, 1993, and reentered the Earth's atmosphere on March 2, 2001, having spent more than 8 years in orbit. During the mission lifetime, ASCA performed over 3000 observations, and produced over 1000 publications in refereed journals so far. Although the *ASCA* archive contain plenty of data for future analyses, we would like to celebrate the completion of a highly successful mission by reflecting on what scientists in many counties have accomplished using *ASCA* data so far.

The US has contributed significantly to ASCA's scientific payloads. In return, 40% of ASCA observing time was made available to US scientists. (ISAS also opened up 10% of the time to ESA scientists as a good-will gesture.) In addition, all ASCA data enter the public domain after a suitable period (1 year for US data, 18 months for Japanese data) and become available to scientists worldwide. The design of ASCA was optimized for X-ray spectroscopy; thus it complimented ROSAT (optimized for X-ray imaging) and RXTE (optimized for timing studies).

See also **Rosat (Roentgen Satellite)**; and **Rossi X-Ray Timing Explorer (RXTE)**.

ASCA carried four co-aligned, large-area X-Ray Telescopes (XRTs). At the focus of two of the telescopes is a Gas Imaging Spectrometer (GIS),

while a Solid-state Imaging Spectrometer (SIS) is at the focus of the other two. All 4 instruments observe the same celestial target and obtain data simultaneously.

XRT. X-rays tend to scatter, rather than reflect cleanly, except when the incident X-rays are almost parallel to the reflecting surface (i.e., grazing). Conventional X-ray mirrors use a pair of hyperbolic and parabolic surfaces. The design of the ASCA telescopes is a conical approximation, realized as a set of closely nested concentric thin foils.

This allows for a lightweight telescope with a large effective area, which is important for spectroscopy, while sacrificing the spatial resolution somewhat. See also http://heasarc.gsfc.nasa.gov/docs/asca/asca_xrt.html.

GIS. The GIS is a gas imaging scintillation proportional counter and is based on the GSPC that flew on the second Japanese X-ray astronomy mission, Tenma. The GIS has a circular field of view of ∼50 arcmin diameter, which is greater than that of the SIS, and a high efficiency particularly above 4 keV. See also http://heasarc.gsfc.nasa.gov/docs/asca/asca_gis.html.

SIS. The SIS is the first CCD-based instrument for cosmic X-ray astronomy. Each SIS contains 4 MIT Lincoln Lab CCD chips, sensitive to X-rays in the 0.4 to 10 keV range, and provides an unprecedented spectral resolution (2% at 6 keV) over this wide energy range. See also http://heasarc.gsfc.nasa.gov/docs/asca/asca_sis.html. All three upcoming major X-ray astronomy missions (Chandra X-Ray Observatory, XMM-Newton (The High-Throughput X-Ray Spectroscopy), and ASTRO-E) will have CCD-based instruments which are improved versions of the ASCA SIS. See also **Chandra X-Ray Observatory**; and **XMM-Newton (The Throughput X-Ray Spectroscopy) Mission**.

ASCA results cover almost the entire range of objects, from nearby stars to the most distant objects in the universe. They involve important themes such as

- How were elements created and distributed (supernova remnants, clusters of galaxies)?
- What happens to matter in extreme gravities around a black hole (X-ray binaries, active galactic nuclei)?
- Can we learn about how matter is heated to X-ray temperatures (stars, cataclysmic variables)?

For a collection of images with captions for many of the important scientific results obtained with ASCA along with an explanatory page for each of eight broad scientific categories; see http://heasarc.gsfc.nasa.gov/docs/asca/outreach/asca_asca.html. These pages contain a short description to give you the context of these discoveries, as well as links to the actual images with captions.

Astro-1 and Astro-2. The "Astro Observatory" was developed as a system of telescopes that could fly multiple times on the space shuttle. Astro-1 consisted of three ultraviolet telescopes and an X-ray telescope. The primary objectives of this observatory were to obtain (1) imagery in the spectral range 1200-3100 A (Ultraviolet Imaging Telescope, UIT); (2) spectrophotometry in the spectral region 425 to 1850 A (Hopkins Ultraviolet Telescope, HUT); (3)spectrapolarimetry from 1250 to 3200 A (Wisconsin Ultraviolet Photopolarimetry Experiment, WUPPE); and (4) X-ray data in the bandpass between 0.3 and 12 keV (Broad Band X-ray Telescope, BBXRT). Since many science objectives and selected astronomical targets of the three instrument teams were inter-related, simultaneous observations by all four instruments were planned.

The telescopes were mounted on a Spacelab pallet in the payload bay of the shuttle (flight STS-35). The Spacelab Instrument Pointing System (IPS), pallets, and avionics were utilized for attachment to the Shuttle and for control and data handling. Astro-1 required both mission specialists and payload specialists to control its operations from the Shuttle aft flight deck. Instrument monitoring and quick-look data analysis were performed for real-time ground operations. During the flight both on-board Digital Display Units malfunctioned, and the star guidance system calibration was not possible. The observing sequences were rescheduled during the flight, and instrument pointing was done by hand by the astronauts, and from the ground.

As a result of the numerous technical glitches, the returned data volume was less than half of that originally planned, and the scientific return was about 67% of the stated goals of the mission. The Astro-1 mission was launched December 2, 1990, and returned to Earth December 11, 1990.

Following the scientific success of the Astro-1 mission, Astro-2 was approved as a follow-up flight. The three ultraviolet telescopes, which flew on Astro-1, were reassembled for Astro-2. The three telescopes were planned to make simultaneous observations of objects such as stars, galaxies and quasars, since many science objectives and selected astronomical targets of the three instrument teams are interrelated. BBXRT, which was onboard ASTRO 1, was not flown on ASTRO 2.

The telescopes were mounted on a Spacelab pallet in the payload bay of the shuttle (flight STS-67). The Spacelab Instrument Pointing System (IPS), pallets, and avionics were utilized for attachment to the Shuttle and for control and data handling. The IPS provides a stable platform, keeps the telescopes aligned, and provides various pointing and tracking capabilities to the telescopes. The Astro observatory requires both mission specialists and payload specialists to control its operations from the Shuttle aft flight deck. Instrument monitoring and quick-look data analysis are planned for real-time ground operations.

Astro-2 was the second Astro mission flown in the shuttle payload bay. The mission launched on March 2, 1995 and returned to earth after a 16-day flight. The Guest Observer Program was included for Astro-2. The telescopes observed over 250 astronomical objects

Broad Band X-Ray Telescope (BBXRT). The Broad Band X-ray Telescope (BBXRT) was flown on the space shuttle Columbia (STS-35) on 1990 December 2-December 11, as part of the ASTRO-1 payload. The flight of BBXRT marked the first opportunity for performing X-ray observations over a broad energy range (0.3-12 keV) with a moderate energy resolution (typically 90 eV and 150 eV at 1 and 6 keV, respectively). This energy resolution, coupled with an extremely low detector background, made BBXRT a very powerful tool for the study of continuum and line emission from cosmic sources. The observing program was designed to be an even mix of Galactic and extragalactic targets, although the Galactic Center region was not available due to the time of year that BBXRT was launched.

BBXRT was designed and built at the Laboratory for High Energy Astrophysics at NASA/GSFC, with Dr. Peter Serlemitsos as Principal Investigator. During the mission, the instrument was controlled by the scientists and staff of the X-ray group from an operations center at GSFC, and the group as a whole handled mission planning and real-time data analysis.

For more information on NASA's BBXRT, visit http://heasarc.gsfc.nasa.gov/docs/bbxrt/bbxrt_about.html#instrument.

Compton Gamma-Ray Observatory (CGRO). CGRO, the second of NASA's Great Observatories, was launched April 5, 1991. It had a diverse scientific agenda, including studies of very energetic celestial phenomena: solar flares, cosmic gamma-ray bursts, pulsars, nova and supernova explosions, accreting black holes of stellar dimensions, quasar emission, and interactions of cosmic rays with the interstellar medium. Compton left a legacy of outstanding science and revolutionized our knowledge of the gamma ray sky. Its mission ended on 2000 June 4, when it was de-orbited following the failure of one of its three gyroscopes.

Compton had four instruments that covered an unprecedented six decades of the electromagnetic spectrum, from 30 keV to 30 GeV. In order of increasing spectral energy coverage, these instruments were the Burst And Transient Source Experiment (BATSE), the Oriented Scintillation Spectrometer Experiment (OSSE), the Imaging Compton Telescope (COMPTEL), and the Energetic Gamma Ray Experiment Telescope (EGRET). For each of the instruments, an improvement in sensitivity of better than a factor of ten was realized over previous missions.

The Observatory was named in honor of Dr. Arthur Holly Compton, who won the Nobel prize in physics for work on scattering of high-energy photons by electrons — a process which is central to the gamma-ray detection techniques of all four instruments. See also **Compton Gamma-Ray Observatory (CGRO)**; and **Great Observatory Program**.

Cosmic Background Explorer (COBE). The COBE satellite was developed by NASA's Goddard Space Flight Center to measure the diffuse infrared and microwave radiation from the early universe to the limits set by our astrophysical environment. It was launched November 18, 1989 and carried three instruments, a Diffuse Infrared Background Experiment

(DIRBE) to search for the cosmic infrared background radiation, a Differential Microwave Radiometer (DMR) to map the cosmic radiation sensitively, and a Far Infrared Absolute Spectrophotometer (FIRAS) to compare the spectrum of the cosmic microwave background radiation with a precise blackbody. Each COBE instrument yielded a major cosmological discovery:

- **DIRBE** — Infrared absolute sky brightness maps in the wavelength range 1.25 to 240 microns were obtained to carry out a search for the cosmic *infrared* background (CIB). The CIB was originally detected in the two longest DIRBE wavelength bands, 140 and 240 microns, and in the short-wavelength end of the FIRAS spectrum. Subsequent analyses have yielded detections of the CIB in the near-infrared DIRBE sky maps. The CIB represents a "core sample" of the Universe; it contains the cumulative emissions of stars and galaxies dating back to the epoch when these objects first began to form. The COBE CIB measurements constrain models of the cosmological history of star formation and the buildup over time of dust and elements heavier than hydrogen, including those of which living organisms are composed. Dust has played an important role in star formation throughout much of cosmic history. See also http://lambda.gsfc.nasa.gov/product/cobe/dirbe_image.cfm
- **DMR** The CMB was found to have intrinsic "anisotropy" for the first time, at a level of a part in 100,000. These tiny variations in the intensity of the CMB over the sky show how matter and energy was distributed when the Universe was still very young. Later, through a process still poorly understood, the early structures seen by DMR developed into galaxies, galaxy clusters, and the large scale structure that we see in the Universe today. See also http://lambda.gsfc.nasa.gov/product/cobe/dmr_image.cfm
- **FIRAS** The cosmic microwave background (CMB) spectrum is that of a nearly perfect blackbody with a temperature of 2.725 +/− 0.001 K. This observation matches the predictions of the hot Big Bang theory extraordinarily well, and indicates that nearly all of the radiant energy of the Universe was released within the first year after the Big Bang. See also http://lambda.gsfc.nasa.gov/product/cobe/firas_image.cfm.

For more information on NASA's COBE Mission, visit http://lambda.gsfc.nasa.gov/product/cobe/.

Cosmic Hot Interstellar Plasma Spectrometer (CHIPS). The Cosmic Hot Interstellar Plasma Spectrometer (CHIPS) is a University-Class Explorer (UNEX) mission funded by NASA. See also **Explorers Program**. CHIPS uses an extreme ultraviolet spectrograph to study the "Local Bubble," a tenuous cloud of hot gas surrounding our Solar System that extends about 300 light-years from the Sun. Scientists believe that the million-degree gas in this region is generated by supernovae and stellar winds from hot stars, but want to better understand the origins and cooling of this gas, and apply knowledge of these processes to the study of other galaxies beyond our Milky Way.

The CHIPS instrument is carried in space aboard CHIPSat, a dedicated spacecraft built by SpaceDev, Inc., http://www.spacedev.com/newsite/templates/homepage.php?pid=2, and launched from the second stage of a Boeing Delta II rocket. A successful launch occurred at 16:45 Pacific time on Sunday January 12, 2003.

Diffuse X-Ray Spectrometer (DXS). The Diffuse X-ray Spectrometer (DXS) was a single experiment shuttle payload designed to fly on multiple missions. The primary objective of the DXS payload was to obtain measurements on the diffuse soft X-ray background radiation in the Milky Way Galaxy. This low energy X-ray background apparently arises in the local interstellar plasma which has a temperature of about 1 million degrees. In such a plasma, X-ray emission will be due to collisionally excited lines of a number of ions including Si VIII, Mg IX, S VIII and Ne IX. The purpose of DXS was to study the those emission lines to verify that the lines do indeed arise form such a plasma and in turn to use the emissions as diagnostics for the plasma temperature, its element abundances and its ionic populations. If the plasma is shown not to be in ionization equilibrium, then the X-ray emission may be due to a blast wave (i.e. supernova explosion in the solar vicinity) with an age of about 100,000 years.

DXS consisted of two large area Bragg crystal spectrometers, each covering an energy range of 0.15−0.28 keV. The instrument field of view was 15 degrees by 150 degrees (FWHM). The energy resolution was approximately 10 eV while the spectral range covered the interval from 420-840 nm.

Each DXS instrument was mounted on either side of the Shuttle cargo bay. The instruments faced each other to expand the length of the arc on the sky which could be observed at full spectral coverage. Each detector contained a curved panel of Bragg crystals mounted above a position-sensitive proportional counter. A spectrum was dispersed across the counter, resulting in all portions of the spectrum being simultaneously measured. This eliminated false features from being introduced by a time-varying background, a common problem in conventional Bragg spectrometers. In addition, since all wavelengths were measured simultaneously, but the various wavelengths could come from different directions in the sky, the spectrometers were rocked back and forth about an axis perpendicular to the dispersed direction so that complete spectral coverage along an arc of the sky could be obtained.

DXS flew as a shuttle cargo bay attached payload using the Hitchhiker avionics and Shuttle Payload of Opportunity Carrier (SPOC) hardware, which provided support systems for power, command, and telemetry to the DXS instruments. DXS flew successfully on the Space Shuttle Endeavor STS 54 mission launched January 13, 1993.

Extreme Ultraviolet Explorer (EUVE). The Extreme Ultraviolet Explorer (EUVE) is a NASA-funded astronomy mission operating in the relatively unexplored extreme ultraviolet (70-760 Å band. The science payload, which has been designed and built at the Space Sciences Laboratory at the University of California, Berkeley, under the direction of Dr. Roger F. Malina, consists of three grazing incidence scanning telescopes and an extreme ultraviolet (EUV) spectrometer/deep survey instrument. The science payload is attached to a Multi-Mission Modular spacecraft.

The EUVE mission, was launched on June 7, 1992 on a Delta II rocket from Cape Canaveral, and was completely successful, exceeding its science goals. EUVE was turned off on January 31, 2001.

EUVE is the culmination of nearly thirty years of effort at the University of California at Berkeley to create the field of EUV Astronomy. EUVE opens up this last unexplored spectral window in astrophysics.

For more information on NASA's Extreme Ultraviolet Explorer (EUVE) Mission, visit http://www.ssl.berkeley.edu/euve/.

Highly Advanced Laboratory for Communications and Astronomy (HALCA). HALCA, a project led by Japan's Institute of Space and Astronautical Science, allowed imaging of astronomical radio sources with a significantly improved resolution over ground-only observations. Launched February 12, 1997; U.S. support terminated February 7, 2002; attitude control lost October 2003.

Hipparcos. Launched in August 1989 Hipparcos was a pioneering space experiment dedicated to the precise measurement of the positions, parallaxes and proper motions of the stars. The intended goal was to measure the five astrometric parameters of some 120 000 primary programme stars to a precision of some 2 to 4 milliarcsec, over a planned mission lifetime of 2.5 years, and the astrometric and two-colour photometric properties of some 400 000 additional stars (the Tycho experiment) to a somewhat lower astrometric precision. Having achieved the mission goals, communications with Hipparcos were terminated in August 1993.

The final products of the Hipparcos mission — the Hipparcos and Tycho Catalogues — were published by ESA in June 1997. See also **Hipparcos Mission**.

International Extreme Ultraviolet Hitchhiker (IEH-3). Six experiments make up the IEH-3 payload that flew on the STS-95 Space Shuttle mission. Discovery launched Oct. 29, 1998, with a seven-member crew; http://spaceflight.nasa.gov/shuttle/archives/sts-95/index.html.

The IEH-3 experiments are: Ultraviolet Spectrograph Telescope for Astronomical Research (UVSTAR); Spectrograph/Telescope for Astronomical Research (STARLITE); Solar Extreme Ultraviolet Hitchhiker (SEH); Solar Constant Experiment (SOLCON); Petite Amateur Naval Satellite (PANSAT); Get Away Special-764 (Cosmic Dust Aggregation Experiment — CODAG); and Get Away Special-238.

The six hitchhiker experiments were attached to a carrier in the bay of the Shuttle orbiter for the flight in space. Some experiments were controlled from the Payload Operations Control Center at the Goddard

Space Flight Center in Greenbelt, Md., while others ran automatically with pre-programmed commands which were loaded into their operating computers before launch.

Ultraviolet Spectrograph Telescope for Astronomical Research (UVSTAR). UVSTAR is an extreme ultraviolet spectral imager designed as a facility instrument devoted to solar system and stellar astronomy research. The instrument will obtain and spectrally resolve images of extended plasma sources including the plasma located around Jupiter's moon, Io, and hot stars (stars that put out more energy than regular stars). Io, which is volcanic, spews out volcanic gasses and materials that get trapped in the magnetic field of Jupiter forming a Torus (a donut shape with Jupiter in the middle). The ultraviolet emissions from the Torus will reveal the material on Io, the energy output of Jupiter and so on. The telescope also will measure the emissions from the Earth's atmosphere, acquire data from celestial targets and perform atmospheric science.

The Extreme Ultraviolet Imager (EUVI), another instrument aboard UVSTAR, takes measurements of the Earth's atmosphere in the extreme ultraviolet wavelengths while in any attitude. The EUVI contains two imagers that map the intensity of helium and oxygen ions in the atmosphere by scanning along the Earth's shadow line. With this instrument, precise measurements of the Earth's ionosphere and plasmosphere will be acquired.

The principal investigators for UVSTAR were Dr. Roberto Stalio of the University of Trieste, Italy and Dr. Lyle Broadfoot from the University of Arizona in Tucson.

Spectrograph/Telescope for Astronomical Research (STARLITE). STARLITE is a telescope and imaging spectrograph used to study astronomical targets in the ultraviolet. Targets of scientific investigation include diffuse sky background emission, scattered dust and recombination emission lines from the hot and interstellar medium, supernova remnants, planetary and reflecting nebulae, star forming regions in external galaxies and the Torus formed around Jupiter from the volcanic emissions of the moon Io.

Dr. Jay Holberg from the University of Arizona was the principal investigator.

Solar Extreme Ultraviolet Hitchhiker (SEH). The SEH experiment was designed to obtain absolute Extreme Ultraviolet (EUV)/Far Ultraviolet (FUV) fluxes (energy output) used to interpret EUV/FUV emissions from solar system objects, interplanetary medium, plasmosphere and magnetosphere (layers of the Earth's upper atmosphere). SEH measured changes in the Earth's atmosphere due to solar extreme ultraviolet and daytime temperatures.

The solar science objectives of SEH were to measure the absolute solar EUV irradiance, the flux of radiant energy per unit area for planetary atmosphere studies. Another goal was to analyze and interpret the solar EUV data for purpose of improving global solar atmospheric computer modeling, and thus improve our understanding of solar variability.

Dr. Don McMullin from the University of Southern California in Los Angeles was the principal investigator for SEH.

Solar Constant Experiment (SOLCON). The SOLCON instrument was designed to accurately measure the solar constant (total solar radioactive power absorbed by one square meter at the mean distance between the Earth and Sun) and identify variation during a solar cycle. This measurement was accomplished by determining the power difference required to bring two hollow points into thermal balance when one is open to the Sun and the other closed. The data will ensure continuity of the solar constant level obtained by instruments mounted on other free-flying spacecrafts. Solar energy is the only external energy source for the Earth, thus a primary driver for climate change. This study was important to researchers studying the effects of global warming.

Dr. Dominique Crommelynck from the Royal Meteorological Institute of Belgium was the principal investigator for this experiment.

Petite Amateur Naval Satellite (PANSAT). PANSAT is a small non-recoverable satellite developed by the Naval Postgraduate School (NPS) in Monterey, Calif., and launched via a Hitchhiker Ejection System located in the cargo bay of the Space Shuttle.

The objectives of the PANSAT satellite were to enhance the education of the military officers at NPS through the development and operation of a spread spectrum satellite. Spread spectrum satellites allow communication satellites to capture and transmit a signal that normally would be lost because the original signal was too weak or had too much interference.

The principal investigator for PANSAT was Rudolf Panholzer of the NPS.

G-764 Get Away Special Experiment (CODAG). CODAG was an experiment designed to stimulate the aggregation of dust particles which occurred at the early stages of our solar system. By understanding the dust growth process in the early solar system, it is possible to answer the questions of planet formation.

The experiment consists of a vacuum chamber equipped with windows and sensors. The dust cloud is injected into the chamber and two high speed cameras, mounted at microscopes, record the dust motion in a small control area. Xenon lamps illuminate the experiment chamber and the microscope plane identifies the three dimensional motion. The sensors measure the scattering characteristics of the dust cloud to compare it with astronomical measurements.

The principal investigator for the GAS can was Hans J. Koenighsmann.

G-238 Get Away Special Experiment (GAS). The GAS payload G-238 was sponsored by the American Institute of Aeronautics and Astronautics — National Section and managed by students at DuVal High School in Lanham, Md. Aboard the payload, there was one biological experiment. This experiment looked at the effects of space on the life cycle of the American cockroach.

David Eakman of The Boeing Company in Seabrook, Md., was the payload manager for Get Away Special-238.

The Infrared Telescope in Space (IRTS). The Infrared Telescope in Space (IRTS) was the first Japanese orbiting telescope dedicated to infrared astronomy observations. The IRTS is a cryogenically cooled infrared telescope that flied aboard a multi-purpose space platform SFU (Space Flyer Unit). It was launched by a Japanese new rocket HII on March 18, 1995. It surveyed approximately 7 % of the sky with a relatively wide beam during its 28-day mission. Four focal plane instruments made simultaneous observations of the sky at wavelengths from 1 to 1000 micron.

Infrared Space Observatory (ISO). ISO, is a project of the European Space Agency (ESA). ESA's Infrared Space Observatory (ISO) was an astronomical satellite operational between November 17, 1995 and May 16, 1998. By May 1998, at the end of its two and a half year operational lifetime, ESA's Infrared Space Observatory (ISO) had made nearly 30 000 scientific observations, employing its four sophisticated and versatile scientific instruments to provide astronomers with diverse data of unprecedented sensitivity at infrared wavelengths from 2.5 to 240 microns, in the infrared range of the electromagnetic spectrum.

The Science Operations Center at ESA's Satellite Tracking Station at Villafranca (Spain) was responsible for the control of the satellite. This is also where observations were scheduled. However, for scientific use ISO needed to be in continuous contact with a ground station. NASA's station at Goldstone (US) tracked ISO when it was obscured from Villafranca by the Earth.

By covering this wavelength range ISO was able to explore regions of the Universe obscured in visible light. Infrared light penetrates the obscuring dust which hides much of the Universe from inspection at visible wavelengths. Light at these wavelengths originates from bodies and material which are cool and distinct from the energetic sources of visible light like the stars. But these cool sources are of fundamental importance.

A rich variety of atomic, ionic, molecular and solid-state spectral features trace the chemistry and evolution of the cold gas and dust from which the stars form, and which they in turn enrich with the heavy elements produced during their nuclear burning and terminal phases. New generations of stars and planets form from the enriched interstellar medium, revealing their presence first through the infrared emission associated with proto-stellar and proto-planetary sources. Most of the star formation which has occurred in the history of the Universe is revealed through the infrared emission of the heated dust clouds which would otherwise hide it from our view.

The ISO satellite consisted of a payload module and a service module, which provided the basic spacecraft functions. The payload module carried the conical sun shade and the two star trackers. Overall, ISO was 5.3 meters (17.4 feet) high, 2.3 meters (7.5 feet) wide and had a mass of approximately 2,500 kilograms (5,512 pounds) at launch. See Fig. 11.

The service module included the load path to the launcher, the array of solar cells generating some 600 W mounted on the sun shield,

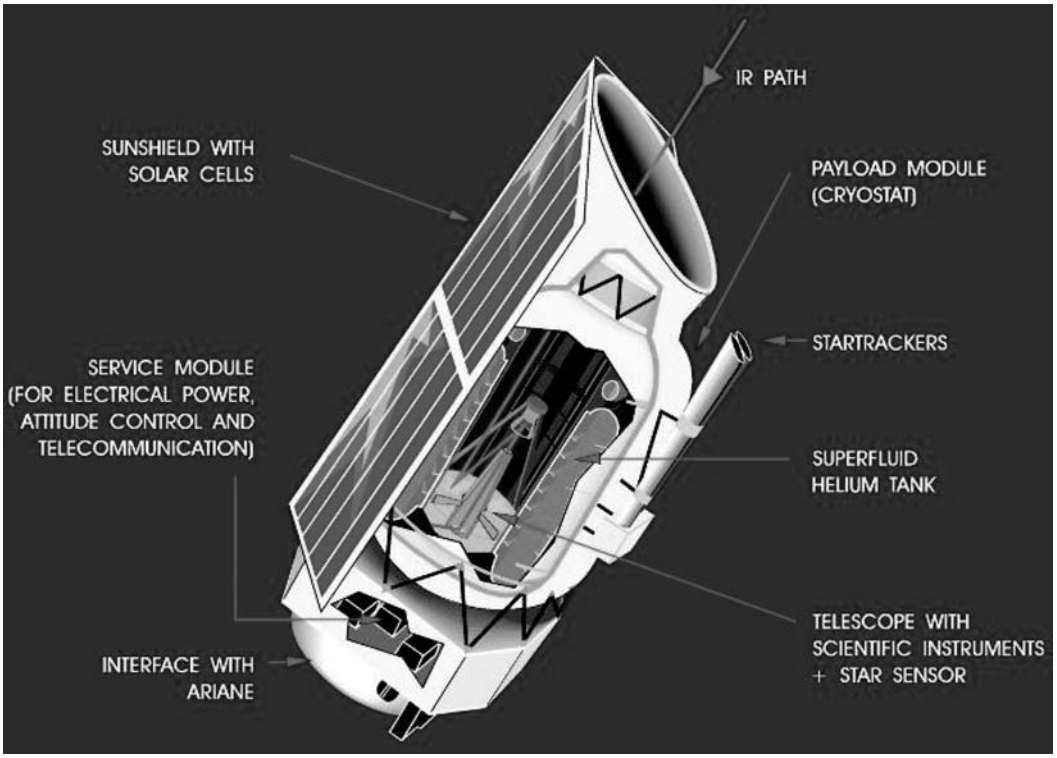

Fig. 11. Diagram of ISO. (*Image courtesy of ESA.*)

and subsystems for thermal control, data handling, power conditioning, telemetry and telecommand, and attitude and orbit control. The last item provided the three-axis stabilization to an accuracy of around an arc second, and also the raster pointing facilities needed for the mission. It consisted of sun and earth sensors, star trackers, a quadrant star sensor on the telescope axis, gyros and reaction wheels, and used a hydrazine reaction-control system. The downlink bit rate was 32 kbit/s, of which about 24 kbit/s was dedicated to the scientific instruments.

The payload module was essentially a large cryostat. The vacuum vessel enclosed a toroidal tank, which at launch was filled with over 2,300 liters (608 gallons) of superfluid helium. Some of the infrared detectors were directly coupled to the helium tank and were held at a temperature of around 2K ($-456\,^{\circ}$F). All other units were cooled by means of the cold boil-off gas from the liquid helium. This was first routed through the optical support structure, where it cooled the telescope and the scientific instruments to temperatures of around 3 K. It then passed along the baffles and radiation shields, before being vented to space. Above the main helium tank was a small auxiliary tank (of volume about 60 liters (16 gallons); this contained normal liquid helium and met all of ISO's cooling needs for the period immediately prior to launch. A sunshade was mounted on the outside of the vacuum vessel. This prevented direct sunlight from entering the cryostat.

The telescope was suspended in the middle of the toroidal Liquid Helium tank. It was of Ritchey-Chretien configuration with an effective aperture of 60 centimeters (23.6 inches). The optical quality of its mirrors permitted diffraction-limited performance at a wavelength of 5 microns. Stringent control over straylight, particularly that from bright infrared sources outside the telescope's field of view, was necessary to ensure that the system's sensitivity was not degraded. This was accomplished by means of the sunshade, the Cassegrain and main baffles, and a light-tight shield around the instruments. Additional straylight control was provided by constraining ISO from observing too close to the Sun, Earth and Moon.

The ISO scientific payload consisted of four instruments: a camera (ISOCAM); an imaging photopolarimeter (ISOPHOT); a long wavelength spectrometer (LWS); and a short wavelength spectrometer (SWS). Each instrument was built by an international consortium of scientific institutes and industry, headed by a Principal Investigator (PI), using national funding. Although developed separately, the four instruments were designed to form a complete, complementary and versatile common-user package.

ISOCAM. The Infrared Camera (ISOCAM), covering the 2.5–17 μm band with two different detectors. It can be compared to a normal photo camera, taking pictures of the 'infrared face' of astronomical objects at a high resolution (so as to distinguish very fine details).

ISOPHOT. The photo-polarimeter (ISOPHOT), designed to detect the amount of infrared radiation emitted by an astronomical object. The broad range of wavelengths at which ISOPHOT operated (between 2.5 and 240 μm) allowed it to 'see' objects as cool as the clouds of dust lying among stars and galaxies, whose temperature may be just a few degrees above absolute zero ($-273\,^{\circ}$C ($-459\,^{\circ}$F).

SWS. The Short-Wave Spectrometer (SWS) covered the 2.4 to 45 μm band. It has provided valuable information about the little known chemistry of the Universe, since many molecules emit copiously in the infrared. Moreover, SWS has been able to find out the physical conditions of those chemical constituents, such as temperature or density.

LWS. The Long-Wave Spectrometer (LWS) operated at the 45 to 196.8 μm band. LWS has focused on cooler objects than SWS. It is especially useful studying the physical condition in very cold dust clouds in the space between stars.

LWS Principal Investigator: P. E. Clegg, Queen Mary and Westfield College, London, United Kingdom.

International Ultraviolet Explorer (IUE). The IUE satellite was launched on January 26, 1978 into an elliptical geosynchronous orbit, in which it is always visible from Goddard Space Flight Center (GSFC). It had an expected lifetime of 3 years, with a goal of 5 years, but exceeded that beyond anyone's wildest dreams. When it was shut down on September 30, 1996, it had been in continuous operation for 18 years and 9 months.

IUE was an international collaboration among three groups: NASA, the European Space Agency (ESA), and the United Kingdom's Science and Engineering Research Council (SERC; now Particle Physics and Astronomy Research Council, or PPARC, http://www.pparc.ac.uk/.) NASA provided the launch, spacecraft engineering support and software. ESA provided the solar panels and a satellite command station outside of Madrid, Spain, and the UK provided the Vidicon cameras. Observing time was split between two spacecraft command stations. NASA operated the spacecraft for 16 hours a day from Goddard Space Flight Center, and VILSPA (the Villafranca satellite control station) operated it for 8 hours a day.

IUE's geosynchronous orbit allowed for real-time operation, which made IUE very flexible. Astronomers came to the spacecraft command stations to direct their observations and inspect the data as they were collected, much as they do at ground-based observatories. Two on-board spectrographs covered ultraviolet wavelengths from 1200 to 3350 Å.

Observers from around the world took advantage of this workhorse observatory, gathering data from a wide variety of astronomical sources. Objects observed by IUE include virtually every type of object in the universe, from planets and stars to galaxies. One of IUE's strengths was the ability to rapidly respond to targets of opportunity such as comets, novae, and supernovae. IUE obtained the only ultraviolet data of the outburst of Supernova 1987a in the Large Magellanic Cloud. By tracking on the nucleus of fast-moving Comet IRAS-Araki-Alcock, IUE was able to obtain the first detection of molecular sulfur in a comet. During July 1994, IUE (along with the rest of the globe) spent a good deal of time observing Jupiter when Comet Shoemaker-Levy collided with the planet.

Astronomers study multiple wavelengths in order to learn more about the objects of the universe. Simultaneous data acquisition is essential in order to gain the most knowledge of certain transient events. Thus, very often IUE was used in conjunction with other telescopes from around the world. These collaborations have involved spacecraft such as the Hubble Space Telescope, the ROSAT, the Compton Gamma Ray Observatory, the Voyager probes, the Space Shuttle's ASTRO-1 and ASTRO-2 missions, the Extreme Ultraviolet Explorer, Japan's ASCA satellite, as well as numerous ground-based observatories.

The spacecraft dimensions were 4.2 meters (13.8 feet) by 1.45 meters (4.8 feet) by 1.45 meters (4.8 feet) and the mass weight at launch was 644 kilograms (1,420 pounds); 462 kilograms (1,415 pounds) in orbit. Spacecraft power was provided by two large solar panels. At most orientations the power generated by the arrays was more than sufficient to run the spacecraft. When the spacecraft was tipped at a large angle from the sun, however, it was necessary to draw additional power from the spacecraft batteries. The primary function of the batteries was to provide power to IUE during Earth shadow periods. Shadow seasons would occur when a portion of the IUE's orbit passed through the Earth's shadow once each day for 3 weeks in the late summer and winter. Additional observing constraints were invoked during these periods to ensure that the batteries were fully recharged before the next day's shadow.

The spacecraft was three-axis stabilized with a normal 1-arc-second pointing accuracy. Control of the telescope pointing and execution of all spacecraft motion was the primary function of IUE's on-board computer (OBC). The OBC also performed other important functions, such as controlling camera exposures. Prior to August 1985, the OBC used data from three or more of IUE's six gyros to control attitude. Following the fourth gyro failure on August 17, 1985, a backup attitude-control system has been used. The new system used the two functional gyros and the spacecraft Fine Sun Sensor (FSS). The FSS measured the orientation of IUE with respect to the sun. In the two- gyro/FSS system, the FSS was used primarily to control the roll motion about the telescope optical axis. The two-gyro/FSS system had operational capabilities and accuracies essentially identical to the original three-gyro control system, with the exception that the telescope could no longer be pointed within 15 degrees of the anti-solar position.

IUE's orbit was frequently monitored to provide accurate pointing predictions for the ground commanding and receiving antennas. A VHF signal was transmitted from the ground and retransmitted by the spacecraft, giving an accurate distance and velocity of the spacecraft (this is referred to as "ranging"). Gravitational perturbations cause the gradual westward precession of the orbit's semi-major axis. A station-keeping maneuver was performed at intervals of 6 to 9 months to prevent the satellite from passing outside the range of ground antennas at GSFC and VILSPA. At this time, the large hydrazine jets were fired to slightly modify the semi-major axis so that the orbit drifts eastward again.

The IUE scientific instrument consists of a telescope, acquisition camera, two ultraviolet spectrographs, and four cameras.

Telescope. The telescope was a 45-centimeter (18 inch) aperture, f/15 telescope of Ritchey-Chretien design. The primary mirror was made of beryllium. Thermal heaters mounted on the back of the mirror and on the camera deck were used for focus control.

Acquisition camera. The Fine Error Sensor (FES) was an image dissector device sensitive to a broad range of visual wavelengths. It had a 16 arcmin field of view and effective image resolution of about 8 arcsec. The device was used in camera mode to obtain a visual star field image for target identification and acquisition. It was then used in tracking mode for offset guiding, providing a pointing stability of about 1/2 arcsec.

Apertures. Each spectrograph may be used with either of two apertures. The large aperture was a slot (approximately 10 by 20 arcsec) and the small aperture was a circle about 3 arcsec in diameter. The apertures were known as LWLA (long-wavelength large aperture), LWSA (long-wavelength small aperture), SWLA (short-wavelength large aperture), and SWSA (short-wavelength small aperture). The image quality of the IUE telescope's optics yields a roughly 3 arcsec image, so observations using the small aperture result in some light loss. The large apertures were used most frequently since they give photometric reliability with little or no loss of resolution.

Spectrograph. The long-wavelength spectrograph operated in a wavelength range of 1850 to 3300 Å. The short-wavelength spectrograph operated in a wavelength range of 1150 to 2000 Å.

Dispersion Modes. Each spectrograph had two dispersion modes. High resolution employs an echelle grating and cross-disperser, giving roughly 0.2 Å resolution). Low resolution employs the cross-disperser grating alone, and yields approximately 6 Å resolution.

Cameras. There were four cameras, two for each spectrograph. One was designated prime and the other backup. In the long-wavelength range, both the prime (LWP) and redundant (LWR) cameras were used during the mission. With the short-wavelength spectrograph, only the prime camera (SWP) was fully functional. The redundant camera (SWR) was used to obtain a handful of images early in the mission. Each camera consisted of an SEC Vidicon with and ultraviolet converter. Each exposure was obtained by integrating over the requested exposure time, then performing a destructive readout of the camera target. The signal was digitized and transmitted to the ground via the spacecraft telemetry stream.

Data format. Each IUE image consisted of a 768 by 768 pixel array of 8-bit values (0 to 255). The raw data were archived with a header recording Telescope Operator comments, automatic activity log, and spacecraft engineering data.

For more information on the International Ultraviolet Explorer Mission, visit http://archive.stsci.edu/iue/instrument/obs_guide/guide.html.

Kuiper Airborne Observatory (KAO). The Gerard P. Kuiper Airborne Observatory (KAO) was a national facility operated by the National Aeronautics and Space Administration to support research in infrared astronomy. The observation platform was a highly modified C-141A jet transport aircraft with a range of 6,000 nautical miles, capable of conducting research operations to 45, 000 feet (14 kilometers).

The aircraft began as a Lockheed Model L300 Starlifter jet transport, originally configured as a prototype commercial version of the U.S. Air Force C-141A. The telescope system was designed and built by the Fecker Systems Division of the Owens-Illinois Corporation. The telescope cavity was designed and installed by Lockheed Aircraft Services in May 1973. Research operations began in February, 1974, and the facility was dedicated as the Gerard P. Kuiper Airborne Observatory (KAO) in May, 1975.

The KAO's telescope was a conventional Cassegrain reflector with a 36-inch (91.5 centimeter) aperture, designed primarily for observations in the 1 to 500 micron spectral range. The telescope looked out the left side of the aircraft at an elevation of between 35 and 75 degrees.

The KAO was based at the Ames Research Center at Moffett Field, California (near San Jose, CA). It was operated as a facility for scientists whose proposals have been deemed suitable and have been approved by NASA. Those scientists perform research with scientific instruments which had often been developed especially for use on the aircraft. Each instrument could be installed on the aircraft for a few days to several weeks, allowing multiple flights and investigators using the same instrument.

The KAO performed astronomical observations analogous to those made in ground-based or space-based telescopes. The KAO's observing capabilities filled a unique niche in astronomical science, however. Its flight capability allowed it to rise above much of the water vapor in the earth's atmosphere (allowing observations of infrared radiation which

is blocked before reaching ground-based facilities), as well as travel to almost any point on the earth's surface for an observation. At the same time, in between flights the facility was ground-based, allowing systems development, maintenance, and repair.

To perform astronomy while in flight, a number of systems must work together to provide a stable observation platform. Several sub-systems or steps were involved in this process. They include: the aircraft autopilot; the vibration isolation system; the spherical air bearing; the gyro-stabilization system; the video star tracker.

The KAO ended its long service to astronomy in October, 1995, so that work could begin on its successor, the Stratospheric Observatory for Infrared Astronomy (SOFIA).

Orbiting Retrievable Far and Extreme Ultraviolet Spectrometer (ORFEUS). The ORFEUS-SPAS II mission followed the ORFEUS-SPAS I mission flown in 1993, motivated by improvements in instrument performance and the critical need for additional observation time. The purpose of the ORFEUS-SPAS II mission was to conduct investigations of celestial sources in the far and extreme ultraviolet spectral range, and to increase understanding of the evolution of stars, the structure of galaxies, and the nature of the interstellar medium. ORFEUS-SPAS II was one of a series of planned joint DARA (German Space Agency) /NASA missions. The name arises from the reusable Astro-Shuttle Pallet Satellite (Astro-SPAS), and the Orbiting Retrievable Far and Extreme Ultraviolet Spectrometers (ORFEUS) Telescope carried on Astro-SPAS.

The ORFEUS-SPAS was a free-flying platform designed to be deployed and retrieved from the Space Shuttle Columbia on the STS-80 mission, launched on November 19, 1996. The platform was released from the Shuttle's robot arm 8 hours later, allowing astronomers to probe stars, galaxies, planets and quasars in ultraviolet light. Astronomers from around the world gathered data on over 200 targets during 427 pointings during the ORFEUS-SPAS mission. ORFEUS-SPAS II was retrieved by the Shuttle's remote arm on December 4, 1996 after 14 days of free-flight, and stowed in the Shuttle's payload bay for landing.

The Astro-SPAS carrier was powered by batteries, and data from the instruments were stored on tape. Absolute pointing was accurate to within a few arc seconds. The ORFEUS-SPAS platform was 4.5 meters (14.8 feet) in length and has a 2.5 meter (8 foot) width base. Operation of ORFEUS-SPAS was approximately 40 kilometers (25 miles) from the shuttle.

ORFEUS-SPAS II carried the same three spectrometers, operating over the wavelength range 400 — 1250 Angstroms, as was carried on ORFEUS-SPAS I. The Tubingen Ultraviolet Echelle Spectrometer (TUES) and the Berkeley Extreme and Far-UV Spectrometer (BEFS) were housed on the primary instrument — the ORFEUS 1-m telescope. The Interstellar Medium Absorption Profile Spectrograph (IMAPS) was operated independently from ORFEUS.

Roentgen Satellite. ROSAT, the *Roentgen* Satellite, was an X-ray observatory developed through a cooperative program between Germany, the United States, and the United Kingdom. The satellite was proposed by the Max-Planck-Institut für extraterrestrische Physik (MPE) and designed, built and operated in Germany. It was launched by the United States on June 1, 1990. The mission ended after almost nine years, on February 12, 1999. See also **Rosat (Roentgen Satellite)**.

Submillimeter Wave Astronomy Satellite (SWAS). SWAS is one of NASA's Small Explorer Program (SMEX) missions. SWAS was launched into low Earth orbit on December 05, 1998. The overall goal of the mission is to gain a greater understanding of star formation by determining the composition of interstellar clouds and establishing the means by which these clouds cool as they collapse to form stars and planets. See also **Explorers Program**.

SPACE SHUTTLE. The space shuttle is a two-stage spacecraft designed to transport personnel and cargo between Earth and orbiting satellites or space stations in outer space. The space shuttle program is part of the National Aeronautics and Space Administration (NASA) Space Transportation System (STS).

History

In September 1969, two months after the first manned lunar landing, a Space Task Group appointed by the President of the United States to study the future course of U.S. space research and exploration made the recommendation that... "The United States accept the basic goal of a balanced manned and unmanned space program. To achieve this goal, the United States should ... develop new systems of technology for space operation...through a program directed initially toward development of a new space transportation capability..."

In early 1970, NASA initiated extensive engineering, design, and cost studies of a space shuttle. These studies covered a wide variety of concepts ranging from a fully reusable manned booster and orbiter to dual strap-on solid propellant rocket motors and an expendable liquid propellant tank. Each concept evaluated development risks and costs in relation to the suitability and the overall economics of the entire system.

On January 5, 1972, President Richard M. Nixon announced that NASA would proceed with the development of a reusable low cost space shuttle system. NASA and its aerospace industry contractors continued engineering studies through January and February of 1972; finally on March 15, 1972, NASA announced that the shuttle would use two solid propellant rocket motors. The decision was based on information developed by studies that showed that the solid rocket system offered lower development cost and lower technical risk.

On September 17, 1976, the first suborbital spacecraft, *Enterprise*, was rolled out. A total of thirteen test flights were performed. The *Enterprise* was built as a test vehicle and not equipped for space flight.

Five captive flights, with the *Enterprise* perched atop a 747 jumbo jet with no crew and unpowered, were conducted to test the structural integrity of the craft. Three crewed captive flights followed with the crew operating the flight control systems in preparation for the first orbiter free flight. Finally, five free flights occurred with an astronaut crew separating the orbiter from the 747 shuttle carrier and maneuvering to a landing at Edwards Air Force Base. See Fig. 1.

For all of the captive flights and the first three free flights, the orbiter was outfitted with a tail cone covering its aft section to reduce aerodynamic drag and turbulence. The final two free flights were made without the tail cone, and the three simulated space shuttle main engines and two orbital maneuvering system engines were exposed aerodynamically.

After numerous tests across the United States, the *Enterprise* was ferried across the Atlantic for several air shows across Europe. Finally,

Fig. 1. The Shuttle *Enterprise* separates from the 747 shuttle carrier aircraft during the approach and landing tests. (*NASA*.)

on November 18, 1985, the *Enterprise* was ferried from Kennedy Space Center to Washington, DC and became the property of the Smithsonian Institution.

Space Shuttle Overview

The space shuttle is the world's first reusable spacecraft, and the first spacecraft in history that can carry large satellites both to and from orbit. The shuttle launches like a rocket, maneuvers in Earth orbit like a spacecraft and lands like an airplane. Each of the four space shuttle orbiters now in operation, *Columbia, Discovery, Atlantis* and *Endeavor*, is designed to fly at least 100 missions. So far, altogether they have flown a combined total of less than one-fourth of that.

The space shuttle consists of three major components: the orbiter which houses the crew; a large external fuel tank that holds fuel for the main engines; and two solid rocket boosters which provide most of the shuttle's lift during the first two minutes of flight. All of the components are reused except for the external fuel tank, which burns up in the atmosphere after each launch. See Fig. 2.

The empty weight at rollout is 158,289 pounds (71,800 kilograms) and 178,000 pounds (80,700 kilograms) with main engines installed. About the size of a commercial DC-9 jetliner, the Orbiter can deliver to orbit single or multiunit payloads up to 65,000 pounds (29,484 kilograms) in a cargo bay that measures 15 × 60 feet (4.5 × 18 meters), and bring back payloads weighing up to 32,000 pounds (14,515 kilograms).

The longest the shuttle has stayed in orbit on any single mission is 17.5 days on mission STS-80 in November 1996. Normally, missions may be planned for anywhere from five to 16 days in duration. The smallest crew ever to fly on the shuttle numbered two people on the first few missions. The largest crew numbered eight people. Normally, crews may range in size from five to seven people. The shuttle is designed to reach orbits ranging from about 185 kilometers to 643 kilometers (115 statute miles to 400 statute miles) high.

The shuttle has the most reliable launch record of any rocket now in operation. Since 1981, it has boosted more than 1.36 million kilograms (three million pounds) of cargo into orbit. More than 600 crewmembers have flown on its missions. Although it has been in operation for over 20 years, the shuttle has continually evolved and is significantly different today than when it first was launched. NASA has made literally thousands of major and minor modifications to the original design that have made it safer, more reliable and more capable today than ever before.

Since 1992 alone, NASA has made engine and system improvements that are estimated to have tripled the safety of flying the space shuttle, and the number of problems experienced while a space shuttle is in flight has decreased by 70 percent. During the same period, the cost of operating the shuttle has decreased by one and a quarter billion dollars annually, a reduction of more than 40 percent. At the same time, because of weight reductions and other improvements, the cargo the shuttle can carry has increased by 7.3 metric tons (8 tons.)

NASA plans to continue to improve the shuttle during the next five years, with goals of increasing its safety by improving the highest risk components. In managing and operating the space shuttle, NASA holds the safety of the crew as the highest priority. NASA is prepared to continue flying the shuttle for at least the next decade.

NASA's Orbiter Fleet

In the day-to-day world of Shuttle operations and processing, Space Shuttle orbiters go by a more prosaic designation. *Columbia* is commonly refereed to as OV-102, for Orbiter Vehicle-102. *Challenger, Discovery, Atlantis*, and *Endeavor* are, respectively, OV-99, OV-103, OV-104, and OV-105.

America's fleet of Space Shuttle orbiters is named after pioneering vessels that established new frontiers in research and exploration. NASA delved through the history books to find ships, which achieved historical significance through discoveries about the world's oceans or the Earth itself. Another important criterion in the selection process was consideration for the international nature of the Space Shuttle program.

Columbia (OV-102). *Columbia*, the oldest orbiter in the Shuttle fleet and the first to fly in space, is named after the Boston, Massachussetts-based sloop captained by American Robert Gray. On May 11, 1792, Gray and his crew maneuvered the "Columbia" past the dangerous sandbar at the mouth of a river extending more than 1,000 miles (1,610 meters) through what is today southeastern British Columbia, Canada, and the Washington-Oregon border. The river was later named after the ship. Gray also led Columbia and its crew on the first American circumnavigation of the globe, carrying a cargo of otter skins to Canton, China, and then returning to Boston.

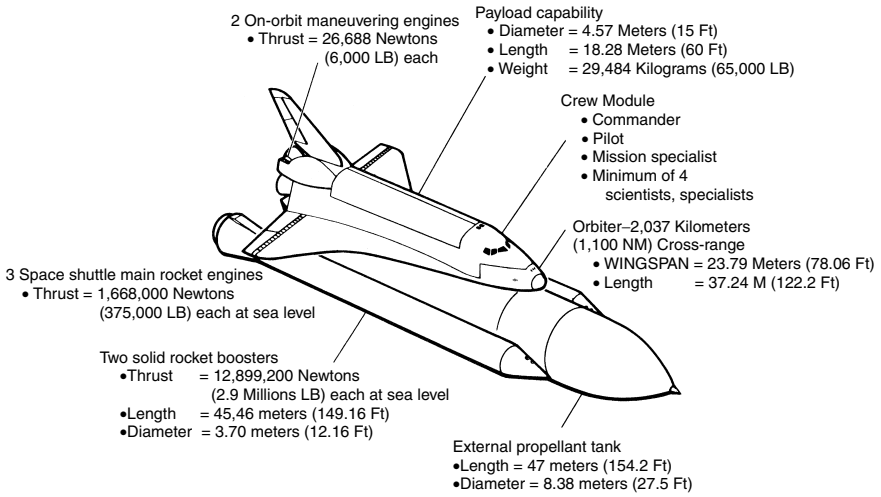

Fig. 2. Principal features of the space shuttle (*NASA*.)

Other sailing ships have further enhanced the luster of the name "Columbia." The first U.S. Navy ship to circle the globe bore that title, as did the command module for *Apollo* 11, the first lunar landing mission.

On a more directly patriotic note, "Columbia" is considered to be the feminine personification of the United States. The name is derived from that of another famous explorer, Christopher Columbus.

The first of NASA's orbiter fleet was delivered to Kennedy Space Center in March 1979. After several years of design, construction, and modification, *Columbia* initiated the Space Shuttle flight program when it lifted off Pad A at the Kennedy Space Center's Launch Complex 39 located on Merritt Island, Florida, just north of Cape Canaveral on April 12, 1981 at 7:00 a.m. (EST). Touchdown occurred at Edwards Air Force Base, California, at 10:21 a.m. (PST) on April 14, for a mission span of 54 hours, 21 minutes in an orbit 198 miles (319 kilometers) from Earth. The orbital speed of the ship was 17,000 miles (27,353 kilometers) per hour. Astronauts John W. Young and Robert L. Crippen flew the space shuttle *Columbia* on the first flight of the Space Transportation System (STS-1). *Columbia* became the first airplanelike craft to land from orbit for refurbishment and use on future missions. The STS-1 mission also was the first to employ both liquid and solid propellant rocket engines for the launch of a spacecraft carrying humans.

The second mission occurred with liftoff from the Kennedy Space Center's Launch Complex on November 12, 1981. Scheduled for a total time in space of about five days, the mission had to be shortened because of a malfunction in one of the three fuel cells that generated electrical power for the *Columbia*. During the shortened mission, the abilities of the craft's manipulating arm to place satellites and other objects into space orbit, as well as to retrieve them, were satisfactorily demonstrated, as was the feasibility of a number of scientific experiments placed aboard the craft. For a chronology of *Columbia* (OV-102) flights with primary payloads; see Table 1.

Upgrades and Features

Columbia was the first on-line orbiter to undergo the scheduled inspection and retrofit program. It was transported August 10, 1991, after its completion of mission STS-40, to prime Shuttle contractor Rockwell International's Palmdale, California assembly plant. The oldest orbiter in the fleet underwent approximately 50 modifications, including the addition of carbon brakes, drag chute, improved nose wheel steering, removal of development flight instrumentation and an enhancement of its thermal protection system. The orbiter returned to KSC February 9, 1992 to begin processing for mission STS-50 in June of that year.

On October 8, 1994, *Columbia* was transported to Palmdale California for its first orbiter maintenance down time (ODMP.) This orbiter modification and refurbishment time is expected to take approximately six months. About 90 modifications will be made to *Columbia* during its stay in California. Upgrades will be made to the main landing gear thermal barrier, tire pressure monitoring system and radiator drive circuitry. Repairs will be made to the radiators in areas where micrometeorites have made impacts. Other work planned includes intensive structural inspections and the application of an upgraded corrosion control coating on the wings and rudder.

On September 24, 1999, *Columbia* was transported to Palmdale California for its second ODMP. While in California, workers will perform more than 100 modifications on the vehicle. *Columbia* will be the second orbiter outfitted with the multifunctional electronic display system (MEDS) or "glass cockpit". See Fig. 3. During the past year, Shuttle *Atlantis* had the full-color, flat-panel displays installed on its flight deck during an OMDP. The new system improves crew interaction with the orbiter during flight and reduces the high cost of maintaining the outdated electromechanical cockpit displays currently onboard.

While her sister ships are being outfitted with external airlocks in support of the *International Space Station* assembly, *Columbia's* internal airlock will not be removed during this OMDP. Thus, *Columbia* will continue to be able to accommodate payloads requiring the orbiter's 60-foot long cargo bay. Though not currently slated to dock with the *International Space Station*, *Columbia* will be given additional wire harnesses and connectors while at Palmdale to allow installation of the Orbiter Docking System at Kennedy Space Center. This prepares *Columbia* for docking operations with the space station if plans change.

While at Palmdale, *Columbia's* 100 miles of wiring will be given a thorough inspection. This is part of NASA's fleet wide wiring inspection. The wiring problem was first identified on *Columbia* as a result of the STS-93 mission.

Preparation work for an enhanced Global Positioning Satellite system capability will also be performed on *Columbia*. When installed, the new system will more accurately pinpoint the orbiter's location in flight. A space-to-space orbiter radio and wireless video modification will increase communication capabilities for *Columbia's* future crewmembers and space walkers. In addition to scheduled weight saving modifications, *Columbia's* radiators or coolant lines will be enhanced for protection from orbital debris.

On February 21, 2002 *Columbia* resumed operation. Astronauts Scott D. Altman and Duane G. Carey piloted space shuttle *Columbia* (STS-109) on a third servicing mission of the Hubble Space Telescope. Mission Specialist installed new science instruments, the Advanced Camera for Surveys (ACS), new rigid Solar Arrays (SA3), new Power Control Unit (PCU) and a new Cryocooler for the Near Infrared Camera and Multi-Object Spectrometer (NICMOS). STS-109 will also reboost HST to a higher orbit.

Challenger (OV-99). The second orbiter to become operational at Kennedy Space Center was named after the British Naval research vessel *HMS Challenger* that sailed the Atlantic and Pacific oceans during the 1870's. The Apollo 17 lunar module also carried the name of *Challenger*. Like her historic predecessors, Space Shuttle *Challenger* and her crews made significant contributions to America's scientific growth. For a

TABLE 1. FLIGHTS OF *COLUMBIA* (OV-102)
(1981 to date)

Mission	Crew	Launch Date	Landing Date and Site	Primary Payload
STS-1[1]	Young, Crippen	04/12/1981	04/14/1981 Edwards Air Force Base	Development Flight Instrumentation package
STS-2	Engle, Truly	11/12/1981	11/14/1981 Edwards Air Force Base	Office of Space and Terrestrial Applications-1 (OSTA-1)
STS-3	Lousma, Fullerton	03/22/1982	03/30/1982 White Sands	Office of Space Science- 1 (OSS-1)
STS-4	Mattingly, Hartsfield	06/27/1982	07/04/1982 Edwards Air Force Base	Department of Defense (DOD 82-1) and Continuous Flow Electrophoresis System (CFES)
STS-5[2]	Brand, Overmyer, Lenoir, Allen	11/11/1982	11/16/1982 Edwards Air Force Base	Satellite Business System (CSBS-C) and Canadian Satellite (ANIK C-3)
STS-9[3]	Young, Shaw, Parker, Garriott, Merbold, Lichtenberg	11/28/1983	11/28/1983 Edwards Air Force Base	Spacelab-1
STS-61-C	Gibson, Bolden, Chang-Diaz, Hawley, Nelson, Cenker, Congressman Nelson	01/12/1986	01/18/1986 Edwards Air Force Base	SATCOM Ku-1 (RCA Americom) Satellite
STS-28	Shaw, Richards, Leestma, Adamson, Brown	08/08/1989	08/13/1989 Edwards Air Force Base	Department of Defense (DOD)
STS-32	Brandenstein, Wetherbee, Dunbar, Ivins, Low	01/09/1990	01/20/1990 Edwards Air Force Base	Synchronous Communication Satellite IV-F5 (SYNCOM IV-5) and Long Duration Exposure Facility Retrieval (LDEF)
STS-35	Brand, Gardner, Lounge, Hoffman, Parker, Parise, Durrance	12/02/1990	12/10/1990 Edwards Air Force Base	Ultraviolet and X-ray astronomy (ASTRO-1)
STS-40	O,Connor, Gutierrez, Jernigan, Seddon, Bagian, Gaffney, Hughes-Fulford	06/05/1991	06/14/1991 Edwards Air Force Base	Spacelab Life Sciences-1 (SLS-1)
STS-50	Richards, Bowersox, Dunbar, Baker, Meade, DeLucas, Trinh	06/25/1992	07/09/1992 Kennedy Space Center	United States Microgravity Laboratory-1 (USML-1)
STS-52	Wetherbee, Baker, Veach, Jernigan, Shepard, MacLean	10/22/1992	11/01/1992 Kennedy Space Center	Laser Geodynamic Satellite-II (LAGEOS II) and U.S. Microgravity Payload-1(USMP-1)
STS-55	Nagel, Hendricks, Ross, Precourt, Harris, Walter, Schlegel	04/26/1993	05/06/1993 Kennedy Space Center	Spacelab-D2 (second German-dedicated Spacelab)
STS-58	Blaha, Searfoss, Seddon, McArthur, Wolf, Lucid, Fettman	10/18/1993	11/1/1993 Edwards Air Force Base	Spacelab (SLS-2)
STS-62	Casper, Allen, Thuot, Gemar, Ivins	03/04/1994	03/18/1994 Kennedy Space Center	Office of Aeronautics and Space Technology-2 (OAST-2) and United States Microgravity Payload-2 (USMP-2)
STS-65[4]	Cabana, Halsell, Haib, Thomas, Walz, Chiao, Naito-Mukai	07/08/1994	07/23/1994 Kennedy Space Center	International Microgravity Laboratory-2 (IML-2)
STS-73[5]	Bowersox, Rominger, Thornton, Lopez-Alegria, Coleman, Sacco, Leslie	10/20/1995	11/05/1995 Kennedy Space Center	United States Microgravity Laboratory-2 (USML-2)
STS-75	Allen, Horowitz, Chang-Diaz, Cheli, Hoffman, Nicollier, Guidoni	02/22/1996	03/09/1996 Kennedy Space Center	Tethered Satellite System Reflight (TSS-1R) United States and Microgravity Payload-3 (USMP-3)
STS-78	Henricks, Kregel, Helms, Linnehan, Brady, Favier, Thirsk	06/20/1996	07/07/1996 Kennedy Space Center	Life and Microgravity Spacelab (LMS)
STS-80	Cockrell, Rominger, Jernigan, Jones, Musgrave	11/19/1996	12/07/1996 Kennedy Space Center	Orbiting and Retrievable Far and Extreme Ultraviolet Spectrograph-Shuttle Pallet Satellite II (ORFEUS-SPAS II) and Wake Shield Facility-3 (WSF-3)
STS-83[6]	Halsell, Still, Voss, Thomas, Gernhardt, Crouch, Linteris	04/04/1997	04/08/1997 Kennedy Space Center	Microgravity Science Laboratory-1 (MSL-1)

TABLE 1. (*Continued*)

Mission	Crew	Launch Date	Landing Date Date	Primary Payload
STS-94[7]	Halsell, Still, Voss, Thomas, Gernhardt, Crouch, Linteris	07/01/1997	07/17/1997 Kennedy Space Center	Microgravity Science Laboratory-1 (MSL-1)
STS-87	Lindsey, Kregel, Scott, Chawla, Doi, Kadenyuk	11/19/1997	12/05/1997 Kennedy Space Center	United States Microgravity Payload-4 (USMP- 4) and SPARTAN 201-04 rescue
STS-90	Searfoss, Altman, Linnehan, Williams, Hire, Buckey, Pawelczyk	04/17/1998	05/03/1998 Kennedy Space Center	Final Spacelab Mission
STS-91[8]	Precourt, Pudwill Gorie, Lawrence, Chang-Diaz, Kavandi, Ryumin,	06/02/1998	06/12/1998 Kennedy Space Center	9th and Final Shuttle-*Mir* Docking
STS-93[9]	Collins, Ashby, Hawley, Coleman, Tognini	07/23/1999	07/27/1999 Kennedy Space Center	Chandra X-ray Observatory

[1]The primary mission objectives for STS-1 were to check out all the systems on the space shuttle, accomplish a safe ascent into orbit and to return to Earth for a safe landing. All of these objectives were met successfully.

The main payload carried on STS-1 was a Development Flight Instrumentation package, which contained sensors and measuring devices to record orbiter performance and the stresses that occurred during launch, ascent, orbital flight, descent and landing.

[2]First Shuttle operational mission deployed two commercial communications satellites, ANIK C-3 for TELESAT Canada and SBS-C for Satellite Business Systems. Each equipped with Payload Assist Module-D (PAM-D) solid rocket motor, which fired about 45 minutes after deployment, placing each satellite into highly elliptical orbit.

First scheduled space walk in Shuttle program canceled due to malfunction of space suit.

[3]Flight carried first Spacelab mission and first astronaut to represent European Space Agency (ESA), Ulf Merbold of Germany. ESA and NASA jointly sponsored Spacelab-1 and conducted investigations, which demonstrated capability for advanced research in space. Spacelab is an orbital laboratory and observations platform composed of cylindrical pressurized modules and U-shaped unpressurized pallets, which remain in orbiter's cargo bay during flight.

[4]Payload Specialist Chiaki Mukai became first Japanese woman to fly in space; she also set record for longest flight to date by female astronaut.

[5]Crew took time out from Spacelab work to tape ceremonial first pitch for Game Five of baseball World Series, marking first time the thrower was not actually in the ballpark for the pitch.

[6]STS-83. First flight of the Microgravity Science Laboratory-1 (MSL-1) cut short due to concerns about one of three fuel cells, marking only the third time in the Shuttle program history a mission ended early.

[7]STS-94. Marked the first reflight of same vehicle, crew and payloads, following shortened STS-83 mission in April due to indications of a fuel cell problem.

[8]STS-91. return of 7th and last U.S. astronaut (Andrew S.W. Thomas) to live and work aboard *Mir*. Ninth and Final Shuttle-*Mir* Docking.

[9]STS-93. On the first day of the scheduled five-day mission, the Chandra X-ray Observatory was deployed from *Columbia's* payload bay. Chandra's two-stage Inertial Upper Stage (IUS) propelled the observatory into a transfer orbit of 205 miles by 44,759 miles in altitude. See also **Chandra X-ray Observatory.**

For more detailed information on *Columbia* missions see: http://spaceflight.nasa.gov/shuttle/archives/year1981.html

chronology of *Challenger* (OV-99) flights with primary payloads; see Table 2 on p. 3251.

Challenger joined NASA fleet of reusable winged spaceships in July 1982. It flew nine successful Space Shuttle missions. On January 28, 1986, the *Challenger* and its seven-member crew were lost 73 seconds after launch when a booster failure resulted in the breakup of the vehicle.

Discovery (OV-103). The third orbiter to become operational at Kennedy Space Center, was named after one of two ships that were used by the British explorer James Cook in the 1770s during voyages in the South Pacific that led to the discovery of the Hawaiian Islands. Another of his ships was the *Endeavor*, the namesake of NASA's newest orbiter.

Cook also used *Discovery* to explore the coasts of southern Alaska and northwestern Canada. During the American Revolutionary War, Benjamin Franklin made a safe conduct with request for the British vessel because of the scientific importance of its research.

Other famous ships have carried the name *Discovery*, including one used to explore Hudson Bay in Canada as well as search for what was hoped to be the northwest passage from the Atlantic to the Pacific in 1610 and 1611. Another, based on whaling ship design, was used by the British Royal Geographical Society for an expedition to the North Pole in 1875. The organization then built another *Discovery* in 1901 to conduct its Antarctic expedition that concluded in 1904. This ship still exists and is being preserved by the Society.

Discovery (OV-103) arrived at Kennedy Space Center in November 1983. It was launched on its first mission, flight STS-41-D, on August 30, 1984. It carried aloft three communications satellites for deployment by its astronaut crew.

Other *Discovery* milestones include the deployment of the Hubble Space Telescope on mission STS-31 in April 1990, the launching of the *Ulysses* spacecraft to explore the Sun's polar regions on mission STS-41 in October of that year and the deployment of the Upper Atmosphere Research Satellite (UARS) in September 1991. For a chronology of *Discovery* (OV-103) flights with primary payloads (see Table 3 on pp. 3251 and 3252).

Upgrades and Features

Discovery benefited from lessons learned in the construction and testing of *Enterprise, Columbia* and *Challenger*. At rollout, its weight was some 6,870 pounds (3,120 kilograms) less than *Columbia*. Two orbiters, *Challenger* and *Discovery*, were modified at KSC to enable them to carry the Centaur upper stage in the payload bay. These modifications included extra plumbing to load and vent Centaur's cryogenic (L02/LH2) propellants (other IUS/PAM upper stages use solid propellants), and controls on the aft flight deck for loading and monitoring the Centaur stage. No Centaur flight was ever flown and after the loss of *Challenger* it was decided that the risk was too great to launch a shuttle with a fueled Centaur upper stage in the payload bay.

On August 25, 1995, *Discovery* underwent a nine-month Orbiter Maintenance Down Period (OMDP) in Palmdale California. The vehicle was outfitted with a 5th set of cryogenic tanks and an external airlock to support missions to the International Space Station. *Discovery* departed Palmdale, CA, riding piggy-back on a modified Boeing 747 at 10:01am EDT June 28, 1996 and arrived at KSC on June 29, 1996. See Fig. 4 on p. 3254.

On February 11, 1997 *Discovery* resumed operations. Astronauts Kenneth D. Bowersox and Scott J. Horowitz piloted space shuttle *Discovery* (STS-82) on a second in a series of planned servicing missions to the orbiting Hubble Space Telescope (HST). Work performed on the telescope will significantly upgrade the scientific capabilities of the HST and keep the telescope functioning smoothly until the next scheduled servicing missions in 2002.

Fig. 3. This "fish-eye" view illustrates NASA's Multifunction Electronic Display Subsystem (MEDS), otherwise known as "glass cockpit." It represents a number of important modifications that have been accomplished on the Orbiter's flight deck. This photo is actually a recent one of the fixed base Space Shuttle mission simulator in the Johnson Space Center's (JSC) Mission Simulation and Training Facility. The fixed base simulator has been outfitted with MEDS to be used by flight crews for training. (*NASA*.)

STS-82 demonstrated anew the capability of the Space Shuttle to service orbiting spacecraft as well as the benefits of human spaceflight. The seven-member crew completed servicing and upgrading of the Hubble Space Telescope during four planned extravehicular activities (EVAs) and then performed a fifth unscheduled space walk to repair insulation on the telescope. See also **Hubble Space Telescope (HST)**.

Atlantis (OV-104). *Atlantis*, the fourth orbiter to become operational in the fleet launched from KSC, is named after the primary research vessel for the Woods Hole Oceanographic Institute in Massachusetts from 1930 to 1966. The two-masted, 460-ton (417 ton) ketch was the first U.S. vessel to be used for oceanographic research. Such research was considered to be one of the last bastions of the sailing vessel as steam-and-diesel powered vessels dominated the waterways.

The steel-hulled ocean research ship was approximately 140 feet long (42.7 meters) and 29 feet wide (8.84 meters) to add to her stability. She featured a crew of 17 and room for five scientists. The research personnel worked in two onboard laboratories, examining water samples and marine life brought to the surface by two large winches from thousands of feet below the surface. The water samples taken at different depths varied in temperature, providing clues to the flow of ocean currents. The crew also used the first electronic sounding devices to map the ocean floor. See also **Ocean Research Vessels**.

Atlantis (OV-104) was delivered to Kennedy Space Center in April 1985. It lifted off on its maiden voyage on October 3, 1985, on mission STS-51-J, the second dedicated Department of Defense flight. *Atlantis* has carried on the spirit of the sailing vessel with several important voyages of its own, including the Galileo interplanetary probe to Jupiter on STS-34 in October 1989, and STS-37 the deployment of the Arthur Holley Compton Gamma Ray Observatory (CGRO) as its primary payload, in April 1991. For a chronology of *Atlantis* (OV-104) flights with primary payloads, see Table 4. See also **Compton Gamma-Ray Observatory (CGRO)**; and **Galileo Mission to Jupiter**.

Upgrades and Features

Atlantis benefited from lessons learned in the construction and testing of *Enterprise*, *Columbia*, and *Challenger*. At rollout, its weight was some 6,974 pounds (3,160 kilograms) less than *Columbia*. The Experience gained during the Orbiter assembly process also enabled *Atlantis* to be completed with a 49.5 percent reduction in man-hours (compared to *Columbia*). Much of this decrease can be attributed to the greater use of thermal protection blankets on the upper orbiter body instead of tiles. During the construction of *Discovery* and *Atlantis*, NASA opted to have the various contractors manufacture a set of "structural spares" to facilitate the repair of an Orbiter if one was damaged during an accident. This contract was valued at $389 million and consisted of a spare aft-fuselage, mid-fuselage, forward fuselage halves, vertical tail and rudder, wings, elevons and a body flap. These spares were later assembled into the orbiter *Endeavor*. *Atlantis* was shipped to California November 5, 1997 to undergo upgrades and modifications. These modifications included a drag chute, new plumbing lines that configure the orbiter for extended duration, more than 800 new heat protection tiles and blankets and new insulation for the main landing gear doors, structural mods to the *Atlantis* airframe. Altogether, 165 modifications were made to *Atlantis* over the 20 months it spent in Palmdale, California.

On May 19, 2000 *Atlantis* resumed operations. Astronauts Terrence W. Wilcutt and Scott D. Altman piloted space shuttle *Atlantis* (STS-106) on a fourth International Space Station assembly flight (ISS-2A.2b.)

TABLE 2. FLIGHTS OF *CHALLENGER* (OV-99)
(1983 to 1986)

Mission	Crew	Launch Date	Landing Date	Primary Payload
STS-6[1]	Weitz, Bobko, Peterson, Musgrave	04/04/1983	04/09/1983 Edwards Air Force Base	Tracking and Data Relay Satellite-1 (TDRS-1)
STS-7[2]	Crippen, Hauck, Fabian, Ride, Thagard	06/18/1983	96/24/1983 Edwards Air Force Base	Two Communications Satellites ANIK C-2 for TELESAT Canada PALAPA B1 for Indonesia
STS-8[2]	Truly, Brandenstein, Gardner, Bluford, Thornton	08/30/1983	09/05/1983 Edwards Air Force Base	Multipurpose satellite for India (INSAT-1B)
STS-41-B[4]	Brand, Gibson, McCandless, McNair, Stewart	02/03/1984	02/11/1984 Kennedy Space Center	Two satellites deployed WESTAR-VI and PALAPA-B2
STS-41-C[5]	Crippen, Scobee, Nelson, van Hoften, Hart	04/06/1984	04/13/1984 Edwards Air Force Base	Long Duration Exposure Facility (LDEF)
STS-41-G[6]	Crippen, McBride, Sullivan, Ride, Leestma, Garneau, Scully-Power	10/05/1984	10/13/1094 Kennedy Space Center	Earth Radiation Budget Satellite (ERBS) Office of Space and Terrestrial Applications-3 (OSTA-3)
STS-51-B	Overmyer, Gregory, Lind, Thagard, Thornton, Wang, van den Berg	04/29/1985	05/06/1985 Edwards Air Force Base	Spacelab-3
STS-51-F	Fullerton, Bridges, Musgrave, England, Henize, Acton, Bartoe	07/29/1985	08/06/1985 Edwards Air Force Base	Spacelab-2 Life Sciences, Plasma Physics, Astronomy, High-Energy Astrophysics, Solar Physics, Atmospheric Physics and Technology Research
STS-61-A	Hartsfield, Nagel, Buchli, Bluford, Jr., Dunbar, Furrer, Messerschmid, Ockels	10/30/1985	11/06/1985 Edwards Air Force Base	D-1 Spacelab Mission (First German-Dedicated Spacelab)
STS-51-L[7]	Scobee, Smith, Resnik, Onizuka, McNair, Jarvis, McAuliffe	01/28/1986	N/A	Tracking Data Relay Satellite-2 (TDRS-2) and Shuttle-Pointed Tool for Astronomy (SPARTAN-203)

[1]First flight of *Challenger* (OV-99) and first space walk of Shuttle program performed by Peterson and Musgrave, lasting about four hours, 17 minutes.
[2]Sally K. Ride became the first American woman to fly in space.
[3]Guion S. Bluford became the first African-American to fly in space.
First night launch and night landing of a space shuttle.
[4]First untethered space walks by McCandless and Stewart, using manned maneuvering unit, and first Kennedy Space Center landing.
[5]First on-orbit spacecraft repair, and first direct ascent trajectory for Space Shuttle.
[6]First flight to include two women, Sally K. Ride and Kathryn D. Sullivan.
Kathryn D. Sullivan first American woman to walk in space.
[7]Explosion 73 seconds after liftoff claimed crew and vehicle. Shuttle flights halted while extensive investigation into accident and assessment of Shuttle program conducted.

TABLE 3. FLIGHTS OF *DISCOVERY* (OV-103)
(1984 to date)

Mission	Crew	Launch Date	Landing Date	Primary Payload
STS-41-D	Hartsfield, Coats, Resnik, Hawley, Mullane, Walker	08/30/1984	09/05/1984 Edwards Air Force Base	Satellite Business System (SBS-D) SYNCOM IV-2 (also known as LEASAT 2) and TELSTAR
STS-51-A[1]	Hauck, Walker, Fisher, Gardner, Allen	11/08/1984	11/16/1984 Kennedy Space Center	Canadian communications satellite (TELESAT-H) and Defense communications satellite (SYNCOM IV-1 also known as LEASAT-1)
STS-51-C[2]	Mattingly, Shriver, Onizuka, Buchli, Payton	01/24/1985	01/27/1985 Kennedy Space Center	Department of Defense (DOD)
STS-51-D	Bobko, Williams, Seddon, Hoffman, Griggs, Walker, Garn	04/12/1985	04/19/1985 Kennedy Space Center	Communications Satellite deployed TELESAT-I (ANIK C-1) and SYNCOM IV-3 failed to deploy
STS-51-G	Brandenstein, Lucid Creighton, Nagel, Thornton, Baudry, Al-Saud	06/17/1985	06/24/1985 Edwards Air Force Base	Three communications satellites deployed: MORELOS-A, for Mexico; ARABSAT-A, for Arab Satellite Communications Organization; and TELSTAR-3D, for AT&T

(*continued*)

TABLE 3. (*Continued*)

Mission	Crew	Launch Date	Landing Date Date	Primary Payload
STS-51-I[3]	Engle, Covey, van Hoften, Lounge, Fisher	08/27/1985	09/03/1985 Edwards Air Force Base	Three communications satellites deployed: ASC-1, for American Satellite Company; AUSSAT-1, an Australian Communications Satellite; and SYNCOM IV-4
STS-26[4]	Hauck, Covey, Lounge, Nelson, Hilmers	09/29/1988	10/03/1988 Edwards Air Force Base	NASA Tracking and Data Relay Satellite-3 (TDRS-3)
STS-29	Coats, Blaha, Bagian, Buchli, Springer	03/13/1989	03/18/1989 Edwards Air Force Base	Tracking and Data Relay Satellite-4 (TDRS-4)
STS-33[5]	Gregory, Blaha, Musgrave, Carter Jr., Thornton	11/22/1989	11/27/1989 Edwards Air Force Base	Department of Defense (DOD)
STS-31[6]	Shriver, Bolden, Jr., Hawley, McCandless II, Sullivan	04/24/1990	04/29/1990 Edwards Air Force Base	Hubble Space Telescope (HST) deploy
STS-41[7]	Richards, Cabana, Shepherd, Melnick, Akers	10/06/1990	10/10/1990 Edwards Air Force Base	ESA-built Ulysses spacecraft
STS-39	Coats, Hammond, Jr., Bluford Jr., Hieb, Harbaugh, Veach, McMonagle	04/28/1991	05/06/1991 Kennedy Space Center	Dedicated Department of Defense Mission
STS-48[8]	Creighton, Reightler, Jr., Buchli, Gernar, Brown	09/12/1991	09/18/1991 Edwards Air Force Base	Upper Atmosphere Research Satellite (UARS)
STS-42	Grabe, Oswald, Thagard, Hilmers, Readdy, Bondar, Merbold	01/22/1992	01/30/1992 Edwards Air Force Base	International Microgravity Laboratory-1 (IML-1)
STS-53[9]	Walker, Cabana, Bluford Jr., Voss, Clifford	12/02/1992	12/9/1992 Edwards Air Force Base	Department of Defense (DOD)
STS-56	Cameron, Oswald, Foale, Cockrell, Ochoa	04/08/1993	04/17/1993 Kennedy Space Center	Atmospheric Laboratory for Applications and Science-2 (ATLAS-2)
STS-51[10]	Culbertson Jr., Readdy, Newman, Bursch, Walz	09/12/1993	09/22/1993 Kennedy Space Center	Advanced Communications Technology Satellite (ACTS) and Orbiting and Retrievable Far and Extreme Ultraviolet Spectrograph-Shuttle Pallet Satellite (OERFEUS- SPAS)
STS-60[11]	Bolden, Reightler Jr., Davis, Sega, Chang-Diaz, Sergei K. Krikalev (Russia)	02/03/1994	02/11/1994 Kennedy Space Center	Wake Shield Facility-1 (WSF-1) and SPACEHAB pressurized module
STS-64[12]	Richards, Hammond, Jr., Linenger, Helms, Meade, Lee	09/09/1994	09/20/1994 Edwards Air Force Base	Lidar In-space Technology Experiment LITE
STS-63[13]	Wetherbee, Collins, Foale, Voss, Harris, Vladimar G. Titov	02/03/1995	02/11/1995 Kennedy Space Center	SPACEHAB-3 and Mir Rendezvous
STS-70	Henricks, Kregel, Currie, Thomas, Weber	07/13/1995	07/22/1995 Kennedy Space Center	Tracking and Data Relay Satellite-G deployed (TDRS-G)
STS-82[14]	Bowersox, Horowitz, Lee, Hawley, Harbaugh, Smith, Tanner	02/11/1997	02/21/1997 Kennedy Space Center	2nd Hubble Space Telescope (HST) servicing
STS-85[15]	Brown, Rominger, Davis, Curbeam, Robinson, Tryggvason,	08/07/1997	08/19/1997 Kennedy Space Center	Cryogenic Infrared Spectrometers and Telescopes for the Atmosphere-Shuttle Pallet Satellite-2 (CRISTA-SPAS02)
STS-91[16]	Precourt, Pudwill Gorie, Lawrence, Kavandi, Chang-Diaz, Valery Victorovitch Ryumin	06/02/1998	06/12/1998 Kennedy Space Center	9th and Final Shuttle-*Mir* docking
STS-95[17]	Brown, Lindsey, Parazynski, Duque, Robinson, Mukai, John H. Glenn	10/29/1998	11/07/1998 Kennedy Space Center	John Glenn's Flight and SPACEHAB module
STS-96[18]	Rominger, Husband, Ochoa, Jernigan, Barry, Payette, Valery Ivanovich Tokarev	05/27/1999	06/06/1999 Kennedy Space Center,	2nd Space Station Flight (ISS)
STS-103[19]	Brown, Kelly, Smith, Foale, Grunsfeld, Nicollier, Clervoy	12/19/1999	12/27/1999 Kennedy Space Center	Hubble Space Telescope repair-3A
STS-92	Duffy, Melroy, Wakata, Chiao, Wisoff, McArthur, Lopez-Alegria	10/11/2000	10/24/2000 Edwards Air Force Base	*International Space Station* Flight 3A Integrated Truss Structure (ITS) Z1, Pressurized Mating Adapter 3 (PMA 3), Ku-band Communications System, Control Moment Gyros (CMGs)

TABLE 3. (*Continued*)

Mission	Crew	Launch Date	Landing Date Date	Primary Payload
STS-102[20]	Wetherbee, Kelly, Thomas, Richards, Voss, Helms, Usachev	03/08/2001	03/21/2001 Kennedy Space Center	*International Space Station* Flight 5A.1
STS-105[20]	Horowitz, Sturckow, Barry, Forrester	08/10/2001	08/22/2001 Kennedy Space Center	*International Space Station* Flight 7A.1

[1]Allen and Gardner, wearing jet-propelled manned maneuvering units, retrieved two malfunctioning satellites: PALAPA-B2 and WESTAR-VI, both deployed on Mission STS-41-B.
[2]First mission dedicated to Department of Defense. U.S. Air Force Inertial Upper Stage booster deployed and met mission objectives.
[3]Fisher and van Hoften performed two extravehicular activities (EVAs) totaling 11 hours, 51 minutes. Part of time spent retrieving, repairing and redeploying LEASAT-3, deployed on Mission STS-51-D.
[4]Mission marked resumption of Shuttle flights after 1986 STS-51-L *Challenger* accident.
[5]Fifth mission dedicated to Department of Defense.
[6]Primary payload, Hubble Space Telescope, deployed in a 380-statute-mile orbit. See also **Hubble Space Telescope (HST)**.
[7]Primary payload, ESA-built Ulysses spacecraft to explore polar regions of Sun, deployed. See also **Ulysses Mission**.
[8]Primary payload, the Upper Atmosphere Research Satellite (UARS), deployed on the third day of the mission. During its planned 18-month mission, the 14,500-pound observatory will make the most extensive study ever conducted of the Earth's troposphere, the upper level of the planet's envelope of life-sustaining gases which also include the protective ozone layer. UARS has ten sensing and measuring devices: Cryogenic Limb Array Etalon Spectrometer (CLAES); Improved Stratospheric and Mesospheric Sounder (ISAMS); Microwave Limb Sounder (MLS); Halogen Occultation Experiment (HALOE); High Resolution Doppler Imager (HRDI); Wind Imaging Interferometer (WINDII); Solar Ultraviolet Spectral Irradiance Monitor (SUSIM); Solar/Stellar Irradiance Comparison Experiment (SOLSTICE); Particle Environment Monitor (PEM) and Active Cavity Radiometer Irradiance Monitor (ACRIM II).
[9]Final Shuttle flight for Department of Defense (DOD). Classified DOD payload deployed on flight day one, after which flight activities became unclassified.
[10]On Sept. 16, Mission Specialists Newman and Walz performed extravehicular activity (EVA) lasting seven hours, five minutes and 28 seconds. Final in series of generic space walks begun earlier in year. Astronauts also evaluated tools, tethers and foot restraint platform intended for upcoming Hubble Space Telescope servicing mission.
[11]First Shuttle flight of 1994 marked the first flight of Russian cosmonaut Sergei K. Krikalev on U.S. Space Shuttle as first element in implementing Agreement on NASA/Russian Space Agency Cooperation in Human Space Flight.
[12]First untethered U.S. extravehicular activity (EVA) in 10 years.
[13]First Shuttle flight of 1995 included several history- making achievements: First flight of a female Shuttle pilot and, as part of Phase I of international space station program, second flight of Russian cosmonaut on Shuttle and first approach and flyaround by Shuttle with Russian space station *Mir*.
[14]STS-82 demonstrated anew the capability of the Space Shuttle to service orbiting spacecraft as well as the benefits of human spaceflight. Six-member crew completed servicing and upgrading of the Hubble Space Telescope during four planned extravehicular activities (EVAs) and then performed a fifth unscheduled space walk to repair insulation on the telescope.

HST deployed in April 1990 during STS-31. It was designed to undergo periodic servicing and upgrading over its 15-year lifespan, with first servicing performed during STS-61 in December 1993. Hawley, who originally deployed the telescope, operated the orbiter Remote Manipulator System arm on STS-82 to retrieve HST for second servicing at 3:34 a.m. EST, Feb. 13, and positioned it in payload bay less than half an hour later.
[15]STS-85 carried a complement of payloads in the cargo bay that focused on Mission to Planet Earth objectives as well as preparations for International Space Station assembly.
[16]At hatch opening, Andy Thomas officially became a member of Discovery's crew, completing 130 days of living and working on *Mir*. The transfer wrapped up a total of 907 days spent by seven U.S. astronauts aboard the Russian space station as long-duration crewmembers.
[17]The scientific research mission also returned space pioneer John Glenn to orbit — 36 years, eight months and nine days after he became the first American to orbit the Earth. Medical research during the mission included a battery of tests on Payload Specialist Glenn and Mission Specialist Pedro Duque to further research how the absence of gravity affects balance and perception, immune system response, bone and muscle density, metabolism and blood flow, and sleep.
[18]All major objectives were accomplished during the mission. On May 29, Discovery made the first docking to the *International Space Station* (ISS). Rominger eased the Shuttle to a textbook linkup with Unity's Pressurized Mating Adapter #2 as the orbiter and the ISS flew over the Russian-Kazakh border. The 45th space walk in Space Shuttle history and the fourth of the ISS era lasted 7 hours and 55 minutes, making it the second-longest ever conducted. The crew transferred 3,567 pounds of material, including clothing, sleeping bags, spare parts, medical equipment, supplies, hardware and about 84 gallons of water, to the interior of the station. The astronauts also installed parts of a wireless strain gauge system that will help engineers track the effects of adding modules to the station throughout its assembly, cleaning filters and checking smoke detectors. Eighteen items weighing 197 pounds were moved from the station to Discovery for a return to Earth.
[19]The Hubble Space Telescope is alive and well and back on duty after a successful December, 1999 Servicing Mission (SM3A). To prove it, NASA released two stunning images taken by Hubble just two weeks after *Discovery's* Christmas-time service call. *Discovery's* seven-member crew included two Hubble Servicing Mission veterans. What was originally conceived as a mission of preventive maintenance turned more urgent on November 13, 1999 when the fourth of six gyros failed and Hubble temporarily closed its eyes on the Universe. Unable to conduct science without three working gyros, Hubble entered a state of dormancy called safe mode. Essentially, Hubble "went to sleep" while it waited for help. NASA decided to split the Third Servicing Mission (SM3) into two parts, SM3A and SM3B, after the third of Hubble's six gyroscopes failed. In accordance with NASA's flight rules, a "call-up" mission was quickly approved and developed and executed in a record seven months!
[20]STS-102 Swaps International Space Station Crews: Space Shuttle *Discovery* spent 13 days in orbit, with nearly nine of those days docked to the ISS. While at the orbital outpost, the STS-102 crew attached the Leonardo Multi-Purpose Logistics Module, transferred supplies and equipment to the station. Space walkers spent a total of 15 hours and 26 minutes during two excursions outside the docked complex. The first space walk was the longest in space history.

Discovery delivered the Expedition Two Crew Commander Yury Usachev and Flight Engineers Jim Voss and Susan Helms for its extended stay aboard the space station. It returned to Earth with Expedition One Commander Bill Shepherd, Flight Engineer Sergei Krikalev and Soyuz Commander Yuri Gidzenko, who had spent 4.5 months living on the station.
[21]Space Shuttle *Discovery* spent 12 days in orbit, with eight of those days docked to the ISS. While at the orbital outpost, the STS-105 crew attached the Leonardo Multi-Purpose Logistics Module, transferred supplies and equipment to the station, completed two space walks and deployed a small spacecraft called Simplesat.
Discovery delivered the Expedition Three crew Commander Frank Culbertson, Pilot Vladimir Dezhurov and Flight Engineer Mikhail Tyurin for its extended stay aboard the space station. It returned to Earth with Expedition Two crewmembers Commander Yury Usachev and Flight Engineers Jim Voss and Susan Helms who had spent about five months living on the station.

Fig. 4. Shuttle returning Piggybacked to a Boeing 747. (*NASA*.)

Veteran Astronaut Terry Wilcutt (Col., USMC) leads the seven-man crew, commanding his second Shuttle flight and making his fourth trip into space. During the 11-day mission, Wilcutt and his crew mates spent a week inside the ISS unloading supplies from both a double SPACEHAB cargo module in the rear of *Atlantis's* cargo bay and from a Russian Progress M-1 resupply craft docked to the aft end of the Zvezda Service Module. Zvezda, which linked up to the ISS on July 26, 1999 will serve as the early living quarters for the station and is the cornerstone of the Russian contribution to the ISS.

The goal of the flight is to prepare Zvezda for the arrival of the first resident, or Expedition, and the start of a permanent human presence on the new outpost. Expedition One Commander Bill Shepherd, Soyuz Commander Yuri Gidzenko and Flight Engineer Sergei Krikalev were launched in a Soyuz capsule from the Baikonur Cosmodrome in Kazakhstan on October 31, 2000. On November 2, 2000 the crew docked with the ISS and spent 136 days as the initial or "shake down" crew for the continuous human presence on the International Space Station. During this time, Shepherd kept a log of the activities aboard the orbiting outpost. See also http://spaceflight.nasa.gov/station/crew/exp1/ex1logs.html.

See also **Space Stations**.

In addition, Dr. Ed Lu and Yuri Malenchenko conducted a $6\frac{1}{2}$-hour space walk to hook up electrical communications and telemetry cables between Zvezda and the Zarya Control Module, whose computers handed over commanding functions to the Service Module's computers in a smooth transition in late July 2000. Lu and Malenchenko also installed a magnetometer to the exterior of Zvezda. The magnetometer will serve as a three-dimensional compass designed to minimize Zvezda propellent usage by relaying information to the module's computers regarding its orientation relative to the Earth.

Endeavor (OV-105). *Endeavor*, the newest addition to the orbiter fleet, is named after the first ship commanded by James Cook, the 18th century British explorer, navigator and astronomer. On *Endeavour's* maiden voyage in August 1768, Cook sailed to the South Pacific to observe and record the infrequent event of the planet Venus passing between the Earth and the sun. Determining the transit of Venus enabled early astronomers to find the distance of the sun from the Earth, which then could be used as a unit of measurement in calculating the parameters of the universe. Cook also discovered and charted New Zealand, surveyed the eastern coast of Australia, and navigated the Great Barrier Reef there.

Cook's voyage on the *Endeavor* also established the usefulness of sending scientists on voyages of exploration. While sailing with Cook, naturalists Joseph Banks and Carl Solander collected many new families and species of plants, and encountered numerous new species of animals.

Endeavor and her crew reportedly made the first long-distance voyage on which no crewman died from scurvy, the dietary disease caused by lack of ascorbic acids. Cook is credited with being the first captain to use diet as a cure for scurvy, when he made his crew eat cress, sauerkraut, and an orange extract.

The *Endeavor* was small at about 368 tons (334 tons), 100 feet (30.5 meters) in length and 20 feet (6.1 meters) in width. See had a round bluff bow and a flat bottom. The ship's career ended on a reef along Rhode Island.

Authorization to construct the fifth Space Shuttle orbiter as a replacement for Challenger was granted by Congress on August 1, 1987. For the first time, a national competition involving students in elementary and secondary schools produced the name of the new orbiter; it was announced by President George Bush in 1989.

The space shuttle *Endeavor* (OV-105) was delivered to the Kennedy Space Center's (KSC's) Shuttle Landing Facility May 7, 1991, atop NASA's new Shuttle Carrier Aircraft (NASA 911). The space agency's newest orbiter began flight operations on May 7, 1992; STS-49 highlighted by the dramatic rescue of a stranded communications satellite. For a chronology of *Endeavor* (OV-105) flights with primary payloads, see Table 5.

Upgrades and Features

Endeavor features new hardware designed to improve and expand orbiter capabilities. Most of this equipment was later incorporated into the other three orbiters during out-of-service major inspection and modification programs. *Endeavour's* upgrades include:

- A 40-foot diameter (12.2-meter) drag chute that is expected to reduce the orbiter's rollout distance by 1,000 to 2,000 feet (305 to 610 meters).
- The plumbing and electrical connections needed for Extended Duration Orbiter (EDO) modifications to allow up to 28-day missions.

TABLE 4. FLIGHTS OF *ATLANTIS* (OV-104)
(1985 to date)

Mission	Crew	Launch Date	Landing Date	Primary Payload
STS-51-J[1]	Bobko, Grabe, Hilmers, Stewart, Pailes	10/03/1985	10/07/1985 Edwards Air Force Base	Second mission dedicated to Department of Defense (DOD)
STS-61-B	Shaw, O'Connor, Cleave, Spring, Ross, Vela, Walker	11/26/1985	12/03/1985 Edwards Air Force Base	Three communications satellites deployed: MORELOS-B (Mexico) AUSSAT-2 (Australia) SATCOM KU-2 (RCA Americom)
STS-27	Gibson, Gardner, Mullane, Ross, Shepherd	12/02/1988	12/06/1988 Edwards Air Force Base	Third mission dedicated to Department of Defense (DOD)
STS-30[2]	Walker, Grabe, Thagard, Cleave, Lee	05/04/1989	05/08/1989 Edwards Air Force Base	Magellan/Venus Radar Mapper Spacecraft.
STS-34[3]	Williams, McCulley, Chang-Diaz, Lucid, Baker	10/18/1989	10/23/1989 Edwards Air Force Base	Galileo/Jupiter spacecraft
STS-36	Creighton, Casper, Mullane, Hilmers, Thuot	02/28/1990	03/04/1990 Edwards Air Force Base	Sixth mission dedicated to Department of Defense (DOD)
STS-38	Covey, Culbertson, Springer, Meade, Gemar	11/15/1990	11/20/1990 Kennedy Space Center	Seventh mission dedicated to Department of Defense (DOD)
STS-37[4]	Nagel, Cameron, Ross, Apt, Godwin	04/05/1991	04/11/1991 Kennedy Space Center	Compton Gamma Ray Observatory (CGRO.)
STS-43	Blaha, Baker, Lucid, Adamson, Low	08/02/1991	08/11/1991 Kennedy Space Center	Tracking and Data Relay Satellite-5 (TDRS-5)
STS-44	Gregory, Henricks, Musgrave, Runco, Voss, Hennen	11/24/1991	12/01/1991 Edwards Air Force Base	Dedicated Department of Defense Mission (DOD) and Defense Support Program (DSP) satellite
STS-45[5]	Bolden, Duffy, Sullivan, Leestma, Foale, Lichtenberg, Frimout	03/24/1992	04/02/1992 Kennedy Space Center	Atmospheric Laboratory for Applications and Science-1 (ATLAS-1)
STS-46[6]	Shriver, Allen, Hoffman, Chang-Diaz, Nicollier, Ivins, Malerba	07/31/1992	08/08/1992 Kennedy Space Center	European Space Agency's European Retrievable Carrier (EURECA)
STS-66	McMonagle, Brown, Ochoa, Parazynski, Tanner, Clervoy	11/03/1994	11/14/1994 Edwards Air Force Base	Atmospheric Laboratory for Applications and Science-3 (ATLAS-3)
STS-71[7]	Gibson, Precourt, Baker, Dunbar, Harbaugh	06/27/1995	07/07/1995	1st Shuttle-*Mir* Docking
STS-74[8]	Cameron, Halsell, Ross, McArthur, Hadfield	12/12/1995	12/20/1995 Kennedy Space Center	2nd Shuttle-*Mir* Docking
STS-76[9]	Chilton, Searfoss, Lucid, Godwin, Clifford, Sega	03/22/1996	03/31/1996 Edwards Air Force Base	3rd Shuttle-*Mir* Docking
STS-79[10]	Readdy, Wilcutt, Akers, Blaha, Apt, Walz	09/16/1996	09/26/1996 Kennedy Space Center	4th Shuttle-*Mir* Docking
STS-81[11]	Baker, Jett, Grunsfeld, Ivins, Wisoff, Linenger	01/12/1997	01/22/1997 Kennedy Space Center	5th Shuttle-*Mir* Docking
STS-84[12]	Precourt, Collins, Foale, Noriega, Clervoy, Kondakova	05/15/1997	05/24/1997 Kennedy Space Center	6th Shuttle-*Mir* Docking
STS-86[13]	Wetherbee, Bloomfield, Titov, Parazynski, Chretien, Lawrence, Wolf	09/25/1997	10/06/1997 Kennedy Space Center	7th Shuttle-*Mir* Docking
STS-101[14]	Halsell, Jr., Horowitz, Helms, Usachev, Voss, Weber, Williams	05/19/2000	05/26/2000 Kennedy Space Center	International Space Station (ISS) Flight 2A.2a
STS-106[15]	Wilcutt, Altman, Burbank, Lu, Malenchenko, Mastracchio, Morukov	09/08/2000	09/20/2000 Kennedy Space Center	International Space Station (ISS) Flight 2A.2b
STS-98[16]	Cockrell, Polansky, Curbeam, Jones, Ivins	02/07/2001	02/20/2001 Kennedy Space Center	International Space Station (ISS) Flight 5A

(*continued*)

TABLE 4. (*Continued*)

Mission	Crew	Launch Date	Landing Date	Primary Payload
STS-104[17]	Lindsey, Hobaugh, Gernhardt, Kavandi, Reilly	07/12/2001	07/24/2001 Kennedy Space Center	International Space Station (ISS) Flight 7A

[1]First flight of Space Shuttle *Atlantis*.

[2]First U.S. planetary mission in 11 years; and first on Shuttle. Primary payload, Magellan/Venus radar mapper spacecraft and attached Inertial Upper Stage (IUS), deployed six hours, 14 minutes into flight. IUS first and second stage fired as planned, boosting Magellan spacecraft on proper trajectory for 15-month journey to Venus. See also **Magellan Mission to Venus**; and **Venus**.

[3]Primary payload, Galileo/Jupiter spacecraft and attached Inertial Upper Stage (IUS), deployed six hours, 30 minutes into flight. IUS stages fired, placing Galileo on trajectory for six-year trip to Jupiter via gravitational boosts from Venus and Earth and possible observational brushes with asteroids Gaspra and Ida. See also **Galileo Mission to Jupiter**; and **Jupiter**.

[4]Primary payload, Compton Gamma Ray Observatory (CGRO), deployed on flight day three. CGRO high-gain antenna failed to deploy on command; finally freed and manually deployed by Ross and Apt during unscheduled contingency space walk, first since April 1985. Following day, two astronauts performed first scheduled space walk since November 1985 to test means for astronauts to move themselves and equipment about while maintaining planned Space Station Freedom. See also **Compton Gamma-Ray Observatory (CGRO)**.

[5]Mission marked first flight of Atmospheric Laboratory for Applications and Science-1 (ATLAS-1), mounted on nondeployable Spacelab pallets in orbiter cargo bay. U.S., France, Germany, Belgium, United Kingdom, Switzerland, The Netherlands, and Japan provided 12 instruments designed to perform 14 investigations in four fields.

[6]Primary objective was deployment of the European Space Agency's European Retrievable Carrier (EURECA) and operation of the joint NASA/Italian Space Agency Tethered Satellite System (TSS).

[7]STS-71 marked a number of historic firsts in human spaceflight history: 100th U.S. human space launch conducted from Cape; first U.S. Space Shuttle-Russian Space Station *Mir* docking and joint on-orbit operations; largest spacecraft ever in orbit; and first on-orbit changeout of Shuttle crew.

When linked, *Atlantis* and *Mir* formed largest spacecraft ever in orbit, with a total mass of almost one-half million pounds (about 225 tons) orbiting some 218 nautical miles above the Earth. After hatches on each side opened, STS-71 crew passed into Mir for welcoming ceremony. On same day, *Mir* 18 crew officially transferred responsibility for station to *Mir* 19 crew, and two crews switched spacecraft.

[8]STS-74 marked second docking of U.S. Space Shuttle to Russian Space Station *Mir*, continuing Phase I activities leading to construction of international space station later this decade. Unlike first docking flight during which crew exchange took place, second docking focused on delivery of equipment to Mir. Primary payload of mission was Russian-built Docking Module (DM), designed to become permanent extension on *Mir* to afford better clearances for Shuttle-*Mir* linkups. Two solar arrays were stowed on DM for later transfer to Mir by spacewalking cosmonauts.

[9]Third linkup between U.S. Space Shuttle and Russian Space Station *Mir* highlighted by transfer of veteran Astronaut Shannon Lucid to *Mir* to become first American woman to live on station. Her approximately four-and-a-half month stay also will eclipse long-duration U.S. spaceflight record set by first American to live on *Mir*, Norm Thagard. Lucid will be succeeded by astronaut John Blaha during STS-79 in August, giving her distinction of membership in four different flight crews, two U.S. and two Russian, and her stay on *Mir* kicked off continuous U.S. presence in space for next two years.

[10]STS-79 highlighted by return to Earth of U.S. Astronaut Lucid after 188 days in space, first U.S. crew exchange aboard Russian Space Station *Mir*, and fourth Shuttle-*Mir* docking. Lucid's long-duration spaceflight set new U.S. record as well as world record for a woman. She embarked to *Mir* March 22 with STS-76 mission. Succeeding her on *Mir* for an approximately four-month stay is Blaha, who will return in January 1997 with STS-81 crew; U.S. Astronaut Jerry Linenger will replace him.

[11]First Shuttle flight of 1997 highlighted by return of U.S. Astronaut John Blaha to Earth after 118-day stay aboard Russian Space Station *Mir* and the largest transfer to date of logistics between the two spacecraft. *Atlantis* also returned carrying the first plants to complete a life cycle in space, a crop of wheat grown from seed to seed. This fifth of nine planned dockings continued Phase 1B of the NASA/Russian Space Agency cooperative effort, with Linenger becoming the third U.S. astronaut in succession to live on *Mir*. Same payload configuration flown on previous docking flight featuring SPACEHAB Double module−flown again.

[12]Sixth Shuttle-*Mir* docking highlighted by transfer of fourth successive U.S. crew member to the Russian Space Station. U.S. Astronaut Mike Foale exchanged places with Jerry Linenger, who arrived at *Mir* Jan. 15 with the crew of Shuttle Mission STS-81. Linenger spent 123 days on *Mir* and just over 132 days in space from launch to landing, placing him second behind U.S. Astronaut Shannon Lucid for most time spent on-orbit by an American. Another milestone reached during his stay was one-year anniversary of continuous U.S. presence in space that began with Lucid's arrival at *Mir* March 22, 1996.

Other significant events during Linenger's stay included first U.S.-Russian space walk. On April 29, Linenger participated in five-hour extravehicular activity (EVA) with *Mir* 23 Commander Vasily Tsibliev to attach a monitor to the outside of the station. The Optical Properties Monitor (OPM) was to remain on *Mir* for nine months to allow study of the effect of the space environment on optical properties, such as mirrors used in telescopes.

[13]The seventh *Mir* docking mission continued the presence of a U.S. astronaut on the Russian space station with the transfer of physician David A. Wolf to *Mir*. Wolf became the sixth U.S. Astronaut in succession to live on Mir to continue Phase 1B of the NASA/Russian Space agency cooperative effort.

Foale returned to Earth after spending 145 days in space, 134 of them aboard Mir. His estimated mileage logged was 58 million miles (93 million kilometers), making his the second longest U.S. space flight, behind Shannon Lucid's record of 188 days.

First joint U.S.-Russian extravehicular activity during a Shuttle mission, which was also the 39th in the Space Shuttle program, was conducted by Titov and Parazynski. During the five-hour, one-minute space walk on Oct. 1, the pair affixed a 121-pound Solar Array Cap to the docking module for future use by Mir crewmembers to seal off the suspected leak in Spektr's hull.

[14]Space Shuttle *Atlantis* spent nearly 10 days in space six of which were spent docked with the ISS. While docked with the space station, the crew refurbished and replaced components in both the Zarya and Unity Modules. Voss and Williams performed a 6.5-hour space walk the day after docking to install a Russian Strela cargo boom on the outside of Zarya. They also replaced a faulty radio antenna and performed several other tasks in advance of space walks on future station assembly missions.

[15]The STS-106 crew spent five days, 9 hours and 21 minutes inside the International Space Station. The seven crewmembers completed a long checklist aimed at making the station a home for its first residents. Lu and Malenchenko performed a space walk to connect power, data and communications cables to the newly arrived Zvezda Service Module and the station.

[16]The primary objective of STS-98, International Space Station Assembly Mission 5A, was to deliver and install the U.S. Destiny Laboratory onto the ISS. The centerpiece of research on this world-class scientific orbiting outpost, this workshop in space will support experiments and studies in cancer, diabetes and materials, just to name a few. The arrival of the Destiny Lab brought the space stations mass to about 101.6 metric tons (112 tons), surpassing that of the Russian Mir space station for the first time. See also **Space Stations**.

[17]Top priority of the STS-104 mission of *Atlantis* was installation on the *International Space Station* of the Joint Airlock. This gave the station crewmembers the capability of conducting spacewalks from the orbiting laboratory using either the Russian Orlan spacesuits or U.S. spacesuits. The airlock was attached to the station's Unity Node, on the module's starboard Common Berthing Mechanism, and its "survival heaters" activated. The installation used the station's new Canadarm2 robotic arm during the mission's first spacewalk.

- Updated avionics systems that include advanced general purpose computers, improved inertial measurement units and tactical air navigation systems, enhanced master events controllers and multiplexer-demultiplexers, a solid-state star tracker and improved nose wheel steering mechanisms.
- An improved version of the Auxiliary Power Units (APU's) that provide power to operate the Shuttle's hydraulic systems.

On July 30, 1996 the orbiter *Endeavor* riding atop the modified 747 Shuttle Carrier Aircraft (SCA) arrived at Palmdale, CA, at 3:45 p.m. EDT. *Endeavor* remained in California eight months undergoing numerous modifications and structural inspections as part of its first Orbiter Maintenance Down Period (OMDP). The most significant modification will be in the installation of an external air lock making *Endeavor* capable of docking with the International Space Station.

On January 22, 1998, *Endeavor* returned to space after completing its first (OMDP), becoming the first orbiter other than *Atlantis* to dock with *Mir*. Astronauts Terrence W. Wilcutt and Joe F. Edwards, Jr. piloted NASA's first Shuttle mission of 1998 (STS-89). The continuing cooperative effort in space exploration between the United States and Russia and a joint spacewalk was the focus of the mission. During the mission, more than 7,000 pounds of experiments, supplies and hardware were transferred between the two spacecraft.

Space Transportation System (STS)

Launch Sites. There are two launch sites for the Space Shuttle. Kennedy Space Center (KSC) in Florida is used for launches to place the orbiter in equatorial orbits (around the equator), and Vandenberg Air Force Base launch site in California will be used for launches that place the orbiter in polar orbit missions.

Landing sites are located at the KSC and Vandenberg. Additional landing sites are provided at Edwards Air Force Base in California and White Sands, N.M. Contingency landing sites are also provided in the event the orbiter must return to Earth in an emergency.

Since the late 1960s, Pads A and B at Kennedy Space Center's Launch Complex 39 have served as backdrops for America's most significant manned space flight endeavors; *Apollo, Skylab, Apollo-Soyuz*, and the *Space Shuttle*.

Located on Merritt Island, Florida, just north of Cape Canaveral, the pads were originally built for the huge *Apollo/Saturn V* rockets that launched American astronauts on their historic journeys to the Moon and back. Following the joint U.S.-Soviet *Apollo-Soyuz* Test Project mission of July 1975, the pads were modified to support Space Shuttle operations.

Both pads were designed to support the concept of mobile launch operations, in which space vehicles are assembled and checked out in the protected environment of the Vehicle Assembly Building, then transported by large tracked vehicles to the launch pad for final processing and launch. During the *Apollo* era, key pad service structures were mobile. For the Space Shuttle, two permanent service towers were installed at each pad for the first time, the Fixed Service Structure and the Rotating Service Structure.

On April 12, 1981, Shuttle operations commenced at Pad A with the launch of Columbia on STS-1. After 23 more successful launches from A, the first Space Shuttle to lift off from Pad B was the ill-fated *Challenger* in January 1986. Pad B was designated for the resumption of Shuttle flights in September 1988, followed by the reactivation of Pad A in January 1990.

Major Features. Both pads are octagonally shaped and share identical features. Pad A is located 18,159 feet (5,530 meters) from the Vehicle Assembly Building via the crawlerway, Pad B 22,400 feet (6,830 meters). The pads are 8,716 (2,660 meters) feet apart. Each pad covers about a quarter-square mile of land. Launches are conducted from atop a concrete hardstand 390 by 325 feet (119 by 99 meters), located at the center of the pad area. The Pad A and Pad B hardstands are 48 feet (14.6 meters) and 55 feet (16.8 meters) above sea level, respectively.

Space Shuttle Requirements. The Shuttle will transport cargo into near Earth orbit 100 to 217 nautical miles (115 to 250 statute miles) above the Earth. This cargo, or payload, is carried in a bay 15 feet (4.57 meters) in diameter and 60 feet (18.3 meters) long.

Major system requirements are that the orbiter and the two solid rocket boosters be reusable.

Other features of the Shuttle:

- The orbiter has carried a flight crew of up to eight persons. A total of 10 persons could be carried under emergency conditions.
- The basic mission is seven days in space.
- The crew compartment has a shirtsleeve environment, and the acceleration load is never greater than 3 Gs.
- In its return to Earth, the orbiter has a cross-range maneuvering capability of 1,100 nautical miles (1,265 statute miles).

The Space Shuttle is launched in an upright position, with thrust provided by the three Space Shuttle engines and the two SRBs. See Fig. 5. After about two minutes, the two solid rocket boosters are spent and are separated from the external tank. See Fig. 6. They fall into the ocean at predetermined points and are recovered. A homing device on each booster guides recovery craft to it for towing the equipment back to shore. The boosters are then refurbished, refueled, and made ready for another flight.

The Space Shuttle main engines continue firing for about eight minutes. They shut down just before the craft is inserted into orbit. The external

TABLE 5. FLIGHTS OF *ENDEAVOR* (OV-105)
(1992 to date)

Mission	Crew	Launch Date	Landing Date and Site	Primary Payload
STS-49[1]	Brandenstein, Chilton, Thuot, Thornton, Hieb, Akers, Melnick	05/07/1992	05/16/1992 Edwards Air Force Base	Captured and redeployed INTELSAT VI (F-3) satellite
STS-47[2]	Gibson, Brown, Lee, Davis, Apt, Jemison, Mohri	09/12/1992	09/20/1992 Kennedy Space Center	Spacelab- J (SL-J), utilized pressurized Spacelab module
STS-54	Casper, McMonagle, Runco, Harbaugh, Helms	01/13/1993	01/19/1993 Kennedy Space Center	Fifth Tracking and Data Relay Satellite (TDRS-6)
STS-57[3]	Grabe, Duffy, Low, Sherlock, Wisoff, Voss	06/21/1993	01/01/1993 Kennedy Space Center	SPACEHAB-1 and (EURECA) retrieval European Retrievable Carrier
STS-61[4]	Covey, Bowersox, Musgrave, Thornton, Nicollier, Hoffman, Akers	12/02/1993	12/13/1993	Hubble Space Telescope 1st servicing mission
STS-59[5]	Gutierrez, Chilton, Godwin, Apt, Clifford, Jones	04/09/1994	04/20/1994 Edwards Air Force Base	Space Radar Laboratory (SRL-1)
STS-68[6]	Baker, Wilcutt, Jones, Smith, Bursch, Wisoff	09/30/1994	10/11/1994 Edwards Air Force Base	Space Radar Laboratory (SLR-2)
STS-67[7]	Oswald, Gregory, Jernigan, Grunsfeld, Lawrence, Parise, Durrance	03/02/1995	03/18/1995 Edwards Air Force Base	ASTRO-2

STS-99[12]	Kregel, Gorie, Thiele, Kavandi, Voss, Mohri	02/11/2000	02/22/2000 Kennedy Space Center	Shuttle Radar Topography Mission
STS-97[13]	Jett, Bloomfield, Tanner, Noriega, Garneau	11/30/2000	12/11/2000 Kennedy Space Center	ISS Assembly Flight 4A P6 Integrated Truss Structure
STS-100[14]	Rominger, Ashby, Hadfield, Phillips, Parazynski, Guidoni, Rosaviakosmos	04/19/2001	05/01/2001 Kennedy Space Center	ISS Assembly Flight 6A. Canadarm2 robotic arm
STS-108[15]	Gorie, Kelly, Godwin, Tani,	12/05/2001	12/17/2001	International Space Station Flight UF-1 Raffaello Multi-Purpose Logistics Module and STARSHINE 2

[1]First flight of Space Shuttle *Endeavor*.
First U.S. orbital flight to feature four extravehicular activities (EVAs), two of these longest in U.S. space flight history to date (eight hours, 29 minutes and seven hours, 45 minutes), and longest to date by a female Astronaut. First space flight ever to involve three crewmembers simultaneously working outside spacecraft; first time astronauts attached live rocket motor to orbiting satellite.
[2]Mae C. Jemison first African-American woman to fly in space, and Mamoru Mohri the first Japanese to fly on Shuttle.
[3]STS-57 marked first flight of commercially developed SPACEHAB, pressurized laboratory designed to more than double pressurized workspace for crew-tended experiments. Altogether 22 experiments were flown, covering materials and life sciences, and wastewater recycling experiment for space station.
[4]Final Shuttle flight of 1993 was one of most challenging and complex manned missions ever attempted. During record five back-to-back space walks totaling 35 hours and 28 minutes, two teams of astronauts completed first servicing of Hubble Space Telescope (HST). In many instances, tasks completed sooner than expected and few contingencies that did arise handled smoothly. See also **Hubble Space Telescope (HST)**.
[5]First flight of Toughened Uni-Piece Fibrous Insulation, known as TUFI, an improved thermal protection tile. Several test tiles were placed on orbiter's base heat shield between three main engines.
[6]STS-68 marked second flight in 1994 of Space Radar Laboratory (first flight was STS-59 in April), part of NASA's Mission to Planet Earth.
[7]STS-67 became first advertised Shuttle mission connected to Internet. Users of more than 200,000 computers from 59 countries logged on to Astro-2 home page at Marshall Space Flight Center; more than 2.4 million requests were recorded during mission, many answered by crew on-orbit.
Endeavor logged 6.9 million miles (11 million kilometers) in completing longest Shuttle flight to date, allowing sustained examination of "hidden universe" of ultraviolet light. Primary payload, Astro Observatory, flown once before (on STS-35 in December 1990) but second flight had almost twice the duration. Planned Astro-2 observations built on discoveries made by Astro-1, as well as seeking answers to other questions.
[8]STS-69 marked first time two different payloads were retrieved and deployed during same mission. Also featured an extravehicular activity to practice for International Space Station activities and to evaluate space suit design modifications.
[9]First Shuttle flight of 1996 highlighted by retrieval of a Japanese satellite, deployment and retrieval of a NASA science payload, and two spacewalks.
[10]Docking of *Endeavor* to *Mir* occurred at 3:14 p.m., Jan. 24, at an altitude of 214 nautical miles. Hatches opened at 5:25 p.m. the same day. Transfer of Andy Thomas to *Mir* and return of David Wolf to the U.S. orbiter occurred at 6:35 p.m., Jan. 25. Initially, Thomas thought his Sokol pressure suit did not fit, and the crew exchange was allowed to proceed only after Wolf's suit was adjusted to fit Thomas. Once on Mir, Thomas was able to make adequate adjustments to his own suit (which would be worn should the crew need to return to Earth in the Soyuz capsule) and this remained on *Mir* with him. Wolf spent a total of 119 days aboard *Mir*, and after landing his total on-orbit time was 128 days.
[11]The STS-88 "Unity" mission is the first manned International Space Station assembly flight. The primary mission objective is to rendezvous with the already launched Zarya control module and successfully attach the Unity connecting module, providing the foundation for future ISS components.
[12]The primary objective of the Shuttle Radar Topography Mission is to acquire a high-resolution topographic map of the Earth's land mass (between 60 °N and 56 °S) and to test new technologies for deployment of large rigid structures and measurement of their distortions to extremely high precision.
The Shuttle Radar Topography Mission represents a breakthrough in the science of remote-sensing and will produce topographic maps of Earth 30 times as precise as the best global maps in use today. The information will be used to attempt to produce one of the most comprehensive and accurate maps of Earth ever assembled.
In addition, this mission offers a number of applications for data products and science, including: geology, geophysics, earthquake research, volcano monitoring; hydrologic modeling; ecology; co-registration and terrain correction of remotely-acquired image data; atmospheric modeling; flood inundation modeling; urban planning; natural hazard consequence assessments; fire spread models; and transportation/infrastructure planning.
[13]STS-97 delivers giant solar arrays to International Space Station. During its 11-day mission, the crew of Space Shuttle *Endeavor* saw the ISS spread its wings, giant solar arrays that quintupled the station's electrical power.
The 73-meter (240-foot) long solar array structure attached and unfolded by *Endeavor's* international crew of five, is the longest human-made object ever to fly in space. *Endeavor* carried aloft the U.S.-developed solar arrays, associated electronics, batteries, cooling radiator and support structure. The entire 15.4-metric ton (17-ton) package is called the P6 Integrated Truss Segment, and is the heaviest and largest element yet delivered to the station aboard a space shuttle.
The addition of the huge solar arrays clearly distinguishes the ISS from any predecessor spacecraft. The arrays provide the station with more electrical power, a key to successful modern research.
[14]*Endeavor* and its crew spent almost 12 days on orbit, eight of which were spent in joint operations with the ISS crew. *Endeavor's* crew delivered and installed a new robotic arm (Candarm2) and helped to transfer equipment and supplies between vehicles.
Mission Specialists Chris Hadfield of the Canadian Space Agency and Scott Parazynski of NASA performed two spacewalks to install the new 17.6-meter (57.7-foot) robotic arm onto the ISS. Canadarm2, a beefier second-generation version of the shuttle's robot arm, is essential to the continued assembly of the space station at the outpost grows beyond the reach of the shuttle's arm.
[15]Top priorities for the STS-108 (UF-1) mission of *Endeavor* are rotation of the International Space Station Expedition Three and Expedition Four crews, bringing water, equipment and supplies to the station and completion of spacewalk and robotics tasks.

tank is then separated from the orbiter. It follows a ballistic trajectory into a remote area of the ocean but is not recovered.

There are 38 primary Reaction Control System (RCS) engines and six vernier RCS engines located on the orbiter. The first use of selected primary reaction control system engines occurs at orbiter/external tank separation. The selected primary reaction control system engines are used in the separation sequence to provide an attitude hold for separation. Then they move the orbiter away from the external tank to ensure orbiter clearance from the arc of the rotating external tank. Finally, they return to an attitude hold prior to the initiation of the firing of the Orbital Maneuvering System (OMS) engines to place the orbiter into orbit.

The primary and/or vernier RCS engines are used normally on orbit to provide attitude pitch, roll and yaw maneuvers as well as translation maneuvers.

The two OMS engines are used to place the orbiter on orbit, for major velocity maneuvers on orbit and to slow the orbiter for reentry, called the deorbit maneuver. Normally, two OMS engine thrusting sequences are used to place the orbiter on orbit, and only one thrusting sequence is used for deorbit.

The orbiter's velocity on orbit is approximately 25,405 feet per second (17,322 statute miles per hour). The deorbit maneuver decreases this velocity approximately 300 fps (205 mph) for reentry.

In some missions, only one OMS thrusting sequence is used to place the orbiter on orbit. This is referred to as direct insertion. Direct insertion is a technique used in some missions where there are high-performance requirements, such as a heavy payload or a high orbital altitude. This technique uses the Space Shuttle main engines to achieve the desired apogee (high point in an orbit) altitude, thus conserving orbital maneuvering system propellants. Following jettison of the external tank, only one OMS thrusting sequence is required to establish the desired orbit altitude.
